VG0236	06-Dec-23	Community Event	Old Crow	Residents of Old Crow	Community Event	Chance held a World Cafe event in Old Crow at the Darius Elias Community Centre from 4:00 pm – 8:00 pm MST. World Cafe attendees were asked to sign in upon arrival and to complete a feedback form before leaving. Chance shared Project information on posterboards and a 1-page handout. Chance provided a catered dinner and presented Project information to World Cafe attendees. After dinner, technical experts from EDI, Ecofor, and Palmer were divided amongst the groups. Focus group #1 had a presentation from EDI on Wildlife and Fish and Fish Habitat. Focus group #2 had presentations from Ecofor and Palmer on Archaeology / Heritage Resources and Permafrost. Once presentations and comments/concerns were addressed, the technical experts switched tables and presented to the rest of the attendees. The World Cafe event had door prizes that were drawn throughout the event which included 2 Air North gift cards, 3 Co-op grocery gift cards, Ecofor packages, and a mug from Indigo.	N/A	Summary Report

GTC0220	07-Dec-23	Community Event	Fort McPherson	Residents of Fort McPherson	Community Event	Chance held a community open house event in Fort McPherson at the Tetlit' Zheh Fort McPherson Hamlet Chamber from 4:00 to 8:00 pm MST. Open house attendees were asked to sign in upon arrival and to complete a feedback form before leaving. Chance shared Project information on posterboards and a 1-page handout. Chance provided a catered dinner and presented Project information to the Open House attendees. The Open House event had door prizes that were drawn throughout the event which included 2 Air North gift cards, 2 Co-op grocery gift cards, and Ecofor packages.	N/A	Summary Report

APPENDIX 2-D-39. June 8, 2021 Meeting Summary

TR'ONDËK HWËCH'IN AND CHANCE OIL AND GAS MEETING

Date: June 8, 2021

Location: Microsoft Teams

Attendees:

Tr'ondëk Hwëch'in:
Chief [redacted]
[redacted], Senior Advisor, Mining & Strategic Initiatives

Chance Oil and Gas Limited:
[redacted], President
[redacted], Regulatory, Environmental and Community Relations Coordinator

Palmer:
[redacted], Principal, Geomorphologist
[redacted] Senior Geoscientist
[redacted], Geoscientist

Hemmera:
[redacted] Human Environment Specialist
[redacted], Human Environment Specialist

Purpose and Objectives

The purpose of this meeting was for Chance and Palmer to present baseline information on Permafrost studies in Chance's Project Area, and to provide an opportunity for parties to discuss engagement preferences, planning, and upcoming engagement reports.

Meeting Discussion:

Introductions of all attendees and overview of meeting agenda.

[redacted]: Chief [redacted], would you like to say anything before we get started?

Chief [redacted]: You can move along; I can speak at the end.

[redacted]: Quick review of the action items of our following meeting.

1. Hemmera to send Memo with tentative engagement schedule to TH. We sent this.
2. Hemmera/Chance to send revised project description to TH. We will send this as soon as it's done.

DRAFT

3. Hemmera/Chance to send baseline information (Environmental Dynamics Inc. (EDI), Palmer, and Peer Solutions) to Tr'ondëk Hwëch'in (TH) as it becomes available. We have been able to send the Palmer maps and reports. We can later discuss sharing studies from other Chance consultants.

If there are no questions, then we'll just move right into the presentation.

[redacted]: Could you summarize what consultation is looking like with other First Nations?

[redacted]: Yes, here is a quick overview. In terms of the big picture we prepared and presented a project description in 2019 to various First Nation communities and Gwich'in communities in NWT. Chance then focused on their Well Maintenance Project for Designated Office for most of 2020. We are now re-engaging this project. We have revised the project description after feedback from communities and feedback from the Designated Office proposal currently in YESAB. I mentioned in our April meeting that we're working on revising the project description. This should be finished soon. In terms of re-engagement with First Nations, we have recently met with Skeeter Wright at Na-Cho Nyäk Dun (NND) and leadership at the Gwich'in Tribal Council (GTC). We're looking for guidance from First Nations on how we should proceed, either in-person or virtual events, and/or where we would share project descriptions and base findings. We've been having open houses in Old Crow for the community in order to collect feedback and concerns. The next open house will be with Environmental Dynamics Inc. (EDI) to present studies on wildlife and vegetation. Chance is working with the Vuntut Gwich'in (VG) Government, but those conversations are currently paused. That's a basic summary of the events since we've resumed engagement on the Executive Committee Project. Aiming for a YESAB submission this fall. Richard, anything to add?

[redacted]: No.

[redacted]: We've also been able to meet with Porcupine Caribou Management Board and the technical committee. This has helped work towards addressing issues with respect to the Porcupine Caribou Herd.

[redacted]: How far along are you from completing the Information Response for the DO project?

[redacted]: My understanding is that the Hemmera proposal management team is working on gathering information from various consultants. We can add this as an action item, to get the timeline for responding to the IR, for us.

[redacted]: Okay thank you. No questions on our end. I'll let you know as we go.

[redacted]: [Opens up presentation] Thanks everyone for taking the time to join us. We want to share our role in the project and how we are helping Chance to understand the grounds in the project area. We will do this in two parts. One, to understand the topography in the area and help inform the decision-making process. Two, to support the YESAB project proposal. We want to work with Hemmera and the other consultants to understand how permafrost is connected with other variables like vegetation and informing the assessment process. For understanding the topography in the region we will do this in two steps:

1. Physical setting: Understand the landscape, why it looks the way it does.
2. Mapping approach: Part of our job is to provide a better sense of the map and what's on the ground.

DRAFT

The bedrock is the in the sedimentary basin. It was once a sea bed. Over time we start to see that the bedrock is cut into deep valleys and gullies. You can see that in the landscape like a network of channels and valleys. Another thing that is really cool about the area is that it escaped being covered by ice glaciers. This provided an opportunity for permafrost to develop. Permafrost from a technical perspective is defined by temperature. Some areas that are quite dry are not that sensitive and others that have more water and ice are quite sensitive. The valley bottoms get quite cold in the winter and warmer in the summer time. That [R. McKillop references presentation] picture of thermokarst, you see the surface pond as permafrost thaws. On the bottom left, you can see the patterned ground. This indicates that you have ice wedges underground which are sensitive. As the active layer thaws, and after rain or storms, you can have a landslide. It's something we want to pay attention to, especially with infrastructure. There could also be a concern for flooding. These are things we need to pay attention to.

Here are some slides from the Yukon Government. The uppermost centimetres of the permafrost is going to thaw with climate change. Precipitation patterns are changing which can also trigger some minor disturbances.

[redacted]: That shows a nice history of the landscape. For understanding the landscape, we use satellite or aerial views of the project area. We also use LiDAR to see through vegetation to get a true reflection of the surface. When it comes to documenting these things, we have a terrain map. We look at the geomorphological process, permafrost depth and ice content. These things are not always straight forward to map, but we get clues from the surface in which areas are permafrost sensitive. We create these exploratory suitability maps to tailor/make guides that provide an overview that shows how easy it will be to develop infrastructure and roads without mitigation measures in place. High suitability is in green and low is in red. Our reconnaissance study was done in July 2019. These green points are where data was collected. We completed terrain interpretations for more than 8,400 terrain polygons.

Interpreting these maps. You can use the colours for understanding what is there. The broad ridges are here [redacted referenced to presentation] the permafrost here is well drained. The field photo shows rocky areas. Moving down we have gentle valley slopes. Colluvial sediments are sediments moved down the slopes and ridges through gravity. Sometimes we may run into surface water constraints and more extreme cases active layer detachment. In these cases, we represent individual landslides as these small arrows [redacted referenced to presentation]. Generally, this will give you a clue of what you will see on the ground. Then on the valley bottoms you will see much more thick organics, ponds, and permafrost layers closer to the surface.

We created these exploration development suitability maps. The green shows well drained areas with permafrost at depths. At the opposite end of things, in red, you will see ice wedges exposed in the flood plain. Generally, these areas are where we would run into trouble. The implications are not a "yes" or "no", but more of an idea of what you are going to run into once you get there. In the green areas we predict Chance will have no issue. The oranges areas show the moderate to low. They give warning that mitigation methods may need to be considered.

[redacted]: There is a lot of information in the mapping. We are happy to help people and communities understand what the maps means and guide that information. Our next steps are a short field program to start getting some subsurface information and to see a little bit deeper. To understand the makeup of the materials. A lot of time we will hit bedrock. When we do hit thicker areas, we want to make sure we map it,

to record the areas that require more attention. We want to form a baseline report and wrap it up into an effects assessment. That was a quick version of what we have been up to.

[redacted]: Thank you, couple of questions. Will the subsurface work be done before Executive Committee project proposal?

[redacted]: It will be done in the late part of July 2021. We're advancing everything to build off the mapping done to date. We would like to collect that subsurface information to fine-tune the mapping information. This will really demonstrate what it is like and will feed into the YESAB submission this fall.

[redacted]: What was the methodology of the sampling and how did you conduct that to create the map and come up with the numbers for the areas?

[redacted]: The scale is 1 to 20,000 scale. We felt the need to sample representative areas of the landscape. The field sampling is representative of the different areas of the landscape. We tried to be sure that we saw everything on the property and touched down on areas of the landscape. Characterizing those materials and confidently re-assign these characteristics of these areas.

[redacted]: You mentioned climate change. How are you going to see if the project Chance is proposing will affect natural climate change or human driven climate change in the area?

[redacted]: We are hoping to install ground temperature surveyors to get baseline information for ground temperature. We are going off published information and trying to get specific project information from literature.

[redacted]: The well maintenance project going through YESAB right now is looking at the temperature change on the 8 wells. This will give us a modern measure on the permafrost where those 8 wells are.

[redacted]: How much information do you have on the hydrogeology on the existing 8 wells?

[redacted]: We will be going up with Chance to visit the well sites and try to get an idea of the thawing that has occurred over the years. The thawing is really just in the upper layers of the soil that sits above the permafrost. We can have some changes in the upper layer, but no reason to think that the water can get below that upper layer. Any questions?

[redacted]: That is okay, we're waiting to look at the information responses for the Designated Office project.

[redacted]: Any other questions?

[redacted]: No thank you, I'm satisfied with the technical side.

[redacted]: The way that we consider permafrost in the effects assessment can differ between projects. For example, having permafrost as value component or as a pathway of effects. Any opinions on how that is best addressed? Is it a concern itself or is the concern on its effect on other things?

[redacted]: Just on behalf of myself, I think the implications would be the pathways of effects as they relate to the Porcupine Caribou. As a value component that would be much more a question for VG.

DRAFT

[redacted]: I think potentially as both. Especially with respect to the Porcupine Caribou. The VC's are not set in stone at the moment. Since we re-started engagement, the goal is to have meetings with all the technical staff and renewable resources councils. This will guide how we decide these things. As we are actively seek this information. I think the coming months will provide more guidance on those areas. Our selection of socio-economic components will be driven by guidance from First Nations.

It looks like we're all done for the permafrost information. Palmer you're welcome to remain on the call or log off. Chief [redacted], do you have any questions before they leave?

Chief [redacted]: No further questions.

[redacted]: Moving on to discuss the engagements reports.

[redacted]: I will stay on the rest are welcome to leave.

[redacted]: Chance needs to provide engagement reports in accordance with its Ministerial Orders. Usually it summarizes engagement up until May 31st. Pending any objections, we'll look at the communication log and summarize the meetings and emails that have occurred. General issues raised and key concerns that have been raised. We'll share the draft engagement report for review by TH and Chance, address key concerns and areas that have been raised, and, upon having a mutually agreed upon document, submit at the end of July. We will aim to get the draft report to you to early July – does that work for you?

Chief [redacted]: Yes, that's fine.

[redacted]: Engagement reports are usually associated with the Executive Committee Project, but will include DO project and associated engagement activities as well. That is it for the engagement reports. Those will be provided in early July to parties for review.

[redacted]: We are looking to you for your preferences for engagement with lands and wildlife staff and your citizens. It is also up to you, your preference, for our next meetings in general. This includes presenting information from EDI and Palmer.

Chief [redacted]: We will discuss and get back to you. We'll need the project description.

[redacted]: We will get that to you. With respect to concern related to best practices for safety during covid. We'd be happy to plan an open house in Dawson. If you want. If you are open to that. We're also waiting on other consultants out of the territory to get their second shots, but EDI can come at this point to present their findings. As they are based in Whitehorse.

[redacted]: I'll likely get my second shot by the end of the month.

[redacted]: [redacted], in the past you mentioned that Chance should send along technical materials. We can send along EDI's information if that's ok with you?

[redacted]: Yes, you can send that along.

DRAFT

[redacted]: We can also give a presentation of that later if you, or your, technical staff want. Questions or concerns? Closing statements?

Chief [redacted]: Thank you, I am happy to be a part of this presentation today. Our efforts in this project are limited with respect to Tr'ondëk Hwëch'in Traditional Territory and the Porcupine Caribou habitat and wellbeing. One of the things that you mentioned earlier in the overview of the project description and communication that has taken place. I was quite disturbed to learn about the communication breakdown with VG. Social responsibility is important. Our three First Nations work together in regard to our interests throughout the North Yukon area. We have key values that we must ensure are protected and ensure are sustainable. We collectively work together to support projects. I'm disturbed to hear that there isn't a strong dedication to social responsibility. That may have an impact on our three First Nations. Regarding the permafrost, there's always the concern of the project's impact on the Porcupine Caribou. The Porcupine Caribou is of high value for traditional food. They provide for our cultural and spiritual wellbeing. We will do all we can to protect the Porcupine Caribou. We're already having an impact on the Porcupine Caribou. We know that there has not been data collection on the Porcupine Caribou and that shows that there hasn't been respect for the Porcupine Caribou. Moving forward, we need to see that some changes are made with VG. Also, we do not support fracking. We are going to do all that we can to protect the water. You need to have respect – you need seek VG's permission before you move into their land. You need to be able to seek that permission from VG before you go onto their land or before you go present information. Ensure that there is social responsibility and approval from the VG. We look forward to the project description presentation again. We will get back to you at the end of this week on who you will be presenting for. There is nothing stopping you from providing a presentation here in the community since there is not much concern in the community for the project.

[redacted]: Thank you for comments and concerns.

Chief [redacted]: We would like to hear from Chance.

[redacted]: Thank you Chief [redacted], and thank you for your candid comments. It is our desire to have a good working relationship with all First Nations. We have been reaching out to VG. This is why we have hired consultants to reach and address these concerns. We are paused right now and hopefully we can get back on track.

Chief [redacted]: I'm hoping to hear news on this.

Action Items:

- Hemmera to send EDI baseline information to TH.
- Hemmera/Chance to send revised project description to TH as soon as it's done.
- TH to discuss internally preference for next round of meetings/presentations (e.g., with lands staff, citizens, etc.).

Calgary, AB T2R 1L5

Dear Richard Wyman:

Re: Terrain and Permafrost Baseline Report, Eagle Plains Project
Project #: 1903404

Palmer is pleased to submit the enclosed report to Chance Oil and Gas Limited (Chance) to accompany and explain the interpreted terrain and permafrost classification mapping and exploration development suitability mapping within its exploration property near Eagle Plains, northern Yukon. This report provides baseline characterizations of the surficial geology, terrain and permafrost in support of Chance's Project Proposal submission to the Yukon Environmental and Socio-Economic Assessment Board (YESAB).

This report, in combination with previous submissions and background information collected over several years, establishes the types, distribution, characteristics and sensitivities of terrain and permafrost within the project area. It enables proposed project components, such as seismic survey lines, well pads, winter access roads and mix-bury-cover disposal, to be planned and sited in such a way that minimizes their potential effects on permafrost and terrain stability and their potential exposure to associated terrain hazards.

Should you have any questions or require additional information, please do not hesitate to contact Robin McKillop (604-355-8788, robin.mckillop@pecg.ca).

Yours truly,

Robin McKillop, M.Sc., P.Geo.
Vice President, Principal Geomorphologist

Executive Summary

Since the 1950s, the Eagle Plains region has been explored for its petroleum resource potential. Chance Oil and Gas Limited (Chance), which drilled four exploration wells in 2012 and 2013, has retained Palmer to aid with its next phase of exploration, pending approval by Yukon Environmental and Socio-economic Assessment Board (YESAB). Palmer's role was to map and characterize baseline surficial geology and permafrost, thereby informing potential effects of the Project on permafrost and terrain stability as part of an environmental assessment.

This report details the physical setting of the Eagle Plains regions, reviews data sources and background information related to previous reports and mapping, describes the methods and limitations of the study, and presents the results of surficial geology and permafrost mapping within the Project Area. Exploration Development suitability mapping, which largely reflects permafrost-related terrain stability, guides exploration infrastructure planning. Considerations for exploration development, climate change, and future work conducted in the area are provided at the end.

Our approach began with a detailed investigation of the surficial geology and permafrost conditions within the Project Area, building off work done by Kyrotek Arctic Innovation (2015a,b). Based on this characterization, Palmer completed map sets for the entire 2,400 km^2 Project Area at a scale of 1:20,000, based on a combination of multiple stereo-imagery sources and high-resolution LiDAR derived elevation data.

The surficial geology of the Project Area consists of colluvial deposits, weathered bedrock, fluvial deposits, organic deposits, and anthropogenic features, with colluvial deposits being the most abundant in the area. The Project Area is located within the continuous permafrost zone. As such, ground temperature instruments were installed at 12 representative locations on ridge crests, on slopes of different aspects, and in valley bottoms to understand ground temperature variability. The focus was to assess which areas of the landscape are warmer (>-2°C) and cooler (<-2°C), improve definition of active layer thickness and seasonal dynamics, and identify what effects historical and recent wildfires have had on shallow permafrost.

Ice content variability and its relationship with different surficial deposits were incorporated into the mapping, considering that fine-grained deposits, such as colluvial and fluvial deposits, are typically ice-rich, while coarser-grained deposits, such as weathered bedrock, are typically ice-poor. This factored heavily into the determination of terrain stability, as permafrost-related processes such as cryoturbation, solifluction, active-layer detachments and thermokarst subsidence/gullying are dependent on ice content and drainage conditions.

Exploration development suitability mapping was completed to encompass all the above information into a map set. This map set provides guidance for future development of exploration infrastructure by identifying areas least likely to be affected by construction-related disturbance. Exploration development suitability was divided into two primary classifications: road and well pad suitability, which guides the establishment and maintenance of well pads and access roads (although the classification conservatively reflects all-season roadways, which are not proposed as part of the project), and mix-bury-cover (MBC) disposal suitability, which identifies areas of the landscape that are geomorphologically isolated and potentially

suitable for disposal of cuttings using MBC techniques. Road and well pad suitability classification also provides a conservative guied for proposed seismic surveys. The use of this map set in planning helps ensure that permafrost and terrain stability are protected during the exploration process. Recommendations for scenarios where development must occur on less suitable material are provided to aid with permafrost protection.

Lastly, this report acknowledges observed and projected increases in temperature and precipitation, more pronounced in northern regions, that are expected to continue to affect the permafrost and terrain stability in the Project Area. Thawing of permafrost, resulting in thermokarst subsidence, new and potentially larger active-layer detachments, and altered surface hydrology, is expected to occur gradually with time. Additionally, wildfires are expected to intensify with climate change, exacerbating localized instabilities.

Appendix D. Glossary

1. Introduction

This report documents the surficial geology and permafrost baseline assessment in support of Chance Oil and Gas Limited's (Chance's) Project Proposal submission to the Yukon Environmental and Socio-Economic Assessment Board (YESAB). 'Permafrost and terrain stability' have been selected as Valued Environmental and Socio-Economic Component (VESEC) for the Project Proposal. An understanding of their sensitivities to proposed project activities is founded on the mapping and characterizations of surficial geology included in this report.

Exploration development suitability is used throughout this report and accompanying mapping as a proxy for terrain stability – it is a reflection of expected terrain stability considering interdependent permafrost and terrain. Exploration development suitability classifications highlight areas more and less suitable for proposed project activities, thereby enabling optimization of routing and site selection and prioritization of mitigative measures where necessary.

Following a summary of background information collected over the last several years (Section 1.1), this report describes the physical setting in which the project is situated (Section 2), outlines the desktop- and field-based methods used to map and characterize surficial geology and permafrost (Section 3), characterizes dominant soils and permafrost-related terrain stability, with reference to associated project-wide mapping, as well as exploration development suitability and climate change implications (Section 4), and closes with a summary and key conclusions as map sets and text-based and illustrated characterizations showing the current surficial geology and permafrost conditions within the Project Area. Data was gathered via desktop study and field investigations from 2019 to 2023.

1.1 Program Overview

Chance's proposed exploration for oil and gas (the Project) is focused on the Eagle Plains Basin area of Yukon, covering an area of approx. 2396 km^2, and aligning with km 300 to 347 of the Dempster Highway. The Project aims to improve the understanding of oil and natural gas resources in the Eagle Plains basin, with the aim of identifying an economically viable resource that could potentially contribute to Yukon's long-term goal of energy independence and support numerous careers for decades.

The Project got underway in 2014, and has since then incorporated studies focused on surficial geology, permafrost and related terrain processes, water resources, fish and fish habitat, vegetation, wildlife, and linear disturbances. Palmer's role has been to improve understanding of the characteristics and implications of surficial geology and permafrost processes in the Eagle Plains Basin since original retention in 2015. Both desktop studies and field investigations have occurred from 2019 to 2023 to gather information on surficial geology, permafrost, and permafrost-related terrain processes, as a basis for evaluating terrain stability and associated exploration development suitability.

2. Project Setting

2.1 Physiography and Climate

The Project Area is within the Eagle Plains Ecoregion, an area of modest relief within the lowlands between the North Ogilvie and Richardson Mountain ranges (Yukon Ecoregions Working Group, 2004). Elevation ranges between about 350 m asl along the bottoms of the northernmost valleys to about 750 m asl at high points along the long ridge system followed by the Dempster Highway. Greaves and Ch'itr'ihkaiinjik rivers drain northward from the central northern portion of the Project Area, McParlon Creek drains westward from the southern part, and Dalglish and Enterprise creeks drain southeast toward Peel River in its southernmost portion (Figure 2-1). There are no mapped lakes within the Project Area, although some ponds have begun to form in broad valley bottoms.

The property is generally characterized by open black spruce woodlands interspersed with shrub tundra at higher elevations. Tussock tundra dominates the lower, more poorly drained, gentle slopes (Figure 2-2). Paper birch commonly colonizes burns, and aspen and balsam poplar locally occupy well-drained, south-facing slopes. Stream riparian zones are generally dominated by willow, alder and balsam poplar. Further detail on vegetation of the Project Area is available in the Vegetation Baseline Report (Environmental Dynamics Inc., 2024).

Climate is characterized by long, cold winters and short, warm summers. Based on the Ecoregions of the Yukon Territory volume (2004), mean annual air temperature (MAAT) for the area is -7.5˚C, with mean July air temperatures around 13˚C and mean January air temperatures slightly colder on the valley floors (-31˚C) than over higher terrain (-25˚C) due to strong temperature inversions associated with Arctic high-pressure systems. Based on data from the closest weather station to the Project Area (located in Old Crow (67°34'14" N, 139°50'21" W; Climate ID: 2100800)), MAAT is gradually increasing over time. Air temperatures have increased from -9.0˚C (1971-2000), to -8.3˚C (1981-2010), and most recently to -7.7˚C (1991-2020; Government of Canada, 2023). Annual precipitation in this semi-arid region is approximately 400 mm, falling mostly as rain during the summer months (Yukon Ecoregions Working Group, 2004).

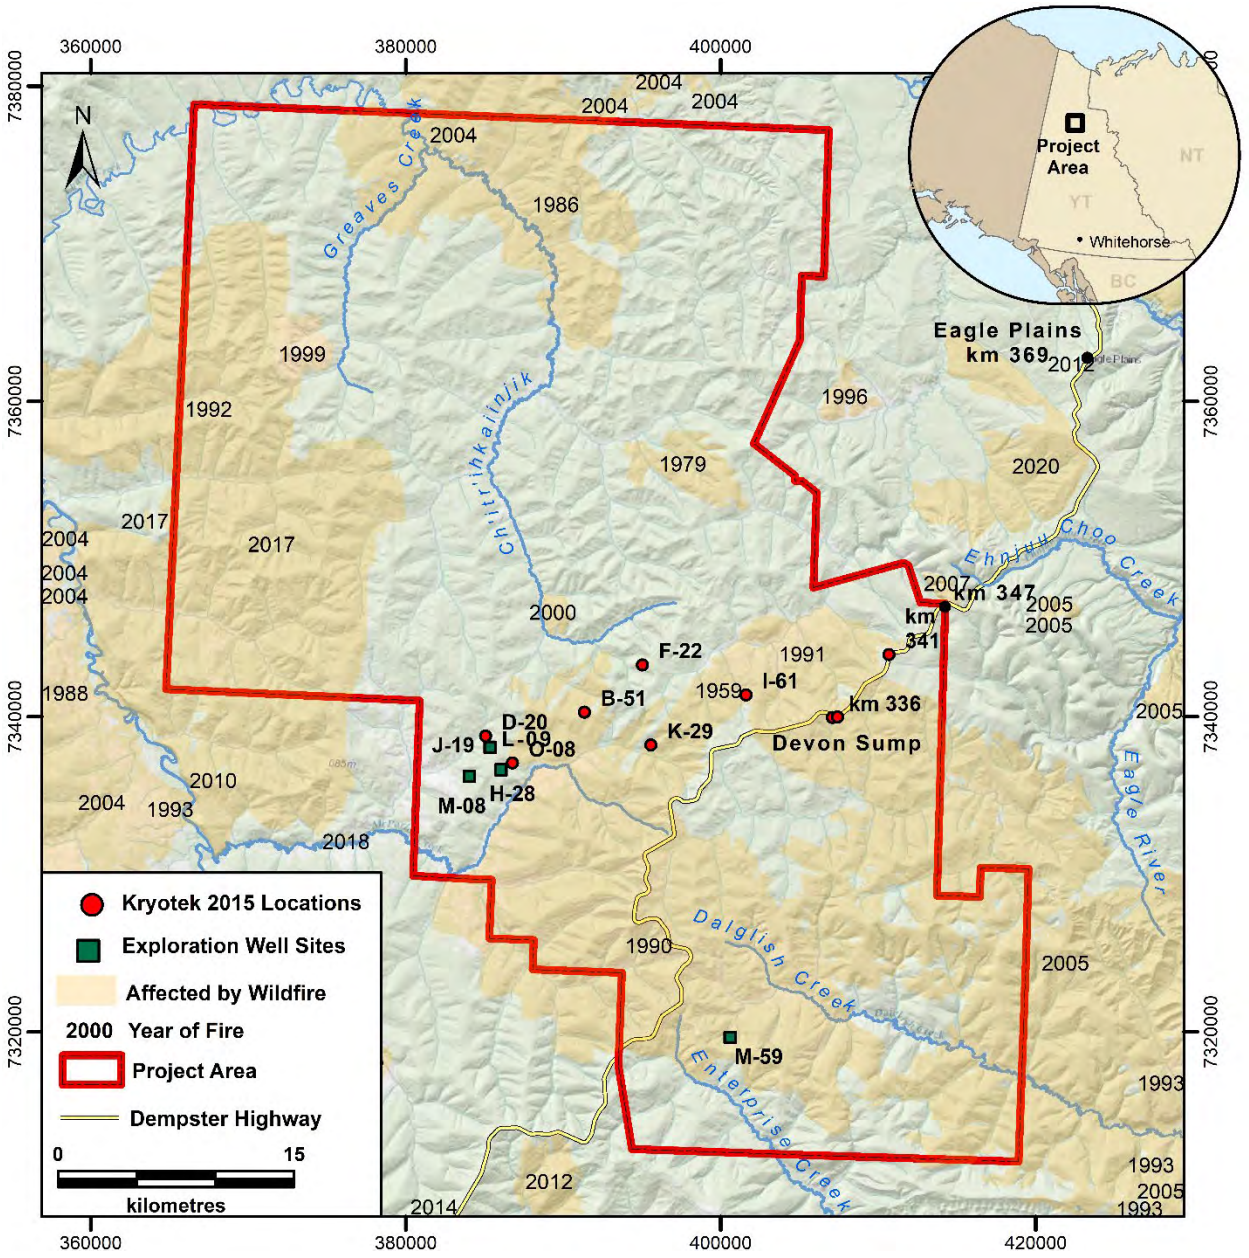

Figure 2-1. Eagle Plains Project Area, indicating wildfire history, existing Chance exploration well sites, and Kryotek Arctic Innovation's 2015 shallow-drilling investigation of proposed wellpad locations.

Figure 2-2. Modest relief, typical vegetation and recent wildfire burn within the Project Area. Note the conspicuous scarp in the left-centre of the photograph, indicative of an erosion-resistant stratum in roughly flat-lying sedimentary bedrock.

2.2 Bedrock Geology

The bedrock geology of the Project Area is dominated by Lower to Upper Cretaceous rocks of the Cody Creek, Burnthill Creek, and Eagle Plain formations (Yukon Geological Survey, 2020). These rocks comprise fine- to medium-grained sedimentary sequences including sandstone, shale, siltstone, bituminous shale, mudstone, and coal. The easternmost edges of the Project Area intersect mixed carbonate and clastic rocks of the Hart River and Ford Lake formations (cherty spiculite and packstone with minor sandstone, siltstone, and shale).

Differential weathering of the various bedrock units has contributed to the unique landscape in the Project Area. Broad ridges are formed by comparatively erosion-resistant sandstone beds. The Dempster Highway and Chance Road generally follow a network of these more resistant ridges. Isolated knolls along the ridge crests are likely remnants of the more competent bedrock in the area.

2.3 Landscape Evolution, Surficial Geology, and Soils

The Project Area escaped direct effects of multiple late Pleistocene glaciations that otherwise covered much of Yukon (Duk-Rodkin, 1999). Indirect effects include a lowering of the base level of the Eagle River and a consequential acceleration of incision of its tributaries (include some reaches within the Project Area) and the widespread deposition of loess – windblow silt and very fine sand – sourced from unvegetated proglacial areas to the south and east. Much of this loess has since been redistributed into valley bottoms through colluviation and slopewash.

The lack of glacial erosion in the Project Area has resulted in broad, rolling uplands that are typically covered by veneers of relatively fine-grained colluvium or weathered bedrock. These uplands commonly bounded by comparatively steep scarps, where more resistant bedrock transitions into fluvially incised, V-shaped valleys. The valley sides are covered by thicker, fine-grained colluvium, locally overlain by organic material. Thick, silty to gravelly fluvial deposits occupy the valley bottoms (Hughes, 1972). Organic-rich soil and peat are found in depressions and along valley bottoms (Hughes, 1972).

The unglaciated history of the Project Area has subjected the soils to long periods of weathering, resulting in heavy oxidation (Yukon Ecoregions Working Group, 2004). Soils in the area have previously been described as Dystric Brunisols in well-drained upper slope and ridge crest positions, and Turbic Cryosols in other upland locations. The latter are commonly found just above treeline, commonly in areas of patterned ground (Yukon Ecoregions Working Group, 2004). The pH of Eagle Plains soils can be as low as 4 in upland areas underlain by weathered sandstone (Yukon Ecoregions Working Group, 2004).

2.4 Permafrost

Permafrost is ground, including both unconsolidated sediments and bedrock, that remains below 0˚C for at least two consecutive years. Locally, permafrost distribution is related to slope aspect, angle and shape, sediment texture, and the presence, thickness, and type of organic cover (Williams 1995; Williams and Burn, 1996). Ice content within permafrost in the Eagle Plains area is variable and generally lower on topographic highs and convexities and higher on gentle slopes and in valleys Permafrost within the Eagle Plains Ecoregion is up to 200 m thick (Yukon Ecoregions Working Group, 2004).

Snowpack, vegetation, substrate, moisture regime and topography are important influences on permafrost temperatures (Zhang et al., 2021). The Project Area is located entirely within the zone of continuous permafrost, and ground temperatures were expected to be in the -1˚C to -2˚C range in 2015 (at 10 m depth) (Burn et al., 2015). A mean annual ground temperature (MAGT) of -1.2 ˚C was measured south of the Eagle Plains Hotel at km 347 on the Dempster Highway by Burn et al. (2015). The average temperature of the permafrost in the J-19 well area (Figure 2-1) in 1998 was about -2˚C (Northern Cross Yukon, 1998).

The active layer is the surface layer, overlying permafrost, that freezes and thaws each year. Its thickness depends on elevation, aspect, slope position/shape, sediment texture/drainage, snowpack and vegetation cover (Williams and Burn, 1996; Bonnaventure et al., 2012; Zhang et al., 2021). The active layer ranges from about 0.2 to 2 m thick within the region encompassing the Project Area (Yukon Ecoregions Working Group, 2004), except in areas where vegetation had been stripped (i.e., in road cuts, as per Heijmans et al., 2022). Well drained, coarse-grained soils tend to have a thicker active layer than poorly drained, fine-grained soils (Li et al., 2012). Active layers may be thicker, locally reaching bedrock at depths of 3-4 m,

following wildfire (Coates, 2008; Kryotek Arctic Innovation, 2015a). Burn et al. (2015) determined that the active layer was 1.5 m thick at km 347 on the Dempster Highway in late summer. Shallow borehole data were acquired at several historical well pad sites and at a few locations along the Dempster Highway (Kryotek Arctic Innovation, 2015a,b). Data from these studies are summarized in Section 3.1.1, and site locations are shown in FigureFigure 2-1. Areas affected by wildfire show locally thicker active layers.

Ice-rich permafrost is common in fine-grained deposits along the Dempster Highway, but the portion of the highway traversing Eagle Plains is relatively unaffected by permafrost "due to the shallow soils and absence of water courses" (Burn et al., 2015). Burn et al. (2015) identified thaw subsidence (i.e., thawing permafrost) as the primary risk factor for infrastructure damage along the length of the Dempster Highway, followed by the effects of freeze/thaw cycles in water-logged soils overlying impermeable permafrost layers. Organic-rich soil and peat are found in depressions and valley bottoms within the Project Area (Hughes, 1972). The lower permeability of these sediments results in the preservation of ice-rich permafrost that is more susceptible to thaw subsidence.

Ice-wedge polygons with slight depressions (furrows) above the wedges were observed at tundra sites along the Dempster Highway (Burn et al., 2015) and are similarly visible on some flat-topped ridges in the Project Area.

2.4.1 Terrain Stability

Terrain stability within the Eagle Plains region, which is typified by modest relief and slope steepness, largely reflects the local ice content, depth, and thaw sensitivity of permafrost. Steeper topography merely compounds permafrost-related instabilities. The principal manifestations of permafrost-related instability are active-layer detachments or thermokarst. Active-layer detachments occur naturally on slopes shallowly underlain by permafrost, whether or not ice-rich, commonly in response to intense or prolonged rainfall/snowmelt and/or warm air temperatures. Active-layer detachments are uncommon, but mainly occur on south- to southeast-facing slopes of 25 to 45% gradient (Haseldine, 2021). The number of active-layer detachments has been increasing in the Eagle Plains region since 1992 (Haseldine, 2021), presumably in association with climate change.

Active-layer detachments commonly occur in response to wildfires, following sudden thickening and saturation of the active layer (Coates, 2008).

Thermokarst is the process, and consequential landforms, of differential subsidence in response to the degradation (thaw) of ice-rich permafrost. It is most common in poorly drained, level or gentle topography, but it can also occur through fluvio-thermal erosion on ice-rich slopes subject to concentrated surface runoff. Retrogressive thaw slumps are a unique form of thermokarst, although their rarity in the Eagle Plains region is likely explained by the absence of buried glacial ice (Haseldine, 2021).

3. Methods

3.1 Historical Data Compilation

Initial understanding of permafrost and terrain within the 2,400 km^2 Project Area and the encompassing 20,400 km^2 Eagle Plains region was gained through compilation and review of a diverse range of information. Accounts of historical petroleum exploration activity, which began in the late 1950s, were documented by Martin (1973) and Hamblin (1990). An excellent overview of the Eagle Plains Ecoregion by the Yukon Ecoregions Working Group (2004) was reviewed for background context on regional physiography, bedrock geology, surficial geology, glacial history, climate, hydrology, permafrost, soils, vegetation, and wildlife. Surficial geology mapping was completed by Hughes (1972) for Northern Yukon and Northwestern-Northwest Territories at a scale of 1:500,000, and by Thomas and Rampton (1982) for Moose Lake. Detailed surficial geology and geomorphology mapping had not been completed for the Project prior to Palmer's involvement. Several permafrost studies have been completed along the Dempster Highway (e.g., Burn et al., 2015; Idrees et al., 2015); however, these studies are limited to the highway corridor and are not broadly applicable to most of the Project Area.

Geotechnical and permafrost investigations were previously carried out in the Project Area by Kryotek Arctic Innovation Inc. (2015a, 2015b), where drilling and geophysics were used to assess ground conditions at existing well pads and several proposed sites.

3.1.1 Palmer's Previous Studies of Permafrost and Terrain Stability

Palmer completed the terrain mapping, terrain stability mapping and fieldwork that is summarized herein. Prior to this submission, derivative maps were created from the surficial geology maps for Chance's use. These included memoranda on exploration development suitability mapping (Palmer, 2015; 2021a), borrow source mapping (Palmer, 2015) and terrain sensitivity mapping reclassification for seismic survey planning (Palmer, 2021b). The latter report also provided initial potential locations for cuttings disposal and best practices for seismic exploration.

Table 3-1. Permafrost data from selected locations within the Project Area (adapted from Kryotek Arctic Innovation, 2015a,b). Site locations are shown in Figure 2-1.

Well Pad/ Site Location	Easting	Northing	Avg active layer thickness (m)	Average Ice Content (%)	Ice type	Material Type	Data Acquisition Date
K-29*	395569	7338191	0.2	25	Vx[1], Vs[2]	Silt, some clay, some sand	Late August/early September 2015
B-51*	391347	7340277	2.8	-	Vs	Silty clay, rock chips	Late August/early September 2015

3.2 Terrain and Permafrost Field Investigations

Field investigations were completed to ground truth terrain and permafrost mapping, collect preliminary permafrost information, and to establish permafrost (ground temperature) monitoring instrumentation within the Project Area. Field site data were used to update terrain and permafrost mapping as well as exploration development suitability classifications.

3.2.1 Field Reconnaissance

A one-week field reconnaissance program was completed between July 1 and 7, 2019. The program focussed on characterizing the diversity of landforms, surficial materials, and permafrost conditions across the Project Area. Field measurements and observations were acquired at 103 ground-based sites, and helicopter-based observations of landforms (e.g., colluvial aprons, fluvial fans) and permafrost features (e.g., patterned ground, active layer detachment failures) were acquired opportunistically. Ground-based field observations were made through a series of foot traverses commencing at helicopter drop-off locations. Field assessment involved examining sediments and visible ice in hand-dug soil pits and natural exposures (e.g., landslide scarps, gullies, stream cut banks); measuring depth to permafrost with a permafrost probe (which provides apparent depth to permafrost due to fieldwork being completed before the late-summer maximum thaw period); determining material textures, origins, and expressions; and describing geomorphological processes. Field photographs were taken at each site and additional observations were made from helicopter where possible. The program was completed in parallel with an ecological field program undertaken by EDI. Where possible, terrain interpretations were supplemented by opportunistic field observations made and shared by EDI's ecologists as part of their field program.

Additionally, from July 28 to August 6, 2021, helicopter-supported fieldwork in the Project Area was completed to expand coverage and to examine and document representative soils within the Project Area. Soil horizons were examined and described in hand-dug test pits. Additional examination and sampling of soils is warranted once well pad locations are determined.

3.2.2 Permafrost Investigation, Instrumentation and Monitoring

A six-day, helicopter-supported field program was completed from July 28 to August 6, 2021 to investigate and install ground temperature sensors in the active layer and uppermost permafrost at widely distributed sites representative of the diversity of permafrost and terrain settings. Shallow subsurface ground conditions were investigated using a helicopter-portable Talon drill and hand-dug pits at 15 locations (test pits were dug at all borehole locations; FiguresFigure 3-1, Figure 3-2). The Talon drill uses a combination of percussive augering and/or coring to penetrate through the active layer into permafrost and collect representative core samples. Boreholes were drilled to approximately 2.5 m depth or to refusal. FrostLink ground temperature sensor instruments were installed at four of these sites (FiguresFigure 3-1, Figure 3-2). FrostLink sensors record ground temperatures and phase state (i.e., thawed versus frozen) at 5 cm and 1 m depths and are useful for understanding active layer dynamics and the evolving susceptibility of underlying permafrost to thaw.

A second, three-day, helicopter-supported field program was completed from July 24 to 27, 2022 to download ground temperature data from the four FrostLinks installed during 2021 and examine and sample permafrost using a Talon in advance of installation of two additional FrostLinks (Figure 3-1).

A third, three-day, helicopter and truck-supported field program was completed from July 21 to 23, 2023 to download ground temperature data and examine and sample permafrost using a Talon in advance of installation of six more FrostLink instruments (Figure 3-1). Shallow subsurface ground conditions were also examined in hand-dug testpits at eight locations. Boreholes were drilled to approximately 1.5 m depth or to refusal.

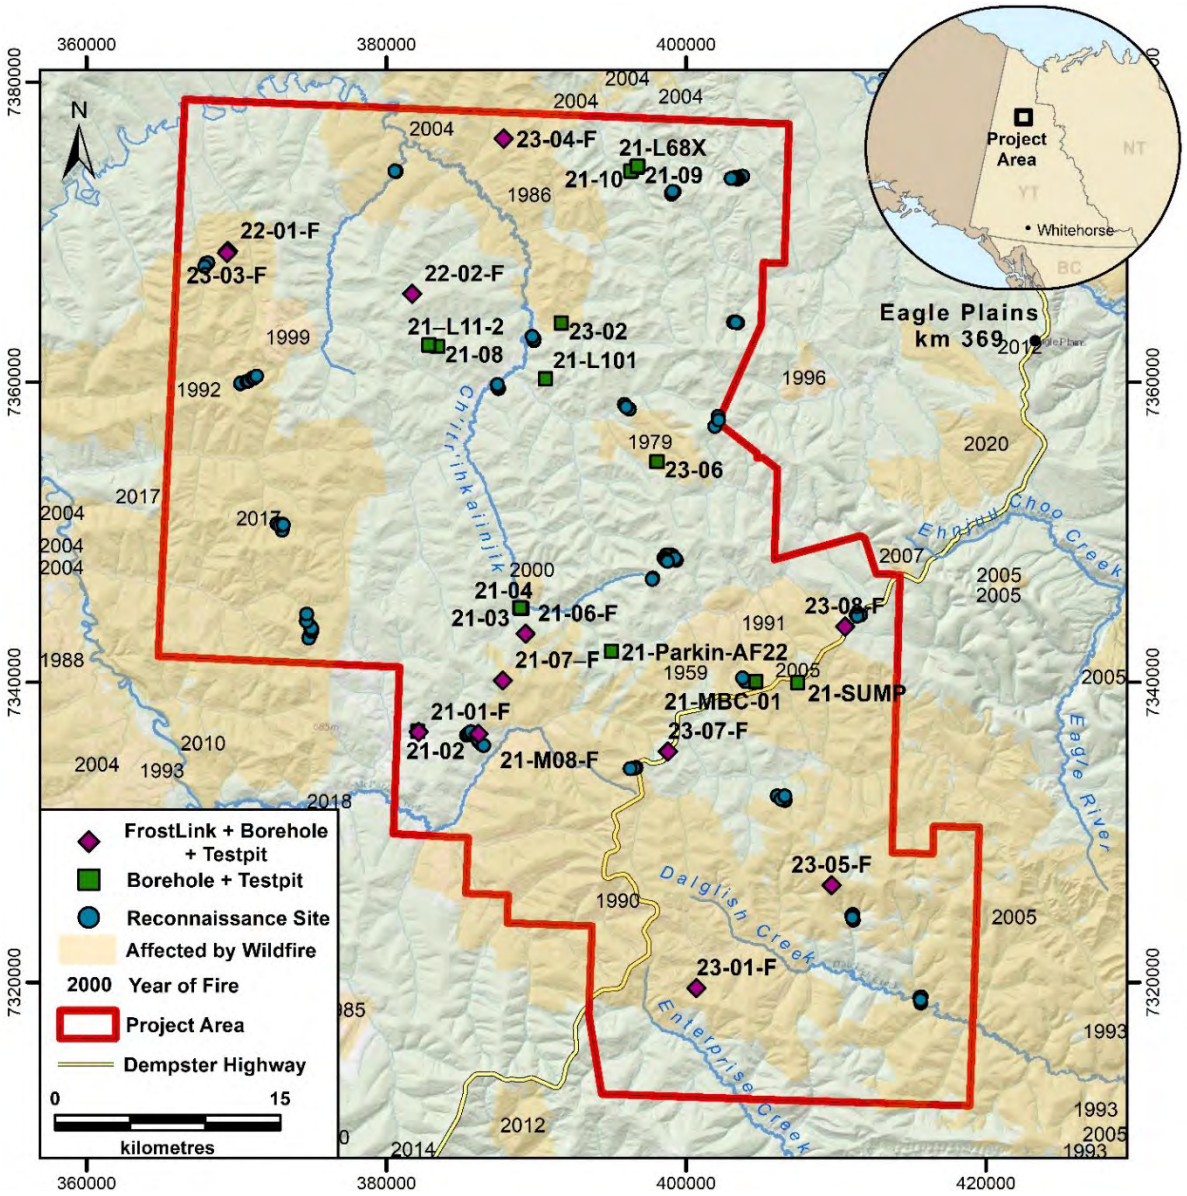

Figure 3-1. Locations of FrostLink sensors, Talon borehole locations, and reconnaissance sites within the Project Area. FrostLink sites beginning with the two-digit year of installation i.e. sites with '21' were installed in 2021.

Permafrost probing was done at each field site to identify the best locations for soil pits and boreholes (i.e., areas without boulders or cobbles near surface and with representative depths to permafrost). Permafrost probing was also completed at historical well sites H28 and M08 (Figure 2-1), in early August 2021, to gain insight into the extent of permafrost degradation (thaw) and any associated ground settlement at former well pad sites. Depth measurements were likely shallower than true active layer thickness, which is generally not achieved until early September.

A spade was used to dig testpits at each field site to inform drill sites, examine and describe soil characteristics and to obtain near-surface soil samples for analysis (Figure 3-2). Soils were preliminarily classified according to the Canadian System of Soil Classification (Soil Classification Working Group, 1998) prior to subsequent refinement based on the results of laboratory analyses. Representative samples of near-surface soils were acquired from the active layer at select testpits. These were analyzed in a laboratory for background geochemistry (e.g., trace metals, hydrocarbons, organic carbon content, etc.).

Talon-drilled boreholes were initiated with auger tooling to condition the holes. Because auger samples are disturbed, the adjacent soil pit was used to log the uppermost portion of the boreholes. A side-smear sampler was used to acquire core segments in 10 or 30 cm sections. Each core section was extracted, split in half lengthwise using a hatchet, logged, and photographed prior to thaw caused by exposure to ambient air. Boreholes were drilled to bedrock, to refusal, or to a point where sloughing or squeezing of the material at depth precluded further penetration. Depth to permafrost (apparent active layer thickness) was recorded at each borehole and in adjacent soil pits to document local variability (generally <20 cm).

Samples of frozen material at the bottom of the boreholes, likely within permafrost, were collected for grain size and moisture content analysis. Where ice content was high, samples were acquired from a greater depth range to achieve the required sample size. Ice content in the cores was estimated visually by volume and later confirmed by moisture content analysis of selected samples. Ice type, percentage and clarity were recorded. The volume of nonvisible ice was determined in the field by beaker analysis.

Figure 3-2. Clockwise from upper left: Helicopter after dropping off drill as a sling load at field site 21-L68X; Drilling with the Talon at field site 21-08; Soil pit at field site 21-02; Surface housing of FrostLink ground temperature/phase sensor installed at field site 21-07-F.

3.3 Mapping of Surficial Geology and Permafrost

Palmer completed surficial geology and permafrost mapping within the Project Area. Surficial geology and permafrost interpretations were based on a combination of multiple high-resolution stereo-imagery sources and high-resolution LiDAR-derived elevation data (rendered as a 2 m-resolution hillshade model), with calibratory reference to background regional surficial geology mapping and seismic shothole logs compiled by the Geological Survey of Canada from historical oil and gas exploration (Smith and Lesk-Winfield, 2010). Aerial photographs were acquired by Chance in 2019 within the northern and southern regions of the Project Area, but smoke from wildfires precluded acquisition within the central portion. Satellite images acquired between 2014 and 2019 were obtained and overlain onto a digital elevation model to generate pseudo-stereo imagery, and these were used as a substitute for stereo aerial photographs in the central portion of the Project Area. Delineations and attributions were applied in DATEM's Summit 3D mapping software linked to an ArcGIS platform.

Surficial geology mapping was completed at a scale of 1:20,000, using the standardized Yukon surficial geology mapping protocols (Lipovsky and Bond, 2014), which are an adaptation of the *Terrain Classification System for British Columbia* (Howes and Kenk, 1997). Minor modifications were made to the mapping protocols to ensure local features and variability were captured. Map units (polygons) were delineated based on internally homogenous combinations of surficial materials, textures, surface expressions, drainage classes, and geomorphological processes. Under this system, up to two surficial materials are identified in each polygon as either a primary or secondary material, or in stratigraphic relation to each other. Map units were symbolized based on the primary surficial material. Discrete terrain features and geomorphic processes too small to be mapped as individual polygons, such as thermokarst subsidence and active-layer detachments, have been identified using point and line features, respectively. All codes used in the mapping are defined in the map legend.

Relative depth to permafrost (active layer thickness) and relative ice content of permafrost were interpreted for each map polygon based on surface indicators and calibration and extrapolation (based on landform associations) from field observations. Relative depth to permafrost refers to the approximate maximum (end of summer) thickness of the active layer (Table 3-2). Relative ice content of permafrost is an inference of the relative amount of excess ice within permafrost, whether in pores, segregated seams and lenses, or massive bodies (e.g., wedges) (Table 3-3). Terrain and permafrost interpretations are limited by the mapping scale and represent the average conditions within each map unit. Ground ice may be more or less extensive than mapped due to the necessary generalization of terrain characteristics or geomorphological processes within the map unit.

Table 3-2. Permafrost classification for inferred relative depth to permafrost.

Depth Classification	Definition	Description
Near-surface	Permafrost table likely less than 0.4 m below the ground surface.	Permafrost is typically found within or at the base of surface organics. Includes map units overlain by organic blankets and veneers; very poorly to imperfectly drained fluvial fans, terraces, and veneers; and inactive floodplains.
Shallow	Permafrost table likely between 0.4 and 1.0 m below the ground surface.	Considered the typical depth-to-permafrost class in the Project Area. Common in relatively fine-grained sediments; includes most imperfectly to moderately well drained deposits, active floodplains and most deposits containing evidence of ice-wedge polygons or thermokarst subsidence.
Deep	Permafrost table likely more than 1 m below the ground surface.	Most common in relatively coarse-grained and clast-supported deposits; includes bedrock and most moderately to well drained colluvium and weathered bedrock along convex ridges, spurs, and scarps.

Table 3-3. Permafrost classification for inferred relative ice content.

Ice Content	Pore Ice	Segregated Ice	Massive Ice	Excess Ice	Description
Ice-rich	Continuous	Extensive	Indicated, inferred, or likely; widespread	Major	Typically includes sediments overlain by organic blankets and veneers; poorly to very poorly drained, inactive fluvial deposits; and map units affected by ice-wedge polygons and/or thermokarst subsidence.
Ice-moderate	Continuous	Widespread, in seams and lenses	Possible, locally	Moderate	Includes fluvial deposits not classified as ice-rich; fine-grained colluvial aprons and blankets; imperfectly to poorly drained matrix-supported colluvial blankets; and map units affected by sheetwash or solifluction.
Ice-poor	Discontinuous to continuous	Local, mostly in seams	Unlikely, except in isolated areas	None to minor	Applies to most moderately to well drained terrain, commonly convexities, throughout the rolling uplands and colluvial slopes.

3.4 Classification of Exploration Development Suitability

Exploration development suitability is a reclassification of the surficial geology and permafrost mapping (Section 3.3) that reflects permafrost-related terrain stability and areal differences in sensitivity to disturbance. The classification was developed to inform planning for oil and gas exploration and serve as a basis for avoidance or mitigation of areas most sensitive to disturbance. Exploration development suitability has been divided into two primary classifications:

- Road and well pad suitability:
  - Guides the establishment and maintenance of access roads[1] and well pads.
- Mix-bury-cover (MBC) disposal suitability:
  - Identifies areas of the landscape that are geomorphologically isolated and potentially suitable for disposal of cuttings using MBC techniques, if pre-existing areas of disturbance cannot be used.

The two classifications were derived from the 1:20,000-scale, field-checked surficial geology interpretations and are specific to the Project Area. Map units (polygons) were categorized into five road and well pad suitability classes, ranging from Very High to Very Low, and two MBC disposal suitability classes, Potentially Suitable and Probably Unsuitable. The exploration development suitability classifications were aided by professional experience in unglaciated Yukon (e.g., McKillop et al., 2013; McKillop et al., 2016). Definitions, explanations, and implications of each class are outlined in Section 4.3.

For both classifications, a lower suitability rating does not necessarily mean suitable terrain is absent within the map unit; localized portions of such map units may be suitable for exploration development or MBC disposal based on site-specific terrain characteristics. Similarly, a higher rating does not necessarily mean the entire polygon is suitable for exploration development. Field investigations remain important for final evaluation of suitability classifications at the site-specific scale.

3.5 Quality Assurance and Quality Control

A number of quality assurance/quality control (QA/QC) techniques and procedures were adopted over the course of the work described above. Surficial geology and permafrost field investigations were always completed with a minimum of 2 qualified and experience staff, thereby ensuring agreement in the interpretation and appropriate documentation of permafrost and terrain.

Permafrost investigations involved multiple approaches, including frost probing, shallow drilling and coring, hand-dug testpitting, and installation and monitoring of FrostLink temperature/phase sensors, which strengthen understanding of the shallow permafrost environment and enable detection of any outlier results. Additionally, the ground temperature results were shared with a third party (Kryotek Arctic Innovation Inc.) to confirm interpretations of results.

Soil samples for the Project Area were sent to the accredited Whitehorse laboratory of ALS Environmental for analysis, where they were analyzed for background geochemistry and grain size distribution. Preliminary, field-based classifications were updated, as needed, based on the results.

[1] *This classification conservatively considers all-weather access roads, although only winter roads are proposed.*

4. Results

4.1 Surficial Geology and Soils

The surficial deposits and the character of the landscape reflect the structure and lithologies of underlying bedrock and the unglaciated history of the region. Overall, the Project Area exhibits a dendritic drainage pattern that has dissected a plateau comprising gently dipping sedimentary bedrock beds (mostly shale and sandstone). The surficial geology mapping completed within the Project Area reveals broad, rounded complexes of ridges and spurs are divided by valleys with colluvium-mantled walls locally interrupted by concentric scarps of relatively erosion-resistant weathered bedrock (Figure 4-1) (Appendix A). Streams are found in the valley bottoms and fluvial fans are locally present (Figure 4-1). Most landforms and materials in the Project Area are interpreted to have originated prior to the last glaciation. The landscape is dominated by deeply weathered colluvium and unconsolidated weathered bedrock units that have developed on slopes and ridges over many millennia (Table 4-1).

Table 4-1. Areal distribution of surficial materials and landforms by primary surface material.

Surficial Material and Landform	Terrain Code	Areal Extent	Areal Percentage
Colluvial Veneer	Cv	810.5 km^2	33.8%
Weathered Bedrock Veneer	Dv	413.6 km^2	17.3%
Colluvial Blanket	Cb	397.4 km^2	16.6%
Colluvial Mantle of Variable Thickness	Cw	324.8 km^2	13.6%
Colluvial Apron	Ca	188.5 km^2	7.9%
Fluvial Plain (active and inactive)	FAp; Fp	111.8 km^2	4.7%
Fluvial Veneer (active)	FAv	49.5 km^2	2.1%
Fluvial Fan (active and inactive)	FAf; Ff	36.6 km^2	1.5%
Organic Veneer	Ov	10.2 km^2	0.4%
Organic Blanket	Ob	28.9 km^2	1.2%
Bedrock	R	20.5 km^2	0.9%
Fluvial Terrace	Ft	2.9 km^2	0.2%
Anthropogenic	A	1.4 km^2	< 0.1%
Total		**2,396.6 km^2**	**100%**

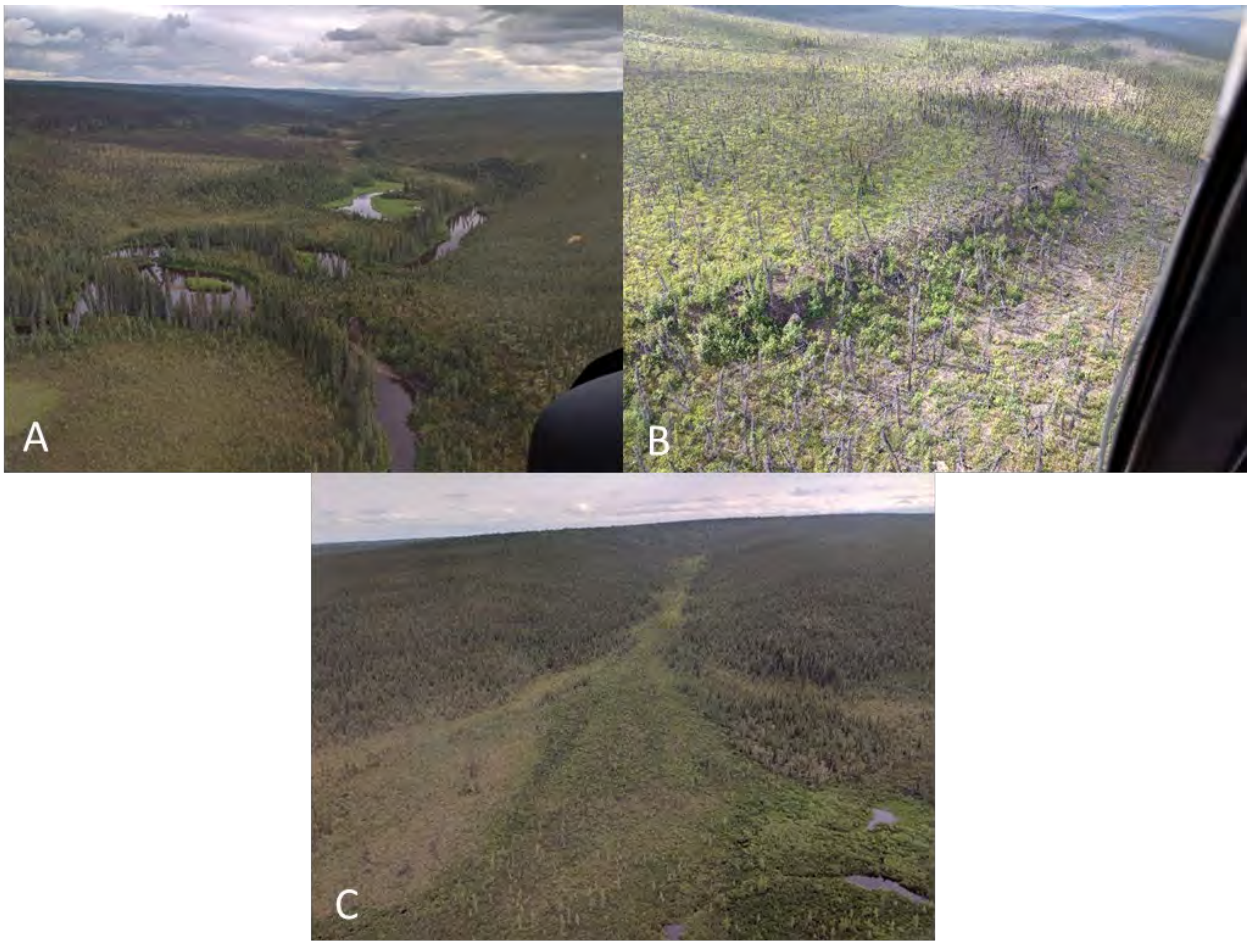

Figure 4-1. Field photographs representative of the landscape and geomorphological processes within the Project Area: A) Dalglish Creek valley, showing an irregularly meandering channel and several areas of lateral erosion where the creek has cut into the gently sloping valley walls; B) Convex, mid-slope ridge comprising erosion-resistant bedrock mantled by a veneer of weathered bedrock and colluvium; C) Gently sloping fluvial fan exhibiting a typical wedge shape and transitioning into a modern stream valley on lower right.

Geomorphological processes related to permafrost include ice-wedge polygons, thermokarst subsidence and mass movement, including a few active-layer detachments (Figure 4-2). Permafrost features are touched upon below but are discussed in more detail in Section 4.2.

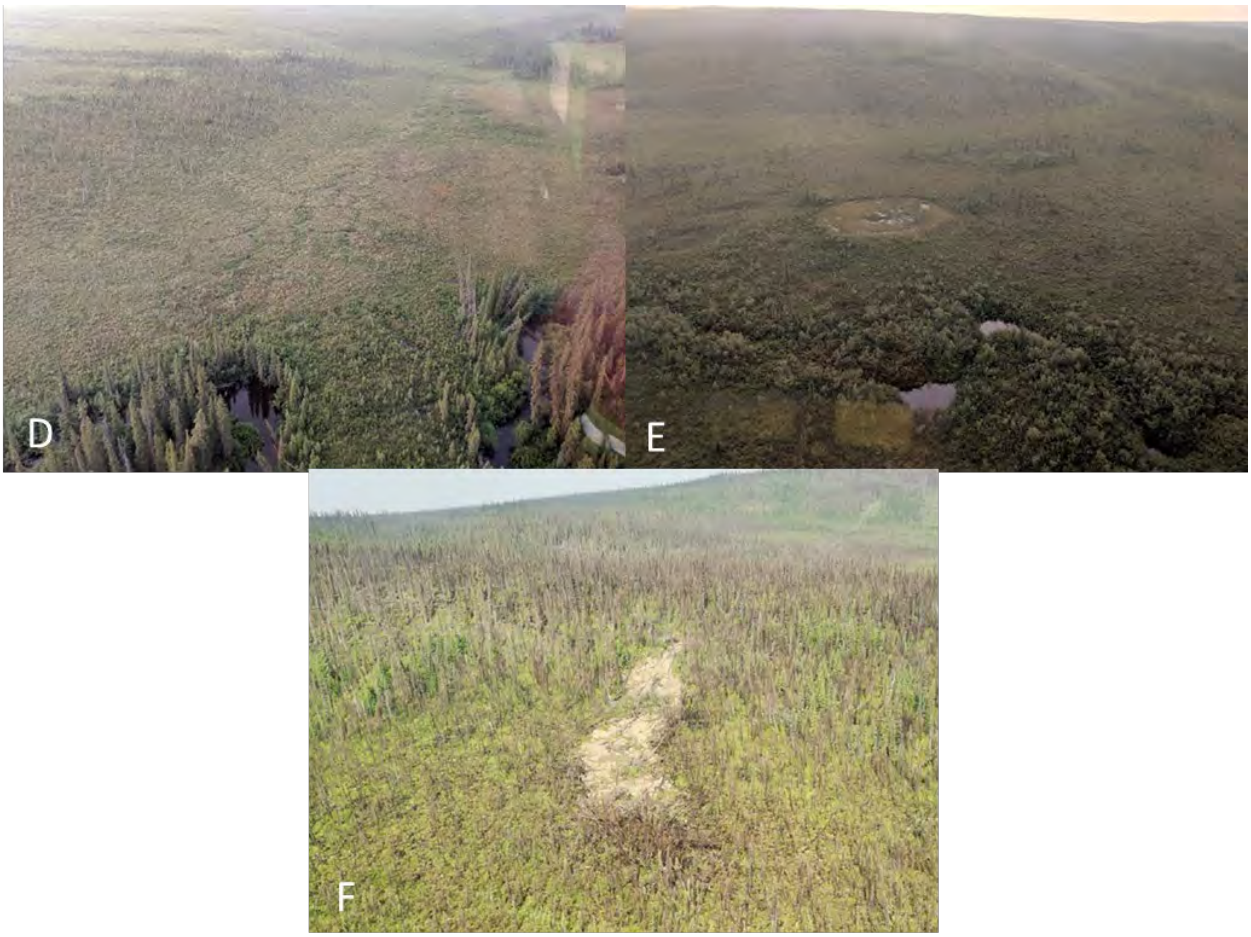

Figure 4-2. Field photographs representative of common landforms and permafrost-related geomorphological processes within the Project Area: D) Surface expression of ice-wedge polygons within an inactive floodplain; E) Thermokarst depression within an inactive floodplain; and F) Recent active-layer detachment initiated at the crest of a gentle colluvial slope.

The following subsections characterize the terrain conditions within the Project Area, by dominant surficial material, and acknowledge the nature of anthropogenic features and near-surface soils.

4.1.1 Colluvial Deposits (C)

Colluvial deposits (C) are the most extensive surficial material. They are found on slopes and sloping ridges, covering 71.9% of the Project Area (Table 4-1). Colluvial deposits are typically fine-grained (mainly silt and clay), locally overlain by or intermixed with loess, with imperfect to poor drainage. Locally sandier deposits, with 10-40% pebbles, cobbles and less commonly, boulders, are moderate to well drained. Sandy deposits are more common in areas of sandstone bedrock. Locally, colluvial deposits can include disseminated organics, in layers and lenses, with or without fragments of wood.

Colluvium is typically thin on upper slopes, thickening toward the base of slopes (ranging from veneer (Cv) to blanket (Cb) deposits). In some areas, colluvium is thick enough to form an apron covering the base of

a slope (Ca). These areas tend to be rich in silt (including resedimented loess), organics and ice, especially on north-facing slopes, so they are particularly sensitive to disturbance.

North-facing colluvial slopes are cooler and may display different vegetation than warmer, south-facing slopes. The active layer is expected to be thinner on cooler slopes than on warmer slopes. A few active-layer detachments, sheetwash, and solifluction have been identified on some colluvial slopes, with instances of ice-wedge polygons in medium to fine-grained material. Their locations are shown on the maps in Appendix A.

4.1.2 Weathered Bedrock (D) and Bedrock (R)

Bedrock within the Project Area is commonly fissile and deeply weathered, forming veneers of material overlying competent bedrock (Figure 4-3). Weathered bedrock (D) is found on ridge tops and convex slope breaks along valley walls, typically moderately to well drained, and covers 17.3% of the Project Area (Table 4-1-1). Weathered bedrock commonly consists of silt and/or clay, similar to colluvium (or sand in areas of sandstone). However, it is denser and harder to drill than colluvium and contains sand or pebbles/cobbles derived from the underlying more solid bedrock. It commonly grades downward to more solid bedrock. Competent bedrock (R) is rare at surface and is limited to exposures in steep scarps adjacent to ridge tops; it covers only 0.9% of the Project Area (Table 4-1-1). Examples include several conspicuous outcrops of sandstone and conglomerate near the Dempster Highway (Figure 4-3).

Some instances of ice-wedge polygons are present within weathered bedrock material, potentially by exploiting existing bedrock fractures, and is further discussed in Section 4.2.

Figure 4-3. Field photographs representative of typical surficial material characteristics: G) Outcrop of competent conglomerate exposed in a bluff near the Dempster Highway; H) Sandy veneer of weathered bedrock, typical of deposits found on ridge crests.

4.1.3 Fluvial Deposits (F)

Fluvial deposits (F) comprise 8.5% of the Project Area (Table 4-1-1; Figure 4-4). They generally have poor drainage and are found along the bottoms of broad valleys, as active (FAp) or inactive (Fp) plains, although fans (Ff or Faf) and veneers (Fv or Fav) of fluvial sediments are mapped at confluences and within narrow ravines, respectively. Fluvial sediments comprise silt and clay with some sand and are interbedded with organic-rich layers and peat. The peat may include pieces of wood.

A number of geomorphological processes are present within fluvial deposits, such as irregularly sinuous channels, and permafrost features, such as ice-wedge polygons and thermokarst that are typically present due to their poor drainage and fine-grained materials.

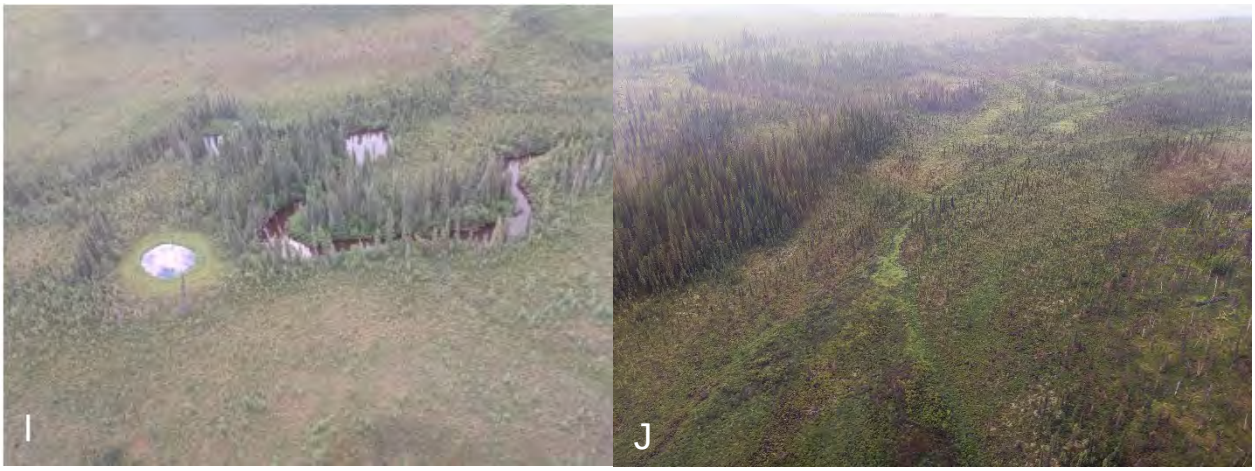

Figure 4-4. Field photographs representative of fluvial deposits within the Project Area: I) Active fluvial plain with irregularly meandering channel; J) Active fluvial fan, especially the areas with brighter green vegetation.

4.1.4 Organic Deposits (O)

Organic material (O) accumulates on most imperfectly to very poorly drained deposits throughout the Project Area (Figure 4-5), but it is only identified in the terrain code (map label) when its thickness is interpreted to exceed about 0.5 m, mainly in valley bottoms. Organic veneers (Ov) and blankets (Ob) are generally mapped in low valley positions near active streams and comprise 1.6% of the Project Area (Table 4-1-1).

Typical geomorphological processes in organic deposits are thermokarst and ice-wedge polygons due to the poorly-drained and fine-grained materials that are often dominated by ice-rich permafrost.

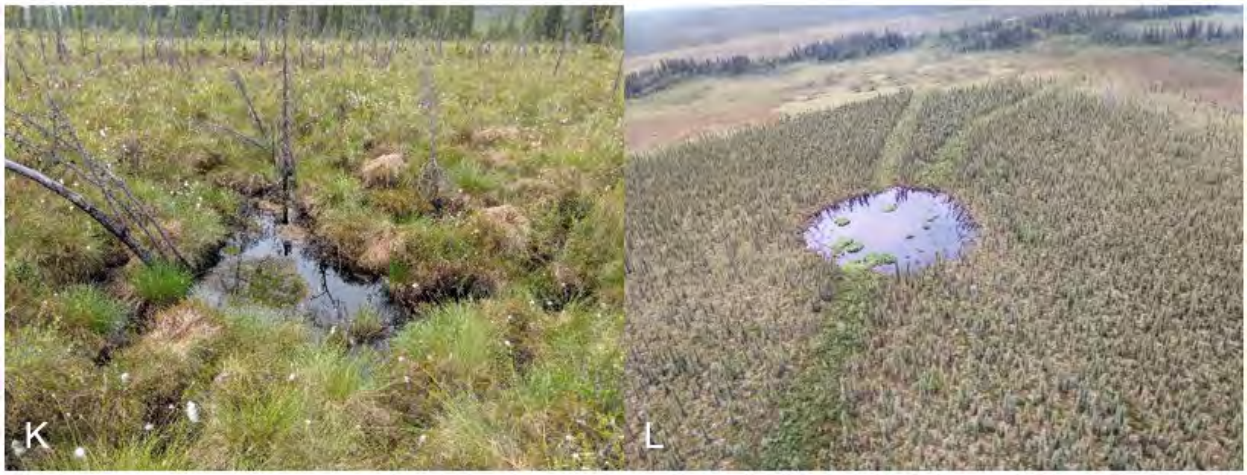

Figure 4-5. Field photographs representative of organic deposits within the Project Area: K) Organic veneer with poor to very poor drainage; L) Organic blanket with poor to very poor drainage and an actively expanding thermokarst pond along a former winter trail.

4.1.5 Anthropogenic Features (A)

Areas significantly disturbed by human activity (excluding trail/road networks, which are unmapped linear features) have been mapped as anthropogenic landforms (A), and cover <0.1% of the Project Area (Table 4-1-1). They mainly include camp areas and borrow pits near the Dempster Highway.

4.1.6 Soils

All soils identified within the Project Area are Cryosols, as expected for an area within the zone of continuous permafrost. Static Cryosols are found in areas of fine-grained colluvium or weathered bedrock veneer and fine-grained fluvial sediment. Twelve of the sixteen soils specifically examined and classified within the Project Area (Figure 4-6) are static, due to no clear evidence of cryoturbation, especially within saturated pits. Turbic Cryosols exhibit lenses or layers of organic material, incorporated wood pieces, and/or inverse grading. These cryoturbated soils are found in fluvial, weathered bedrock, or colluvial material that is also fine-grained. Coarser-grained colluvium and weathered bedrock on upper slopes and ridges tends to develop Orthic Static Cryosols.

Gleysolic Crysols are gleyed (due to saturation) and/or contain rusty mottles (due to periodic wetting). Soils at low elevations are either Gleysolic or Regosolic, and can be either Turbic or Static. Soils on slopes at higher elevations can be Brunisolic, Orthic, or Gleysolic and the sites investigated in this study were all Static. Ridge-top soils are Regosolic, Gleysolic, or Orthic and are most commonly Static.

Samples were not analyzed for pH; soils are assumed to be dystric as noted in Yukon Ecoregions Working Group (2004). Each testpit ended on permafrost, except for field site 21-09, which ended on cobbles.

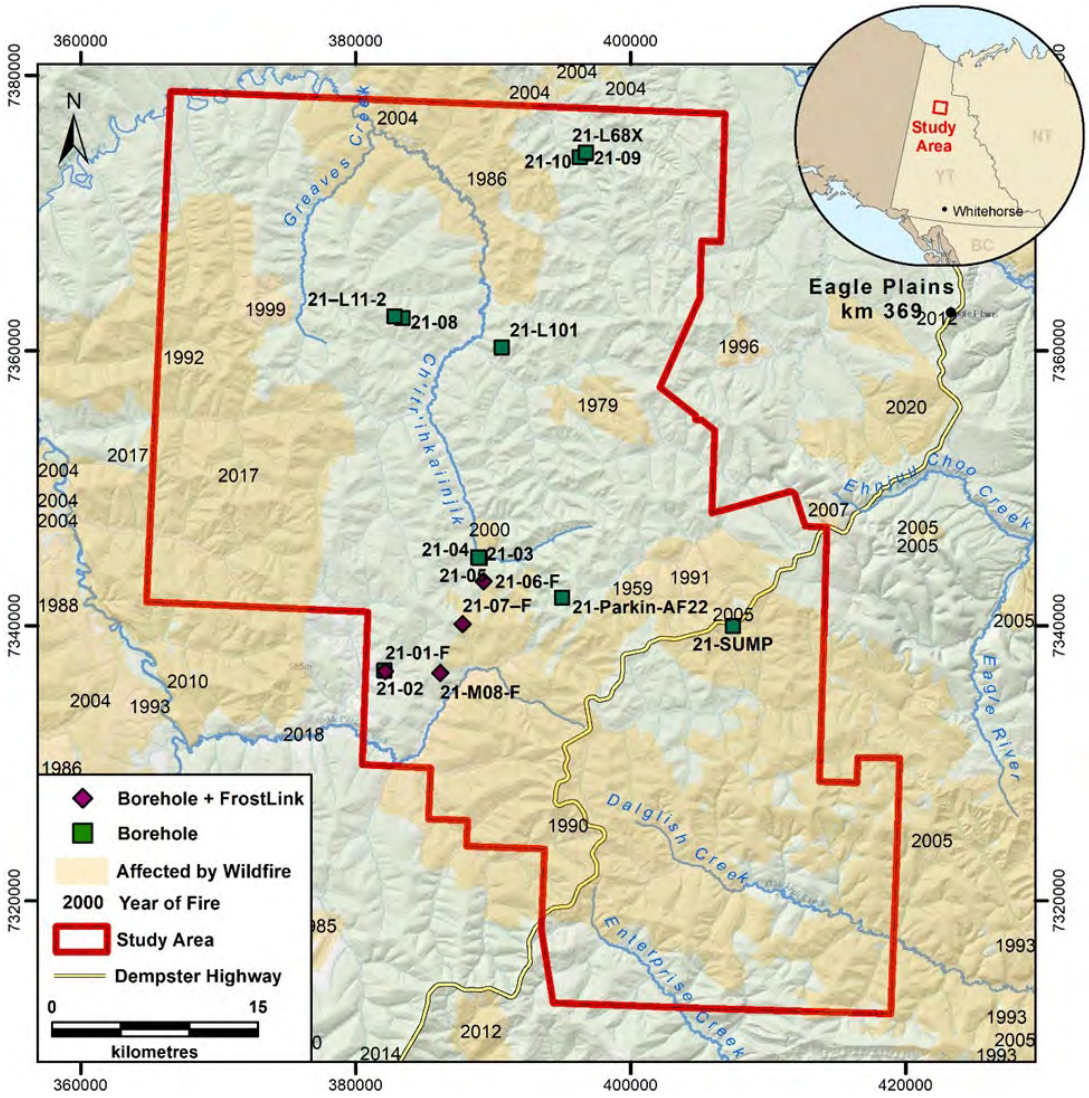

Figure 4-6. Locations of 2021 soil examination and classification sites.

4.2 Permafrost

Permafrost has a strong influence on drainage conditions, the rates, and mechanisms of colluvial (mass movement) processes, and overall hillslope and valley bottom morphology. An appreciation of permafrost characteristics and processes is therefore important for the planning of exploration projects in the region.

Permafrost is ubiquitous across the Project Area. The active layer is thicker in areas of weathered bedrock and areas affected by recent forest fires and thinner in valley bottoms and on lower slopes. Ground ice expression ranges from nonvisible (Nb) to tiny crystals (Vx) to lenses and layers of segregated ice (Vs) (Appendix C, borehole logs); massive ice is also inferred to underlie portions of the ground, based on local surface expressions of ice-wedge polygons and observation of a buried ice wedge in a recent erosion scar along a creek bank.

Relative active layer thickness and ice content were interpreted, field-calibrated, and mapped across the Project Area as described in Section 4.2.1. The borehole data (Appendix C) provide additional information on active layer thickness (shown as “permafrost depth” on borehole logs), ice content and permafrost sensitivity to disturbance.

4.2.1 Active Layer Thickness

The active layer thickness (the bottom of which is referred to in borehole logs as the permafrost table depth) varies spatially at regional and local scales, and over time in association with climate change and/or anthropogenic disturbance. The depth to thaw can fluctuate seasonally, increasing following snowmelt in the spring and peaking to total active layer thickness in late summer. The relative thinness of snow cover in the semi-arid environment of the Project Area allows cold temperatures to penetrate the ground and refreeze the active layer in most years. Observations of incomplete active layer refreezing have been reported in areas where the active layer is anomalously thick due to wildfire (this study; Kryotek Arctic Innovation, 2015a,b).

Well-drained ground insulated by thick annual snow cover tends to have thicker active layers than wind-swept or poorly drained areas.

In areas of thick, mossy organic cover or in poorly drained valley bottoms, permafrost may be encountered at depths as shallow as 22 cm below the surface. North-facing colluvial aprons are also expected to have thin active layers. These “near-surface” active layers are rare, however, interpreted to represent only 3.9% of the Project Area Table 4-2.

Active layers are interpreted to be moderately thick (0.4-1.0 m) across the majority of the Project Area (85.9%, Table 4-2). These areas of “shallow” permafrost are most common on poorly drained valley bottoms, including fluvial terraces and inactive floodplains, in fine-grained colluvium, in fine-grained weathered bedrock and beneath insulating organic deposits.

Active layers appear to be thicker (>1.0 m) in areas of coarser-grained colluvial or weathered bedrock deposits typically found on bedrock scarps and ridges (10.2%, Table 4-2). Ridgetops, when exposed, sparsely vegetated, and well drained, also have such “deep” active layers, regardless of grain size, with thicknesses that may exceed the borehole depth (for example site 23-05-F; Appendix C).

Additionally, active layers can thicken in response to wildfire. An example of this can be observed at site 22-01-F, in contrast to active layer thickness at site 22-02-F. While the material and ice content are the same at both sites, a thicker active layer of 0.9 m is evident at site 22-01-F, compared to an active layer of 0.35 m at site 22-02-F (Appendix C). This difference in active layer thickness was likely caused by the 2017 wildfire that affected site 22-01-F. Based on borehole information from sites affected by older wildfires (Figure 3-1; Appendix C), recovery of permafrost occurs with time and re-establishment of insulating vegetation cover.

Table 4-2. Areal distribution of field-calibrated, interpreted permafrost conditions by relative depth and ice content.

Permafrost Condition Classification		Estimated Relative Ice Content			
		Ice-poor (<10% ice)	Ice-moderate (10-20% ice)	Ice-rich (>20% ice)	Total
Estimated Active Layer Thickness	Near surface (<0.4 m)	0% (0 km^2)	0.1% (2.2 km^2)	3.8% (91.9 km^2)	3.9% (94.1 km^2)
	Shallow (0.4 – 1 m)	33.2% (794.6 km^2)	43.0% (1029.8 km^2)	9.8% (234.1 km^2)	85.9% (2,058.5 km^2)
	Deep (>1 m)	9.3% (222.5 km^2)	0.9% (21.6 km^2)	0% (0 km^2)	10.2% (244.0 km^2)
	Total	42.5% (1,017.1 km^2)	44% (1053.6 km^2)	13.6% (326 km^2)	100% (2396.6 km^2)

4.2.2 Ice Content

Permafrost may or may not contain ice, depending primarily on material composition and moisture regime. Data collected from FrostLink sensors (21-06-F, 21-M08-F, 22-02-F) installed within the Project Area in 2021 and 2022 confirm that in areas of undisturbed vegetation, cold, stable permafrost with relatively thin active layers are present (Figure 3-1).

Permafrost ice content varies significantly with depth but without any obvious trends (Appendix C: borehole logs). Ice content ranges from 5 to 95%, commonly within the same borehole, but on average is 10-50%.

Permafrost is interpreted to be ice-rich (>20% ice; Heginbottom et al., 1995) across 13.6% of the Project Area (Table 4-2), as ice content varies with depth, grain size, and drainage. Segregated ice forms lenses and layers; ice crystals are also common. Massive ice may be present locally. Ice-rich areas may be present along some ridges where the surface expression of ice-wedge polygons is visible in LiDAR data and/or aerial imagery. Here, it appears that ice wedges may have exploited existing bedrock fractures and it is uncertain if these features are relict or active. Ice-rich/ice-moderate permafrost is common in valley bottoms below imperfectly to poorly drained, fluvial deposits or poorly drained organic deposits, but is also abundant in thick, fine-grained colluvial deposits and even in some ridge-top weathered bedrock deposits.

Ice-moderate permafrost contains 10-20% ice by volume (Heginbottom et al., 1995) and is found where textures are sandy and ground moisture is moderate. Thin seams or lenses of ice are common. Ice-moderate terrain is interpreted to comprise 44% of the Project Area (Table 4-2) and is commonly found below imperfectly drained fluvial deposits and thick, fine-grained colluvial deposits. Ice-moderate permafrost is also inferred in regions affected by sheetwash or solifluction. Ice-moderate deposits were found at boreholes 21-02, 21-07-F, 21-10, and 23-01-F (Appendix C). Boreholes 21-07-F and 21-10 were only drilled to 0.8 m; their fine-grained material suggests that these deposits are likely ice-moderate to ice-rich at greater depth. Borehole 21-10 is a fluvial deposit of clay and silt that was expected to be ice-rich

given its valley bottom location. Borehole 23-01-F is a thick, fine-grained colluvial deposit that was ice-moderate to the drilled depth of 1.3 m.

Ice-poor permafrost is considered to have volumetric ice contents of less than 10% (Heginbottom et al., 1995) and is interpreted to comprise 42.5% of the Project Area (Table 4-2). It is commonly only found in areas (or layers) of coarse-grained material, often with sparser vegetation and better drainage, such as exposed ridgetops. Ice-poor permafrost was identified at boreholes 21-SUMP, 23-05-F, and 23-06.

Ground ice content in permafrost is highly variable, both laterally and vertically. While sandier, well drained deposits are expected to be ice-poor, this is not always the case. Similarly, not all valley floor deposits are ice-rich. As such, site-specific investigation of confirmed well pad and MBC disposal areas will be important prior to establishment.

4.2.3 Permafrost-related Features

As permafrost acts as an impenetrable barrier to water flow, the active layer above permafrost can become quite saturated during the summer months. As such, freeze and thaw of this saturated material commonly results in differential frost heave, resulting in irregular micro-topography and the formation of earth hummocks. Additionally, this terrain is favourable for the formation of ice-wedge polygons, as continuous freeze and thaw cycles can cause contraction cracks, which are then infilled by water retained in the active layer, and lead to the development of ice wedges (Figure 4-7). Ice-wedge polygons occur in many gentle valley bottoms and on some of the broad, near-level ridge crests, although some upper-elevation occurrences may be relict features and more so a reflection of underlying bedrock fracturing and are considered ice-rich permafrost terrain (Table 4-2).

Massive ice may be present in some low-lying areas. It grows and shrinks in response to changing climatic conditions and ground thermal regime (e.g., organic cover thickness, local drainage conditions; Burn et al., 2015; Watanabe et al., 2017).

Geomorphological processes related to permafrost are indicated by cryoturbation, solifluction, active-layer detachments (Figure 4-2), ice-wedge polygons (FiguresFigure 4-2 andFigure 4-6), thermokarst subsidence (Figure 4-2) drunken forest (Figure 4-8) and earth hummocks.

Figure 4-7. Ice wedge exposed in freshly eroded stream bank within the Project Area (1.9 m-tall person for scale).

Figure 4-8. Drunken and burnt forest at field site 21-SUMP.

4.2.3.1 Permafrost-related Mass Movement

On slopes, summertime saturation reduces the shear strength of surface deposits overlying permafrost and promotes solifluction and active-layer detachments (Figure 4-2). Solifluction is best recognized at surface by conspicuous lobes of material with steep, rounded fronts, and tapering tails. Areas of active solifluction

can gradually destabilize roads, in the long-term, through irregular settlement and mounding. Some slopes appear more prone to active-layer detachments than others within the Project Area; most occur on south- to southeast-facing slopes of 25 to 45% gradient. Evidence of past failures can be seen in aerial photography, where conspicuous downslope-oriented stripes of deciduous trees have recolonized the landslide scars. Both solifluction and active-layer detachments increase in frequency and magnitude shortly after wildfire, mainly due to loss of rooting strength and insulating organic cover (Coates, 2008). This is consistent within observations within the Project Area: active layer detachments are most common on previously burnt slopes.

In areas of ice-rich permafrost, even minor ground disturbances may trigger thermokarst activity (e.g., natural windthrow of trees that tears the surface organic mat and exposes underlying sediments). When this occurs, the ground subsides or, if on a slope, fails in response to the melting of buried ice bodies. Thermokarst commonly continues for years to decades once initiated, through a positive feedback cycle caused by increases in thaw leading to increases in water ponding, which leads to increases in thaw.

Slopewash is a widespread and important process on slopes underlain by permafrost. Material is transported downslope through a combination of sheetwash (entrainment of sediment grains in surface runoff; Appendix A) and piping (entrainment of grains in water percolating through the active layer). Shallow runnels, also known as water tracks, are the surface manifestation of slopewash, formed by the repeated and preferential downslope transport of sediments along natural drainage paths. As slopewash runnels deepen, they concentrate and prolong the conveyance of surface runoff and shallow groundwater, resulting in local depression of the permafrost table (thickening of the active layer). The interception of slopewash runnels by roads necessitates cross-ditching or drainage culvert installation; still, such sites may form ‘icings’ during the winter and spring months, which increase maintenance requirements on road surfaces and embankments.

4.2.4 Ground Temperatures

Ground temperatures from three distinct sites within the Project Area were recorded from summer 2021 to summer 2022. Sensor 21-06-F (Figure 3-1), located on a gentle, south-facing slope within a forested area, recorded a mean near-surface (5 cm depth) temperature of -2.1°C (Palmer, 2023; Table 4-3). Battery malfunction prevented 1-m depth ground temperature data from being recorded. Sensor 21-07-F (Figure 3-1), located in a wildfire-affected area, recorded a mean annual near-surface temperature of 0.9°C and a mean annual 1-m depth temperature of -0.2°C (Palmer, 2023; Table 4-3). This area is consistent with expected wildfire effects and the potential for incomplete freeze-back of the active layer, indicating degrading permafrost. Lastly, sensor 21-M08-F (Figure 3-1; Table 4-3), located on a northeast-facing slope, recorded a near-surface (5 cm depth) MAGT of -1.3°C and a MAGT of -3.8 °C at 1 m-depth, representing an area of colder, more stable permafrost (Palmer, 2023).

From the summer of 2022 to the summer of 2023, sites 21-07-F and 21-M08-F continued to record ground temperatures, with negligible change in ground temperatures at depth for both sites across the 2-year recording period (Figure 4-8 to

Figure 4-11). Two additional FrostLinks were installed at sites 22-01-F and 22-02-F in the summer of 2022 (Figure 3-1). However, the FrostLink at site 22-01-F was destroyed by wildlife and no data could be

recovered. Site 22-02-F recorded ground temperatures from 2022 to 2023, but this data is several days short of a full year (August 3rd, 2022, to July 20th, 2023) and should be recalculated when a full year of data is available. A 1 m-depth temperature was not recorded due to grounding issues, but a mean near-surface (5 cm depth) temperature of -2.3°C was recorded (Figure 4-13; Table 4-3). This site is on a north- to northeast-facing slope in colluvium and represents an area of colder, more stable permafrost, as temperatures at the 1 m depth are expected to be colder than those near surface.

Thawing degree days (TDD), or thawing index, are calculated from the mean daily temperatures by taking the sum of all the surface housing air temperature values above 0°C during the thawing season. Freezing degree days (FDD), or freezing index, are calculated in the same manner, but use mean daily temperatures below 0°C during the freezing season. A higher FDD than TDD value means permafrost can aggrade (or re-aggrade following disturbance). This situation is evident at sites 21-06-F, 21-M08-F, and 22-02-F (Table 4-3). At site 21-07-F, TDD is higher, indicating that permafrost is not likely to recover if the vegetation is disturbed or burnt.

Table 4-3. FrostLink Data Summary by Site for 2021-2022 and 2022-2023.

FrostLink Sensor	Location	Mean Annual Temp, 5 cm depth (°C)	Mean Annual Temp, 1 m depth (°C)	Thawing Degree Days[2] (TDD)	Freezing Degree Days[1] (FDD)	Record Start Date	Record End Date
21-01-F	Valley bottom fluvial deposit affected by icing (aufeis).	N/A	N/A	N/A	2175	2021-08-03	2022-05-11
21-06-F	South-facing slope in colluvium, with sphagnum, forested.	-2.1	N/A	1299	2063	2021-08-03	2022-08-08
21-07-F	Northwest-facing slope in colluvium, affected by wildfire in 1990.	0.9	-0.2	1702	1313	2021-08-03	2022-07-27
		N/A	-0.2	N/A[3]	N/A[2]	2022-07-20	2023-07-19
21-M08-F	Northeast-facing slope in colluvium, with sphagnum and stunted black spruce.	-1.3	-3.8	2195	2775	2021-08-03	2022-08-08
		N/A	-3.8	2127	2470	2022-07-19	2023-07-18
22-02-F	North to northeast-facing slope in colluvium.	-2.3	N/A	1692	2200	2022-08-03	2023-07-20
23-01-F	Anthropogenic area around well pad M-59, northwest-facing slope in colluvium, affected by wildfire in 1990.	Data to be collected in 2024				2023-07-22	TBD
23-03-F	Northwest-facing slope in colluvium, affected by wildfire in 2017.	Data to be collected in 2024				2023-07-22	TBD
23-04-F	At slope break between valley bottom and south-facing colluvium slope, affected by wildfire in 1986 and 2004.	Data to be collected in 2024				2023-07-22	TBD
23-05-F	East-facing ridgetop in weathered bedrock.	Data to be collected in 2024				2023-07-22	TBD
23-07-F	Southeast-facing ridgetop in weathered bedrock, affected by wildfire in 2005, forested.	Data to be collected in 2024				2023-07-23	TBD
23-08-F	Ridgetop in weathered bedrock, forested.	Data to be collected in 2024				2023-07-23	TBD

[2] TDD and FDD values are based on air temperatures recorded in the enclosed FrostLink housings, so they are not directly comparable to values from climate stations with a Stevenson screen.

[3] TDD and FDD could not be determined for 21-07-F due to too much daily fluctuation around 0°C during the thawing and freezing seasons.

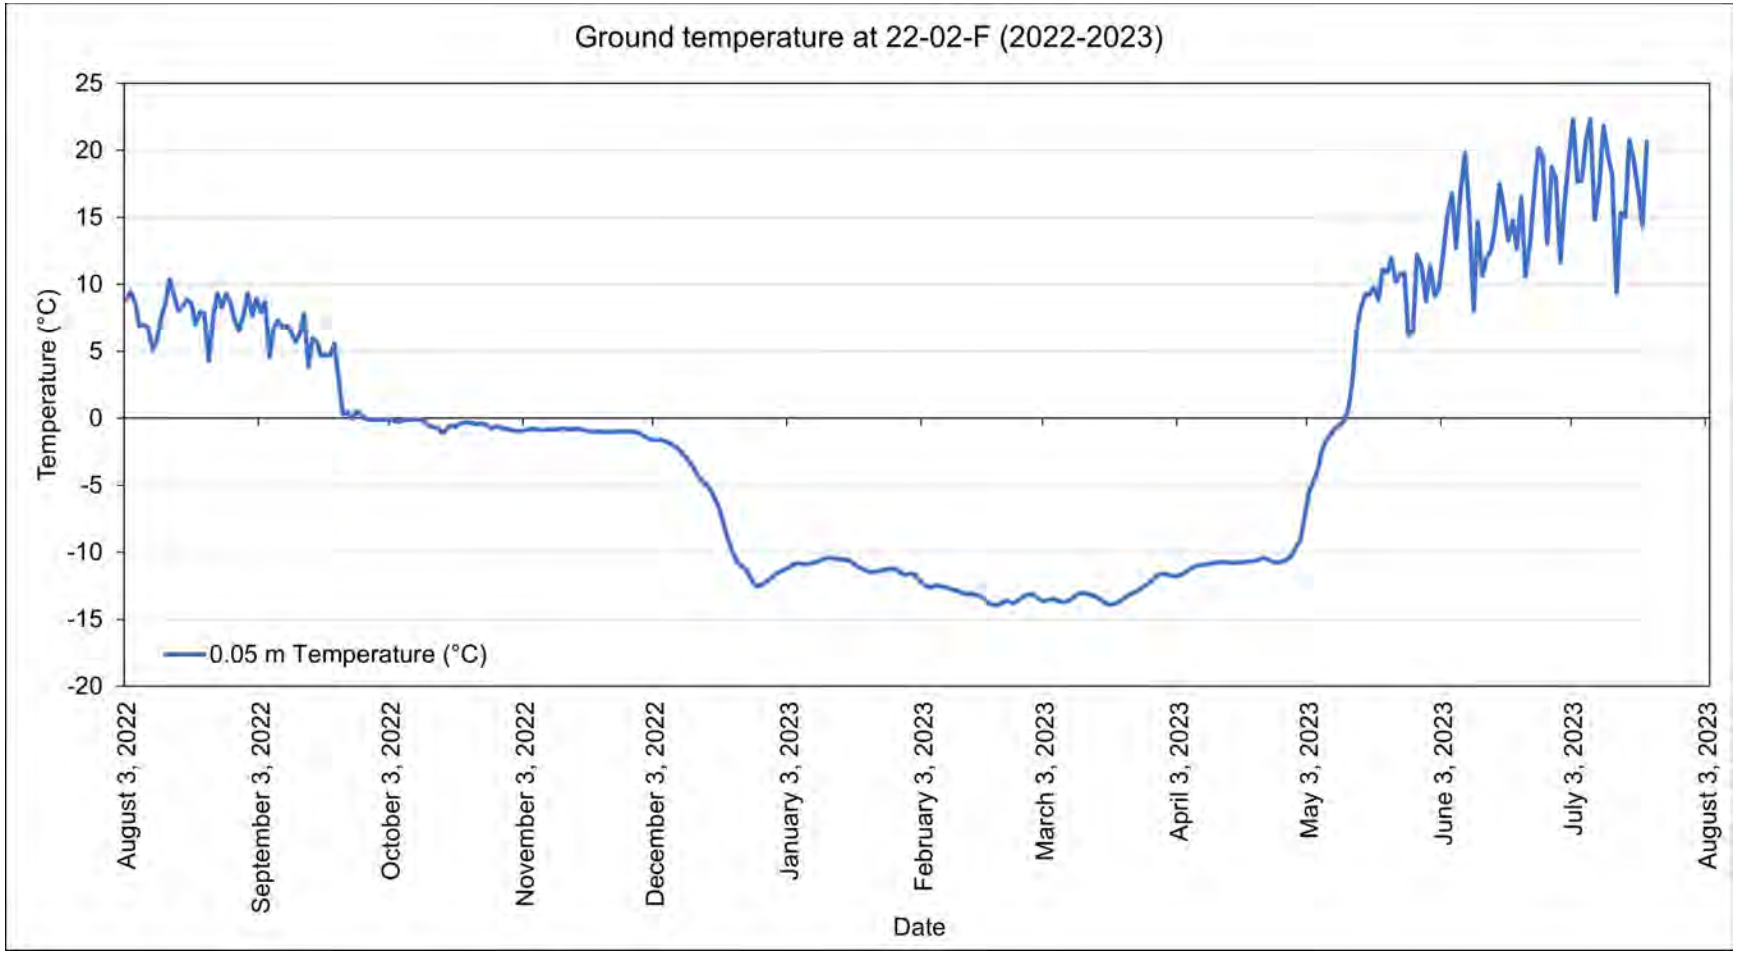

Figure 4-13. Near-surface (0.05 m) ground temperature from August 3rd, 2022, to July 20th, 2023 for site 22-02-F. Permafrost is deeper than the 0.05 m sensor.

4.2.5 Sensitivity to Disturbance

The sensitivity of permafrost to disturbance depends on a variety of factors, including its temperature, ice content, insulating ground cover (e.g., organics) and material texture. Relatively warm permafrost (i.e., warmer than -2°C) is more susceptible to thaw due to localized and even minor disturbances to the ground surface, whereas cooler permafrost is able to withstand minor disturbances without appreciable effect. Ice-rich permafrost is more sensitive to ground disturbance (e.g., stripping or compaction of organics). Ice-rich permafrost within fine-grained materials is more likely to contain discrete bodies of ice (Figure 4-14) and, thus, is more sensitive than that within weathered bedrock or coarse-grained colluvium.

Figure 4-14. Ice lens within fine-grained, colluvial sediment.

4.2.6 Permafrost Probe Analysis

4.2.6.1 Former Well Site H28

Apparent active layer thicknesses (depth of thaw) were measured between July 28 to August 6, 2021, in the area surrounding Former Well Site H28, which was drilled in the winter of 2012. In Figure 4-15, it is apparent that active layer thicknesses are greatest (60-70 cm) close to the well and thin toward the edges of the disturbed area. Undisturbed areas have notably thinner active layers (11-21 cm). On the south side of the well, an imperfectly drained gentle slope directs surface and near-surface runoff towards the well. The well was drilled in the winter when snow was relatively deep. As a result, its corrugated steel cellar is approximately 75 cm above ground surface and its surrounding rig matting has settled (Figure 4-16). It is apparent that some permafrost thaw has occurred within the disturbed zone immediately surrounding the well, mainly at and near the well, but relatively little and without broader effect on surroundings. Permafrost thaw is accompanied by subsidence because water has 10% less volume than ice, and on slopes, the excess meltwater is able to freely drain away. The disturbed area has active layer thicknesses of 43 to 69 cm. Our borehole data show that similar but undisturbed northwest-facing or northeast-facing colluvial slopes have active layers ranging from 26 to 53 cm thick at this time of year (no time of year depth

adjustment applied) (Boreholes 21-06-F, 21-07-F and 21-M08-F, Appendix C). In time, natural revegetation should help restore shallow permafrost at the site despite ongoing climate change. However, wetting caused by the slope to the south may slow this process and may have caused more thaw in the area immediately north of it. Any future site restoration initiatives must account for local surface drainage patterns, material properties and vegetation resilience.

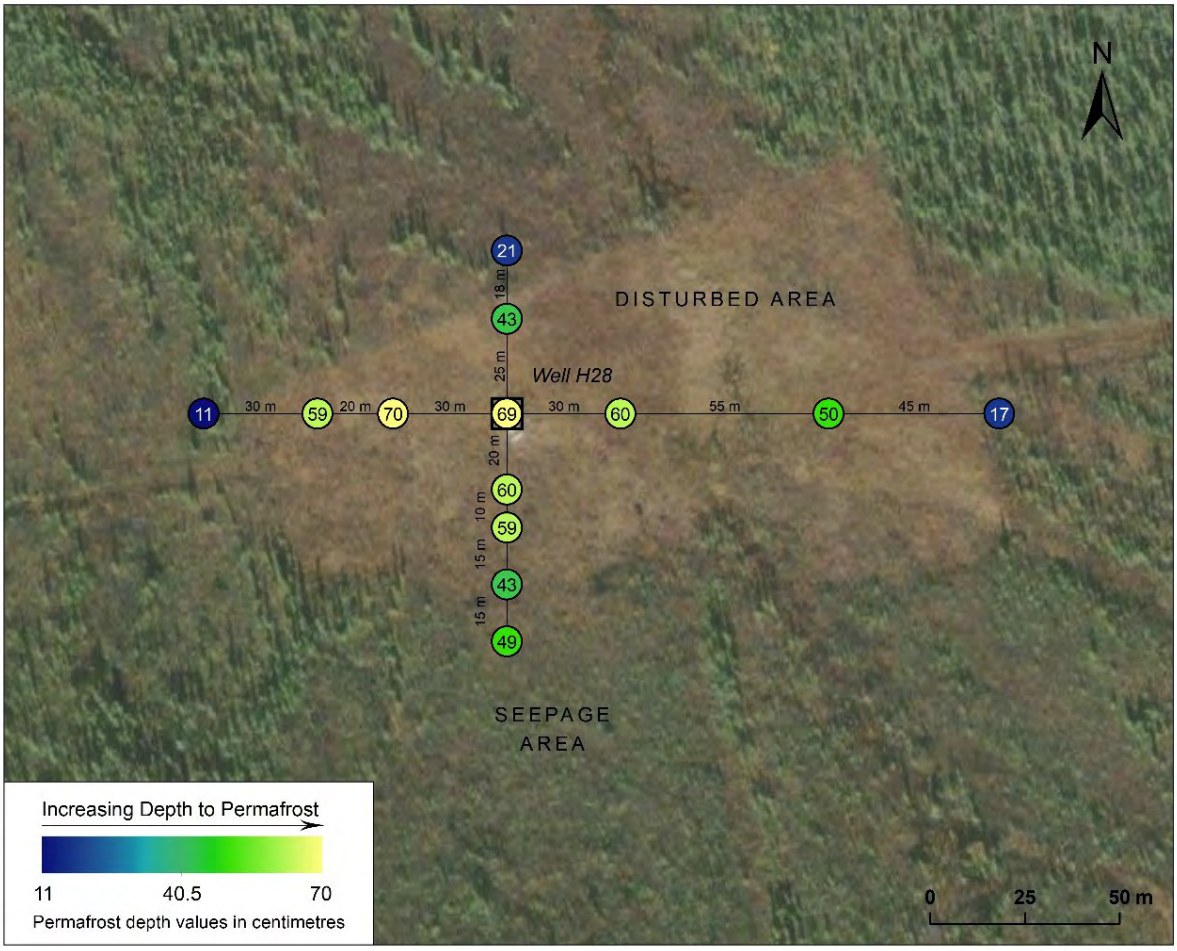

Figure 4-15. Apparent active layer thicknesses (in cm) at former well site H28, measured with a frost probe between July 28 to August 6, 2021. Ground generally slopes downhill from south (bottom) to north (top).

Figure 4-16. Former Well Site H28. Above-ground cellar and apparent settlement of rig mats is due to wintertime installation when snow was relatively deep.

4.2.6.2 Former Well Site M08

A similar localized, minor disturbance to permafrost occurred at Former Well M08 (Figure 4-17). The site was drilled in the winter of 1959 and has a wood frame cellar made of wood piles. Some clearing occurred in January to March 1998, in preparation for flow testing work that was cancelled (older disturbance area). An area 10 m in radius is cleared around the well head approximately every five years to meet Yukon oil and gas regulations (recent disturbance area).

The well is located on a gentle, northeast-facing, ice-rich colluvial slope. Here, the active layer is thicker, both in the recently disturbed area and in the adjacent older disturbed areas that are now forested with young deciduous trees (Figure 4-18). Cracks in the soil around the base of the well and the slow exposure of the wood piles, which have mostly occurred in the last 10 to 12 years (pers. comm., Richard Wyman), show that the well has either heaved or that the land around it has subsided.

Apparent active layer thicknesses are greatest near and at the well (70-82 cm) in the recently disturbed zone and thin toward the older disturbed zone. The older disturbed areas have thicknesses ranging from 53-80 cm (Figure 4-17). These active layer thicknesses are greater than that observed on a nearby undisturbed slope (26 cm thick, Borehole 21-M08-F, Appendix C). It is apparent that the permafrost table is more depressed in the recently disturbed zone, as would be expected due to the removal of vegetation.

The older disturbed zone has naturally revegetated with pioneer species of trees over the past 63 years. Here, permafrost is slowly recovering. The recovery may be more noticeable if a wider area is examined in future. Our data provide baseline information as of July 30, 2021. Active layer thicknesses near the well head are expected to remain the same due to the periodic clearing that is required by Yukon oil and gas regulations.

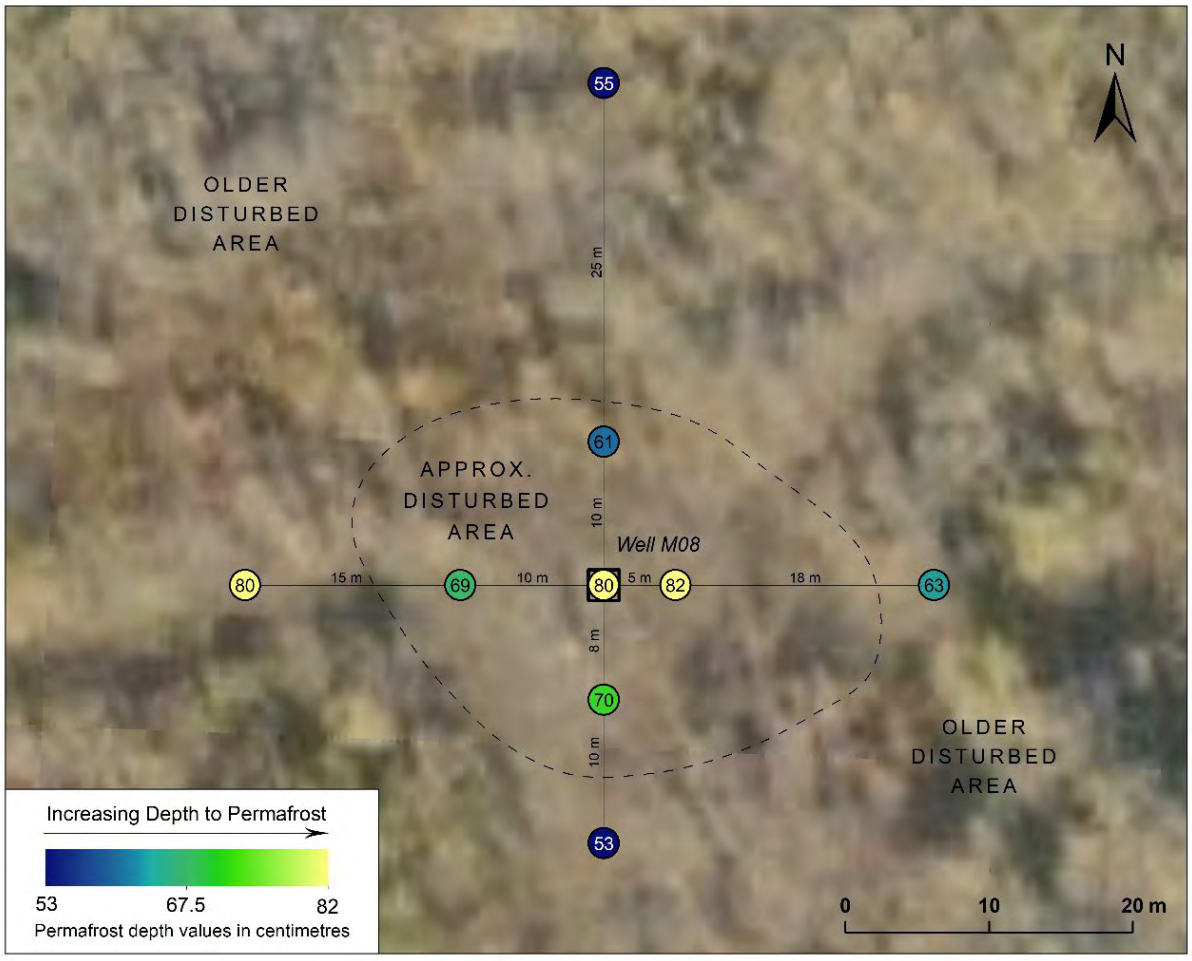

Figure 4-17. Active layer thicknesses (in cm) at former well site M08, measured with a frost probe on July 30, 2021. Slope dips gently to the northeast.

Figure 4-18. Former Well Site M08. Note exposed wood pile in foreground and young forest growth in older disturbed area in background.

4.3 Exploration Development Suitability

Exploration development suitability mapping, which builds on the characterizations of surficial geology (Section 4.1) and permafrost (Section 4.2) and reflects on permafrost-related terrain stability and areal differences in sensitivity to disturbance (Section 4.2), is presented for the Project Area in Appendix B. The mapping combines the results of the road and well pad suitability classifications (Table 4-4) with the MBC disposal suitability classifications (Table 4-5). Road and well pad suitability classification also provides a conservative guide for proposed seismic surveys.

Nearly all existing and potential instability within the Project Area is related to permafrost, given the ancient, rolling, relatively low-relief terrain and thinly covered slopes of the Eagle Plains region. Our exploration development suitability maps (Appendix B) show the extent of most (very high classification) to least (very low classification) suitable terrain for exploration activities (Table 4-4)

Areas of high to very high suitability are generally found on wide, rounded ridge tops, commonly with either exposed bedrock and boulders or shallow bedrock, and where shallow colluvium overlies convex topography. They are generally ice-poor and well drained and occupy the least amount of the Project Area, ranging from 9.4% (high suitability) to 7% (very high suitability; Table 4-4).

Areas of moderate suitability are found on imperfectly to moderately drained colluvial slopes, fine-grained ridge tops, and fluvial terraces. These areas have moderate slope gradients, varying permafrost depths, moderate ice contents, and occupy 28.7% of the Project Area (Table 4-4).

Areas of low and very low suitability generally include ice-rich areas, which are most commonly found in valley bottoms, frequently associated with floodplains and fluvial or organic material. These ice-rich areas may exhibit ice-wedge polygons and are particularly susceptible to thermokarst. Steeper slopes with lower suitability are also more commonly associated with active-layer detachments and solifluction, or the potential for localized rock fragment ravelling on scarps. Low and very low suitability areas represent 33.5% and 21.4% of the Project Area, respectively (Table 4-4).

High and very high suitability areas require minimal maintenance requirements and have favourable conditions for access road and well pad establishment when best management practices are applied. Very low suitability areas, by comparison, require comprehensive mitigations to protect thaw-sensitive permafrost and control surface runoff. Required maintenance is likely high and field reconnaissance is critical to make informed route and site selections and mitigation decisions.

The MBC disposal suitability serves to highlight ice-poor, gently-sloping, and relatively stable regions of the landscape set back from significant watercourses as potentially suitable for MBC disposal (Table 4-5). These criteria were generally met along broad ridge systems and isolated knolls. A total of 13.2% of the study area has been classified as potentially suitable for MBC drill cuttings disposal, most commonly in association with areas classified as High or Very High suitability for road and well pad suitability (Appendix B). Runoff may be variable at the mapped scale such that different areas within a polygon may have less or more interaction with surface water. For example, polygons affected by slope wash may show discrete runnels where runoff is concentrated. As a result, field investigations are suggested to refine the MBC

disposal suitability classifications at a site-specific scale which would better determine target areas for cuttings disposal within each mapped polygon unit.

Table 4-4. Road and well pad suitability classifications and implications for construction and maintenance.

Road and Well pad Suitability	Description	Implications for Construction and Maintenance	Percent of Project Area
Very High	Moderately well to well drained, isolated topographic highs with deep or shallow, ice poor permafrost. Generally considered to be stable terrain, and typically located along wide, rounded ridge crests, commonly with shallow bedrock.	Favourable conditions for access road and well pad establishment through standard best management practices. Minimal expectation for maintenance requirements.	7.0%
High	Generally, moderately well to well drained areas with deep or shallow, ice-poor permafrost. Typically associated with ridges of weathered bedrock or shallow colluvium over convex topography.	Generally favourable conditions for access road and well pad establishment through standard best management practices. Low to moderate expectation for maintenance requirements.	9.4%
Moderate	Imperfectly to moderately well drained colluvial slopes with deep to shallow permafrost, commonly with moderate ice content; convex weathered bedrock bluffs, typically at moderate slope gradients; and fluvial terraces above the influence of modern stream processes.	Generally reasonable conditions for access road and well pad establishment. Where necessary, employment of mitigations may be to proactively manage natural concentrations of surface runoff and to protect thaw-sensitive permafrost. Moderate expectation for maintenance requirements. Field reconnaissance would help inform route/site selection and mitigation requirements.	28.7%
Low	Poorly to imperfectly drained, thick colluvial slopes with shallow permafrost, commonly with moderate to rich ice content; imperfectly drained fluvial fans and veneers. Regions affected by sheetwash, gully erosion, and ice-wedge polygons are typically included in this category. Surface runoff becomes concentrated.	Generally unfavourable conditions for access road and well pad establishment, except through mitigations to proactively manage natural concentrations of surface runoff and to protect thaw-sensitive permafrost. Moderate to high expectation for maintenance requirements. Field reconnaissance is necessary to inform route/site selection and mitigation requirements.	33.5%
Very Low	Very poorly to imperfectly drained areas with shallow or near-surface permafrost, commonly with rich to moderate ice content. Includes most floodplains and steep bedrock scarps. Thermokarst subsidence and ice-wedge polygons are common on level to gently sloping ground, and slopes may be subjected to mass movements including solifluction and active-layer detachments.	Unfavourable conditions for access road and well pad establishment. Any necessary crossings will require comprehensive mitigations to protect thaw-sensitive permafrost and manage surface runoff and compressible, fine-grained sediments. Road construction through steep bedrock scarps would require earthworks and potentially localized blasting. Maintenance expectations are high. Field reconnaissance is critical to inform route/site selection and mitigation requirements.	21.4%

Table 4-5. Mix-bury-cover (MBC) disposal suitability classifications and descriptions.

MBC Disposal Suitability	Description	Percent of Project Area
Potentially Suitable	Generally geomorphologically isolated regions on level or near-level, elevated areas with minimal or no receipt of surface runoff (i.e., 'shedding sites'). Areas are typically located along broad to rounded ridge crests and knolls that are set back from significant watercourses.	13.2%
Probably Unsuitable	Includes moderate to steeply sloping regions; areas with ice-rich permafrost; and areas exhibiting evidence of geomorphological instability such as fluvial erosion, thermokarst subsidence, solifluction, and active-layer detachments	86.8%

4.4 Potential Effects of Climate Change on Baseline Conditions

Climate change, which is occurring more rapidly in Yukon than in southern Canada (Perrin and Jolkowski, 2022; BNQ, 2023), is expected to have locally significant impacts on the terrain and permafrost conditions in the Project Area, as it will in many other northern regions. However, permafrost has a high thermal inertia, meaning it does not respond quickly to temperature changes. Permafrost thaw is therefore expected to be a gradual process.

As temperatures rise due to climate change, permafrost is expected to thaw. This thawing can lead to increases in thermokarst subsidence and initiation of new active-layer detachments (and potentially retrogressive thaw flow slides, locally). Thawing permafrost can also lead to changes in the flow of rivers and streams, affecting fish habitat and water quality. The release of previously frozen organic matter from permafrost can also contribute to increased nutrient loading in water bodies and loss of permafrost can accelerate erosion along riverbanks and coastlines.

Climate change is associated with increased frequency and intensity of wildfires. This can have an important impact on terrain and permafrost, as wildfires can accelerate permafrost thaw by removing insulating vegetation and depositing ash that darkens the surface, causing it to absorb more heat. The active layer responds by becoming thicker and thaw subsidence may occur in ice-rich areas.

The exploration development suitability mapping can be used to forecast which areas of the landscape are most likely to respond to climate change, based on the implicit representation of terrain stability. Depending on what climate change scenario occurs (low, moderate or high greenhouse gas emissions scenarios), we expect that the Very Low suitability areas will remain the same and that the Low Suitability areas will eventually become areas of Very Low suitability, although the timing of this is dependent on the actual climate change scenario. Areas of Moderate Suitability are highly variable in terms of terrain and permafrost, so it is more difficult to predict what will happen in those locations. Areas of High and Very High suitability are expected to remain unchanged, as they are stable both in terms of landscape position and low permafrost content. It is possible that some areas of High Suitability could become Moderate Suitability areas, depending on local permafrost conditions in those locations, but these should be very localized.

5. Summary and Conclusions

This report describes the Eagle Plains Project Area's surficial geology and permafrost baseline conditions for the purposes of evaluating potential effects of the Project on permafrost and terrain stability as part of the Project Proposal to YESAB. Detailed (1:20,000) mapping of surficial geology and permafrost was completed for the 2,400 km^2 Project Area and combined to produce exploration development suitability maps, which reflect permafrost-related terrain stability (Appendix B). The mapping was based on interpretation of high-resolution stereo-imagery and LiDAR-derived topographic data, calibrated through reference to pertinent background information and the findings of several field investigations involving the examination, sampling and documentation of soils and surficial materials in hand-dug testpits and shallow (~2 m) Talon-drilled boreholes, installation and monitoring of FrostLink ground temperature/phase sensors, and helicopter overview flights.

The unglaciated landscape of the Eagle Plains region consists of rounded ridges separated by deep, V-shaped valleys. Climate is characterized by long, cold winters and short, warm summers. Bedrock comprises sandstone, shale, bituminous shale, siltstone, mudstone, coal, spiculite and packstone of Cretaceous age.

Surficial materials within the Project Area include weathered bedrock and colluvial, fluvial and organic deposits. Many of these deposits are affected by gullying, solifluction, permafrost processes and active-layer detachments. The abundant colluvial deposits are generally fine-grained (mainly silt and clay), although they are sandier and may include some gravel-sized fragments in areas of sandstone bedrock. They are locally intermixed with organics. Intact bedrock is uncommon, typically limited to erosion-resistant scarps, but weathered bedrock also is widespread on ridges and spurs. Weathered bedrock comprises silt/clay or sand with pebbles or cobbles of the underlying bedrock (if overlying more competent sandstone). Fluvial deposits found in valley bottoms consist of silt and clay with some sand, interfingered with organic layers. Areas disturbed by human activity are rare.

The Project Area is located within the zone of continuous permafrost. As part of the work completed for this report, ground temperature sensors (FrostLinks) were installed at 12 locations on ridge crests, on slopes of different aspect, and in valley bottoms to improve understanding of ground temperatures across the Project Area and in different terrain settings. Mean annual ground temperatures generally range from -0.2°C to -2.3°C near surface to -3.8°C at 1 m depth. Temperatures are warmer in wildfire-affected areas. Permafrost that is warm (warmer than -2°C) is more susceptible to thaw subsidence in response to climate change or disturbance. Continued monitoring of ground temperatures, including the 2023 FrostLink installations, is recommended to monitor ground temperatures, especially in areas of disturbance.

Apparent active layer thicknesses (depth to thaw during the summer months) range from 0.2 to 3.5 m, with the thickest active layers occurring in areas of recent wildfire and the thinnest on poorly drained valley floors, in areas of thick moss or organic material cover, and in areas of fine-grained deposits. Active layer thicknesses of more than 0.6 m are found in areas of coarse-grained colluvium or weathered bedrock (upland areas).

Ice content within permafrost is highly variable. Ice-rich deposits include fine-grained colluvial or fluvial deposits and weathered bedrock, but these deposits can also be ice-moderate. Ice-rich/ice-moderate

permafrost underlies poorly drained, inactive fluvial deposits or organic deposits in valley bottoms. Ice content is lowest in association with coarse-grained weathered sandstone bedrock.

Permafrost-related processes include cryoturbation, solifluction, active-layer detachments and thermokarst subsidence/gullying. Permafrost features include ice-wedge polygons, earth hummocks and drunken forest. Minor, localized degradation of permafrost has occurred at former well sites H28 and M08 but appears to be recovering in areas where the vegetation is regenerating.

The exploration development suitability maps reflect findings of both the desktop- and field-based assessment and provide guidance for the development of exploration infrastructure by identifying those areas least likely to be affected by construction-related disturbance. Areas of potentially suitable MDC disposal have been identified, generally along broad ridge systems and isolated knolls and typically aligning with high to very high road and well pad suitability areas. Chance has located its access roads and well sites using these maps to ensure that permafrost and terrain stability are appropriately protected during the exploration process. Where lower suitability areas are unavoidable, mitigation measures are available to ensure protection of permafrost and address any concerns regarding associated terrain stability.

Finally, climate change is affecting, and will continue to affect, permafrost and terrain stability within the Project Area. The slow response of permafrost to warming air temperature means thawing will occur gradually, ultimately contributing to initiation and expansion of thermokarst subsidence, more widespread and potentially larger active-layer detachments, and altered surface hydrology. Wildfires, intensified by climate change, can expedite permafrost thaw and terrain instability. Exploration development suitability is expected to change as permafrost thaws, with low suitability areas likely transitioning to very low suitability. High and very high suitability areas are expected to remain stable, but some may shift to moderate suitability based on local permafrost conditions. Prioritizing high suitability areas for infrastructure, and incorporating adaptation measures where necessary, can mitigate impacts from such natural processes.

6. Statement of Limitations

The observations and results provided are limited to the scope of work for which Palmer was retained. The information and data provided by the Client or any secondary sources was assumed to be factual and accurate, and any deficiency, misstatement or inaccuracy contained in this report as a result of omissions, misinterpretations or negligent acts from relied-upon data are not Palmer's responsibility. Judgment has been used by Palmer in interpreting permafrost and terrain stability and associated hazards based on desktop interpretation calibrated by first- and second-hand field observations at sites representative of the diversity of conditions within the study area. Ground conditions may differ from those interpreted at a map unit (polygon) scale, even where investigated in the field, due to inherent variability in terrain characteristics.

Palmer is not a guarantor of the terrain, permafrost, or hazard conditions within each of the mapped polygons, but warrants only that its work was undertaken and its report prepared in a manner consistent with the level of skill and diligence normally exercised by competent geoscience professionals practicing in Yukon. Our findings, conclusions and recommendations should be evaluated in light of the limited scope of work.

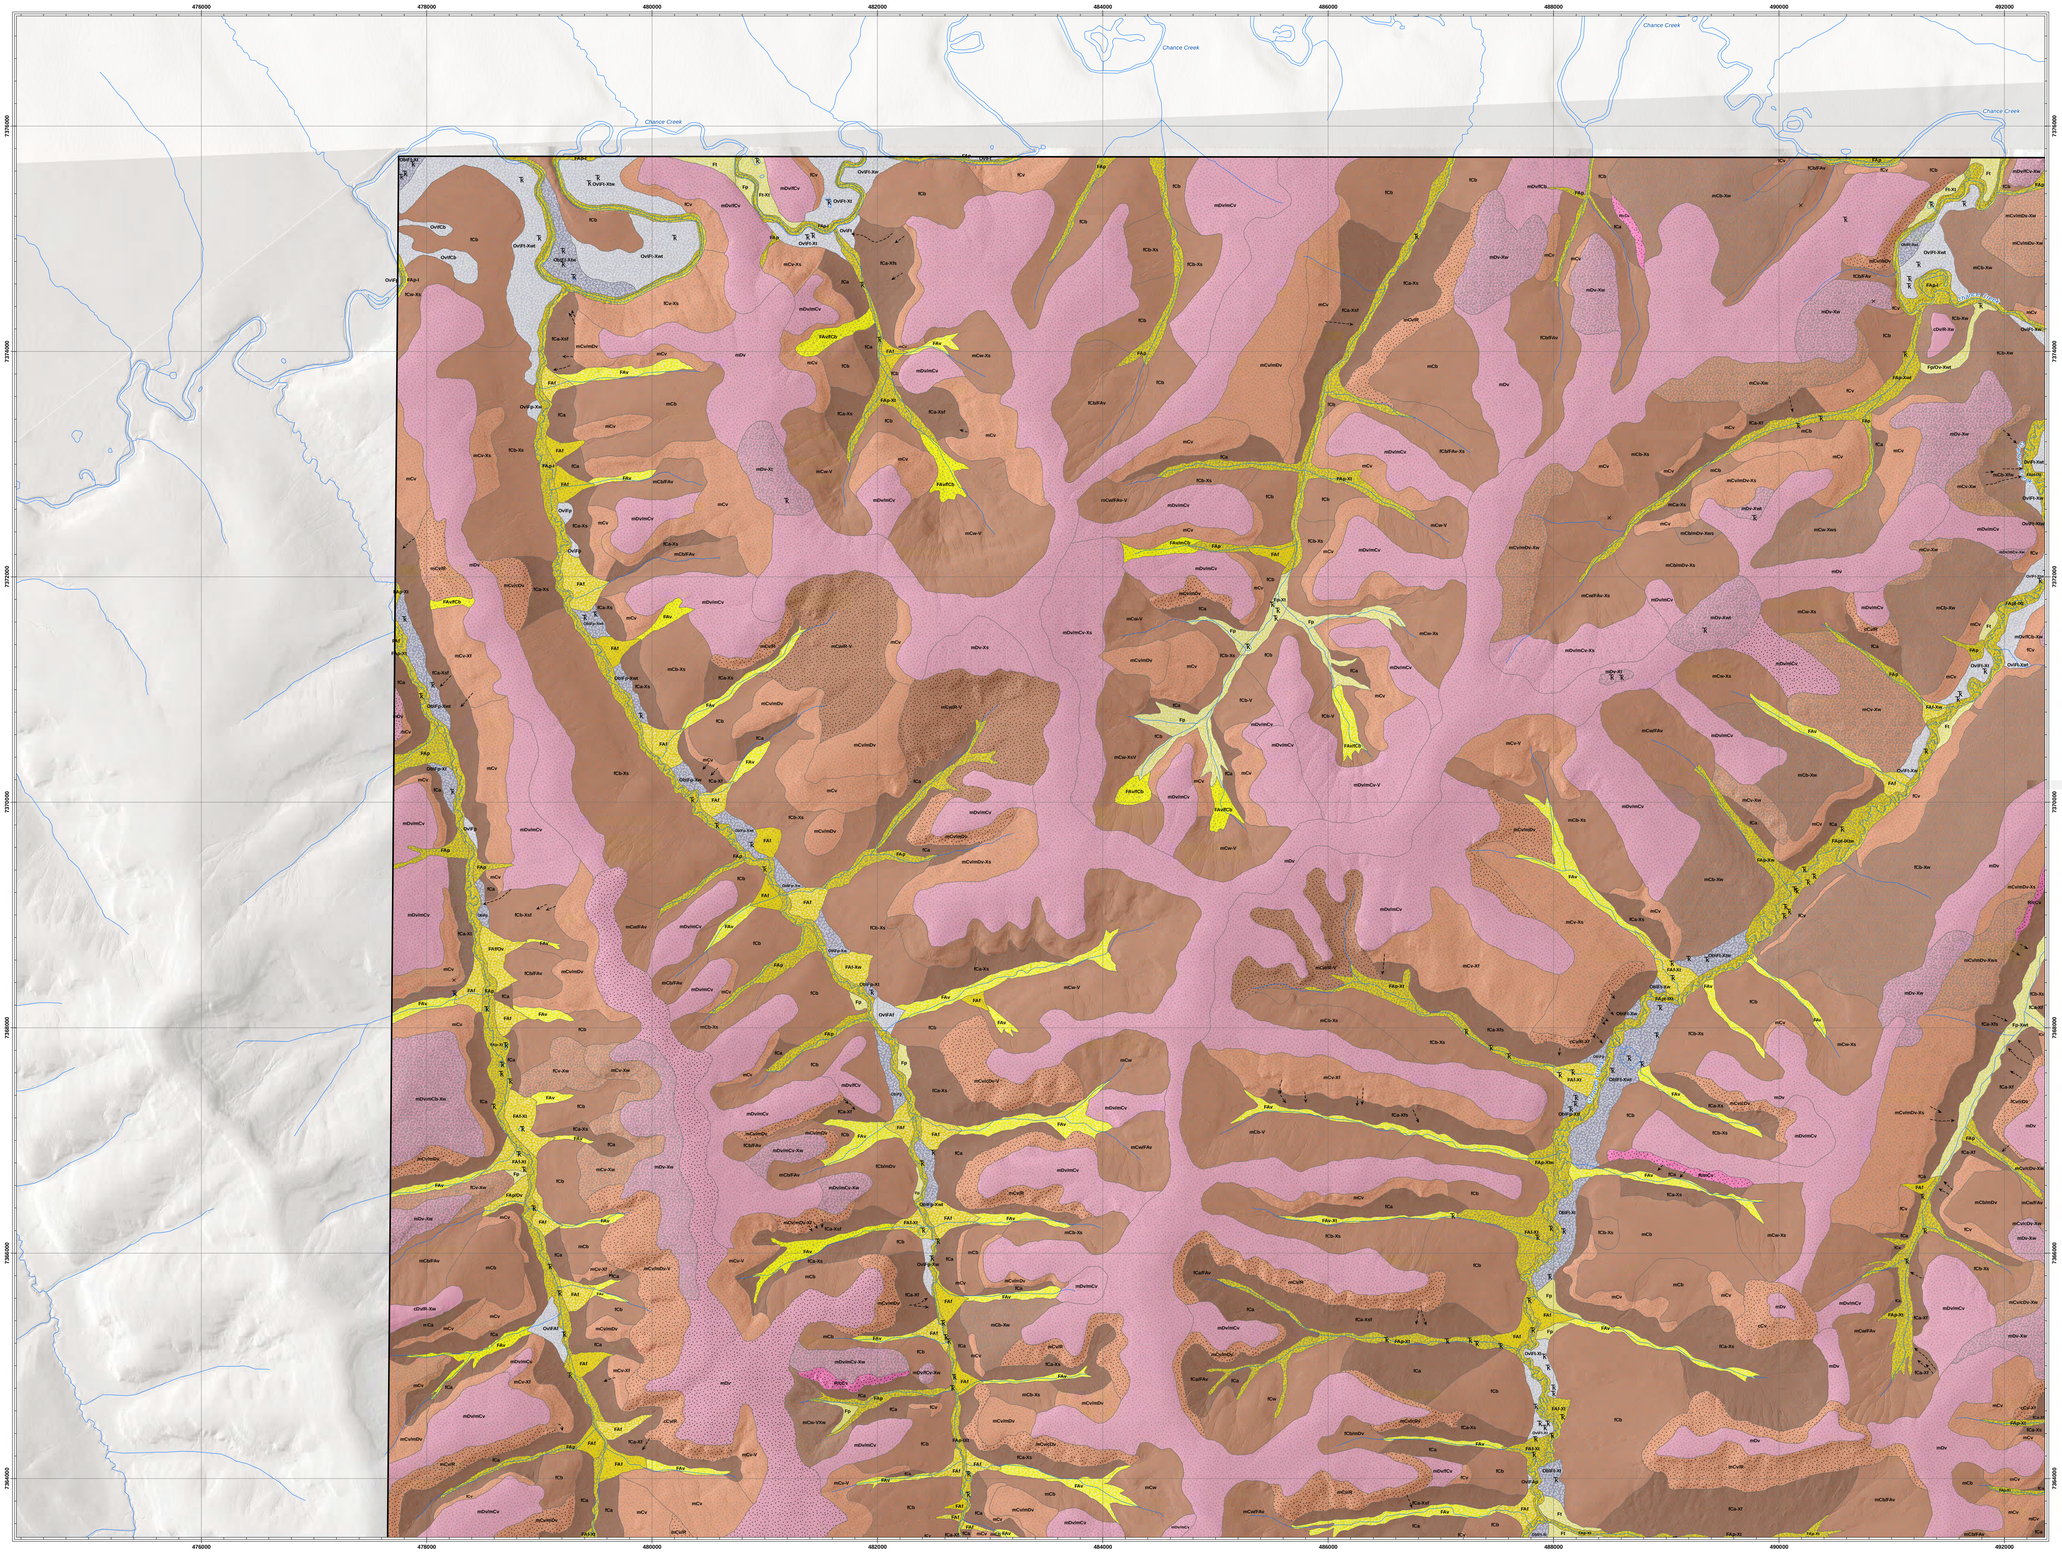
Surficial Geology and Permafrost Classification

Eagle Plains, Yukon



SURFICIAL MATERIAL AND LANDFORM DEFINITIONS

A — **Anthropogenic deposits:** surficial materials modified by human activities such that their original physical properties have been significantly altered, applied to areas modified by excavation and construction activities; not applied to road networks.

Ov — **Organic deposits; veneer:** < 1 m thick; material ider ived fr om the accumulation of plant matter , generally consisting of peat (typically bog or fen) ; occur s on p oor ly dr ained, level to gently slop ing areas; shallow dep r essions; only included in map labels wher e accumulation is thicker than 2 0 cm.

Ob — **Organic deposits; blanket:** > 1 m thick; material ider ived fr om the accumulation of plant matter , generally consisting of peat (typically bog or fen) ; occur s on p oor ly dr ained, level to gently slop ing areas; shallow dep r essions.

FAv — **Fluvial sediments; active veneer:** < 1 m thick; material lai d ar ansp or ted and dep osited by str eams typically exhibiting inter mittent or p er ennial flow; mainly occur s on gentle slop es within gullies at the headwaters of moder n str eams; gener ally comp osed of silt, or ganics, and minor sands.

FAf — **Fluvial sediments; active fan:** mater ials tr ansp or ted and dep osited by str eams; typically occur s where tr ibutar y str eams meet lar ger , lower angle r iver systems and dep osit mater ials; longitudinal profiles fr om slightly concave to slightly convex; gener ally comp osed of silt, sands, and or ganics.

FAp — **Fluvial sediments; active plain:** mater ials tr ansp or ted and dep osited by moder n str eams; typically plains to gently slop ing landfor ms along valley bottoms; gener ally comp osed of silt and sand on flooding lain and gr avels along active channels and bar s.

Fp — **Fluvial sediments; active plain:** mater ials tr ansp or ted and dep osited by str eams in the floodp lain above moder n channels; typically p lanar to gently slop ing landfor ms along valley bottoms; gener ally composed of silts, sands, and or ganics.

Ft — **Fluvial sediments; terrace:** mater ials tr ansp or ted and dep osited by str eams and usually located adjacent to moder n str eams; typically occur s as a p lanar landfor m with a consp icuous scar p along its edge; gener ally comp osed of silts, sands, and or ganics.

Cv — **Colluvial sediments; veneer:** < 1 m thick; mater ials that have been tr ansp or ted downslop e thr ough gr avitational p r ocesses including fr eeze- thaw cycles, cr eep , solifluction, slop ewash and active-layer detachments; dep osit r oughly follows the sur face of the under lying bedr ock and is too thin to mask r r egular ities; gener ally comp osed of silts, sands, and gr avels; may locally include lar ger clasts.

Cb — **Colluvial sediments; blanket:** > 1 m thick; mater ials that have been tr ansp or ted downslop e thr ough gr avitational p r ocesses including fr eeze- thaw cycles, cr eep , solifluction, slop ewash and active-layer detachments; dep osit r oughly follows the sur face of the under lying bedr ock and is thick enough to mask minor ir r egular ities; gener ally comp osed of silts, sands, and gr avels; may locally include lar ger clasts.

Cw — **Colluvial sediments; mantle of variable thickness:** typically 0 - 3 m thick; mater ials that have been tr ansp or ted downslop e thr ough gr avitational p r ocesses including fr eeze- thaw cycles, cr eep , solifluction, slop ewash and active- layer detachments; a layer or discontinuous layer that r oughly follows the sur face of exp r ession of under lying bedr ock and fills or p ar tly fills dep r essions in an ir r egular substrate; comp osed of silts, sands, and gr avels; may locally include lar ger clasts.

Ca — **Colluvial sediments; apron:** < 1 m thick; mater ials that have been tr ansp or ted downslop e thr ough gr avitational p r ocesses including fr eeze- thaw cycles, cr eep , solifluction, slop ewash and active-layer detachments; wedge- shap ed landfor ms occur r ing on lower slop e p ositions wher e sediments accumulate; may be locally inter mixed with fluvial dep osits; gener ally comp osed of silts, sands, and gr avels; locally include lar ger clasts and or ganics.

Dv — **Bedrock, undifferentiated, weathered:** extensively weather ed mater ials der ived dir ectly fr om under lying bedr ock without significant tr ansp or tation; typically occur s on r ounded summits and along br oad and sp ur s; gener ally comp osed of silt, sand, and gr avel- sized r egolith.

R — **Bedrock, undifferentiated:** moder ate- to high- r elief sur face exp r ession; typically exp osed in bluffs along r idges and in up p er slop e p ositions, in association with differential er osion of differ ent sedimentary typically gr adational to weather ed bedr ock.

TEXTURE*

f - Matr ix- dominated: dep osit is comp osed near ly entir ely of silts and clays, with minor sand.

m - Matr ix- sup p or ted: dep osit is a matr ix- sup p or ted mixtur e of gr avels, sands, silts, and minor clay.

c - Clast- sup p or ted: dep osit is a clast- r ich mixtur e of gr avels, sands, and minor silts.

**Texture classes are applied to colluvium and weathered bedrock. Textures for other materials are characterized above in association with the landform definitions.*

GEOMORPHOLOGICAL PROCESSES

I - Ir r egular ly sinuous channel: a clear ly defined main channel disp laying ir r egular meander bends.

S - Solifluction: slow, downslop e gr avitational movement of wet soil acr oss a fr ozen (e. g. p er maf ost) or impe r meable substr ate.

G - Gully er osion: for mation of sub- p ar allel, nar r ow r avines by concentr ated sur face r unoff and mass movement exacer bated by fluvio- ther mal er osion in ar eas of ice- r ich p er maf ost.

X - Permafrost Processes:

-s - Sheetwash: ar eas wher e sur face r unoff flows as diffuse sheetflow, or in concentr ated r unnels (watershallow p er maf ost.

-f - Active- layer detachment: tr anslational landslides along a shallow failur e p lane (also r efer r ed to as the typ ically r esult fr om the loss of str ength at the contact between thawed (above) and fr ozen (below) mp lane may be within or at base of active layer over lying p er maf ost.

-t - Ther mokar st subsidence: gr ound- sur face dep r essions cr eated by the thawing of ice- r ich p er maf ost soil subsidence; dep r essions commonly contain water (thaw p ond) ; may be map p ed as a lake in the base map p ing.

-w - P atter ned gr ound: p olygonal sur face exp r ession of ice wedges in p er maf ost ter r ain; commonly ther mokar st.

PERMAFROST CLASSIFICATION OVERLAY		ESTIMATED RELATIVE ICE CONTENT		
		Ice-poor: little to no excess ice; discontinuous to continuous pore ice; locally include segregated ice in thin seams; most ice unlikely; most common condition in the study area	**Ice-moderate:** moderate amount of excess ice; continuous to continuous pore ice; locally included segregated ice widespread in seams and lenses; massive ice possible locally.	**Ice-rich:** large amount of excess ice; continuous segregated ice; extensive in seams and lenses; massive ice indicated (Xm) , or likely.
ESTIMATED RELATIVE DEPTH	**Near-surface:** < 0 . 4 m; within or at the base of organics.	Typically at surface		
	Shallow: 0 . 4 - 1 m; relatively fine- grained, sup p or ted to matr ix- dominated sediments; most common condition in the study area.	Commonly in matr ix- dominated sediments		
	Deep: > 1 m; typically relatively coar se- gr ained, sup p or ted sediments.	Within Ubds		

** Excess ice refers to the volume of ice that exceeds the total voids (e.g. pore space) that would be present under natural, unfrozen conditions.*
*** Depth to permafrost and ice content classes are relative and inferred based on landform association with reference to limited field observations and secondary source information.*

Mapping Notes

Surficial geology mapping was completed at a scale of 1:20,000 using DAT/EM Summit software in combination with ESRI's ArcGIS. Interpretations were made based on continuous coverage of satellite imagery (2019) and aerial photographs, and further refined using 1 m- resolution, LiDAR-derived (2019). Map units (polygons) were delineated based on surficial materials, expressions, active processes, and surface or ainage in accordance with the Terrain Classification System for British Columbia (Howes and Kenk, 1997), with modifications for use in Yukon (Lipovsky and Bond, 2014) and to accommodate objectives. Under this system, up to two surficial materials may be identified in each polygon as either secondary material, or in strat igraphic relation to each other. Polygons have been symbolized based on surficial material, Discrete terrain features and geomorphic processes too small to be mapped as polygons (either mokarst depressions and active- layer detachments, have been identified using point and line features. Interpretations were calibrated, in part, based on one week of helicopter- supported field reconnaissance in July, 2015.

SURFICIAL MATERIAL AND LANDFORM DEFINITIONS

A — **Anthropogenic deposits:** surficial materials modified by human activities such that their original physical properties have been significantly altered, applied to areas modified by excavation and construction activities; not applied to road networks.

Ov — **Organic deposits; veneer:** < 1 m thick; material ldeived from the accumulation of plant matter, generally consisting of peat (typically bog or fen); occurs on poorly drained, level to gently sloping shallow depressions; only included in map labels where accumulation is thicker than 20 cm.

Ob — **Organic deposits; blanket:** > 1 m thick; material lderived from the accumulation of plant matter, generally consisting of peat (typically bog or fen); occurs on poorly drained, level to gently sloping shallow depressions.

FAv — **Fluvial sediments; active veneer:** < 1 m thick; material lal transported and deposited by streams typically exhibiting intermittent or perennial flow; mainly occurs on gentle slopes within gullies at the headwaters of moderate streams; generally composed of silt, organics, and minor sands.

FAf — **Fluvial sediments; active fan:** material lal transported and deposited by streams; typically occurs where fluvial systems meet lal gentle, lower angle river systems and deposited material lals; longitudinal profile of slightly concave to slightly convex; generally composed of silt, sands, and organics.

FAp — **Fluvial sediments; active plain:** material lals transported and deposited by moderate streams; typically planar to gently sloping landforms along valley bottoms; generally composed of silt and sand on floodplains and gravels along active channels and bars.

Fp — **Fluvial sediments; active plain:** material lals transported and deposited by streams in the floodplains above moderate channels; typically planar to gently sloping landforms along valley bottoms; generally composed of silts, sands, and organics.

Ft — **Fluvial sediments; terrace:** material lals transported and deposited by streams and usually located adjacent to moderate streams; typically occurs as a planar landform with a conspicuous scarp along edge; generally composed of silts, sands, and organics.

Cv — **Colluvial sediments; veneer:** < 1 m thick; material lals that have been transported and deposited by gravitational processes including freeze-thaw cycles, creep, solifluction, slopewash and active-layer detachments; deposits roughly follows the surface of the underlying bedrock and is too thin to mask irregularities; generally composed of silts, sands, and gravels; may locally include larger clasts.

Cb — **Colluvial sediments; blanket:** > 1 m thick; material lals that have been transported and deposited by gravitational processes including freeze-thaw cycles, creep, solifluction, slopewash and active-layer detachments; deposits roughly follows the surface of the underlying bedrock and is too thick enough to mask irregularities; generally composed of silts, sands, and gravels; may locally include larger clasts.

Cw — **Colluvial sediments; mantle of variable thickness:** typically 0 - 3 m thick; material lals that have been transported and deposited by gravitational processes including freeze-thaw cycles, creep, solifluction, slopewash and active-layer detachments; a layer or discontinuous layer that roughly follows the expression of underlying bedrock and fills or partly fills depressions in an irregular substrate; composed of silts, sands, and gravels; may locally include larger clasts.

Ca — **Colluvial sediments; apron:** < 1 m thick; material lals that have been transported and deposited by gravitational processes including freeze-thaw cycles, creep, solifluction, slopewash and active-layer detachments; wedge-shaped landforms occurring on lower slopes positions where sediments accumulate; may be locally intermixed with fluvial deposits; generally composed of silts, sands, and gravels; locally include larger clasts and organics.

Dv — **Bedrock, undifferentiated, weathered:** extensively weathered materials deformed by tectonic forces; typically exposed in bluffs along ridges and in upper slopepositions, in association with differential erosion of different sedimentary units; typically gravitational to weathered bedrock.

R — **Bedrock, undifferentiated:** moderate-to high-relief surface exposition; typically exposed in bluffs along ridges and in upper slopepositions, in association with differential erosion of different sedimentary units; typically gravitational to weathered bedrock.

TEXTURE*

f - Matrix-dominated: deposit is composed nearly entirely of silts and clays, with minor sand.

m - Matrix-supported: deposit is a matrix-supported mixture of gravels, sands, silts, and minor clay.

c - Clast-supported: deposit is a clast-rich mixture of gravels, sands, and minor silts.

*Texture classes are applied to colluvium and weathered bedrock. Textures for other materials are characterized above in association with the landform definitions.

GEOMORPHOLOGICAL PROCESSES

I - Irregularly sinuous channel: a clearly defined main channel displaying irregular meanders bends.

S - Solifluction: slow, downslope gravitational movement of wet soil across a frozen (e.g. permafrost) impermeable substrate.

G - Gully erosion: formation of sub-parallel, narrow ravines by concentrated surface runoff and mass wasting exacerbated by fluvio-thermal erosion in areas of ice-rich permafrost.

X - Permafrost Processes:

-s - Sheetwash: areas where surface runoff flows as diffuse sheetflow, or in concentrated runnels (watertracks) shallow permafrost.

-f - Active-layer detachment: translational landslides along a shallow failure plane (also referred to as the typically result from the loss of strength at the contact between thawed (above) and frozen (below) material; plane may be within or at base of active layer overlying permafrost.

-t - Thermokarst subsidence: ground-surface depressions created by the thawing of ice-rich permafrost soil subsidence; depressions commonly contain water (thaw pond); may be mapped as a lake in the base mapping.

-w - Patterned ground: polygonal surface expression of ice wedges in permafrost terrain; commonly thermokarst.

	Shallow: 0.4 - 1 m; relatively fine-grained, supported to matrix-dominated sediments; massive ice common	commonly in matrix-dominated sediments		
	Deep: > 1 m, typically relatively coarse-grained, supported sediments.	within Upland		

* Excess ice refers to the volume of ice that exceeds the total voids (e.g. pore space) that would be present under natural, unfrozen conditions.
** Depth to permafrost and ice content classes are relative and inferred based on landform association with reference to limited field observations and secondary source information.

Mapping Notes

Surficial geology mapping was completed at a scale of 1:20,000 using DAT/EM Summit software in combination with ESRI's ArcGIS. Interpretations were made based on continuous coverage of satellite imagery (2019) and aerial photographs, and further refined using LiDAR-derived (2019). Map units (polygons) were delineated based on surficial materials, exposures, active processes, and surface drainage in accordance with the Terrain Classification System for British Columbia (Howes and Kenk, 1997), with modifications for use in Yukon (Lipovsky and Bond, 2014) and to accommodate objectives. Under this system, up to two surficial material ials may be identified in each polygon as either secondary material, or in stratigraphic relation to each other. Polygons have been symbolized based on surficial material. Discrete terrain features and geomorphic processes too small to be mapped as polygons, ther mokarst depressions and active-layer detachments, have been identified using point and line features. Imagery were calibrated, in part, based on one week of helicopter-supported field reconnaissance in July, 2019.

SURFICIAL MATERIAL AND LANDFORM DEFINITIONS

A — **Anthropogenic deposits:** surficial materials modified by human activities such that their original physical properties have been significantly altered, applied to areas modified by excavation and construction activities; not applied to road network.

Ov — **Organic deposits; veneer:** < 1 m thick; material ldeveloped from the accumulation of plant matter, generally consisting of peat (typically bog or fen); occurs on poorly drained, level to gently sloping shallow depressions; only included in map labels where accumulation is thicker than 20 cm.

Ob — **Organic deposits; blanket:** > 1 m thick; material ldeveloped from the accumulation of plant matter, generally consisting of peat (typically bog or fen); occurs on poorly drained, level to gently sloping shallow depressions.

FAv — **Fluvial sediments; active veneer:** < 1 m thick; material ltransported and deposited by streams typically exhibiting intermittent or perennial flow; mainly occurs on gentle slopes within gullies at the headwall moderate streams; generally composed of silt, organics, and minor sands.

FAf — **Fluvial sediments; active fan:** material lstransported and deposited by streams; typically occurs where fluvial streams meet larger, lower angle rivers systems and deposited material lsis longitudinal fluvial from slightly concave to slightly convex; generally composed of silt, sands, and organics.

FAp — **Fluvial sediments; active plain:** material lstransported and deposited by modern streams; typically a planar to gently sloping landform mainly along valley bottoms; generally composed of silt and sand on floodplains gravels along active channels and bars.

Fp — **Fluvial sediments; active plain:** material lstransported and deposited by streams in the floodplain above modern channels; typically a planar to gently sloping landform mainly along valley bottoms; generally composed of silts, sands, and organics.

Ft — **Fluvial sediments; terrace:** material lstransported and deposited by streams and usually located adjacent to modern streams; typically occurs as a planar landform with a conspicuous scarp along edge; generally composed of silts, sands, and organics.

Cv — **Colluvial sediments; veneer:** < 1 m thick; material lthat have been transported and deposited by downslope gravitational processes including freeze-thaw cycles, creep, solifluction, slope wash and active-layer detachments; deposits roughly follows the surface of the underlying bedrock and is too thin to irregularities; generally composed of silts, sands, and gravels; may locally include large clasts.

Cb — **Colluvial sediments; blanket:** > 1 m thick; material lthat have been transported and deposited by downslope gravitational processes including freeze-thaw cycles, creep, solifluction, slope wash and active-layer detachments; deposits roughly follows the surface of the underlying bedrock and is thick enough to minor irregularities; generally composed of silts, sands, and gravels; may locally include large clasts.

Cw — **Colluvial sediments; mantle of variable thickness:** typically 0 - 3 m thick; material lthat have been transported and deposited by downslope gravitational processes including freeze-thaw cycles, creep, solifluction, slope wash and active-layer detachments; a layer or discontinuous layer that roughly follows the surface expression of underlying bedrock and fills or partially fills depressions in an irregular substrate; composed of silts, sands, and gravels; may locally include large clasts.

Ca — **Colluvial sediments; apron:** < 1 m thick; material lthat have been transported and deposited by downslope gravitational processes including freeze-thaw cycles, creep, solifluction, slope wash and active-layer detachments; wedge-shaped landforms occurring on lower slope positions where sediments accumulate; may be locally inter mixed with fluvial deposits; generally composed of silts, sands, and gravels; locally include large clasts and organics.

Dv — **Bedrock, undifferentiated, weathered:** extensively weathered material lsderived directly from underlying bedrock without significant transportation; typically occurs on rounded summits and along broad and subdued; generally composed of silt, sand, and gravel-sized fragments.

R — **Bedrock, undifferentiated:** moderate- to high-relief surface exposition; typically exposed in bluffs along ridges and in upper slope positions, in association with different erosion of different sedimentary typically gravitational to weather bedrock.

TEXTURE*

f - Matrix-dominated: deposits composed nearly entirely of silts and clays, with minor sand.

m - Matrix-supported: deposits is a matrix-supported mixture of gravels, sands, silts, and minor clay

c - Clast-supported: deposits is a clast-rich mixture of gravels, sands, and minor silts.

*Texture classes are applied to colluvium and weathered bedrock. Textures for other materials are characterized above in association with the landform definitions.

GEOMORPHOLOGICAL PROCESSES

I - Irregularly sinuous channel: a clearly defined main channel displaying irregular meander bends.

S - Solifluction: slow, downslope gravitational movement of wet soil across a frozen (e.g. permafrost) impermeable substrate.

G - Gully erosion: formation of sub-parallel, narrow ravines by concentrated surface runoff and mass exacerbated by fluvio-thermal erosion in areas of ice-rich permafrost.

X - Permafrost Processes:

-s - Sheetwash: areas where surface runoff flows as diffuse sheetflow, or in concentrated runnels (watershallow permafrost.

-f - Active-layer detachment: translational landslides along a shallow failure plane (also referred to as thetypically resulting from the loss of strength at the contact between thawed (above) and frozen (belowplane may be within or at base of active layer overlying permafrost.

-t - Thermokarst subsidence: ground-surface depressions created by the thawing of ice-rich permafrost orsoil subsidence; depressions commonly contain water (thaw pond); may be mapped as a lake in thebase mapping.

-w - Patterned ground: polygonal surface expression of ice wedges in permafrost terrain; commonlythermokarst.

SURFICIAL MATERIAL AND LANDFORM DEFINITIONS

A — **Anthropogenic deposits:** surficial materials modified by human activities such that their original physical properties have been significantly altered; applied to areas modified by excavation and construction activities; not applied to road networks.

Ov — **Organic deposits; veneer:** < 1 m thick; material derived from the accumulation of plant matter, generally consisting of peat (typically bog or fen); occurs on poorly drained, level to gently sloping shallow depressions; only included in map labels where accumulation is thicker than 20 cm.

Ob — **Organic deposits; blanket:** > 1 m thick; material derived from the accumulation of plant matter, generally consisting of peat (typically bog or fen); occurs on poorly drained, level to gently sloping shallow depressions.

FAv — **Fluvial sediments; active veneer:** < 1 m thick; material that transports and deposited by streams typically exhibiting intermittent or perennial flow; mainly occurs on gentle slopes within gullies at the headwaters of moderate streams; generally composed of silt, organics, and minor sands.

FAf — **Fluvial sediments; active fan:** material laid transported and deposited by streams; typically occurs where a tributary stream meets larger, lower angle river systems and deposited material; longitudinal profile of slightly concave to slightly convex; generally composed of silt, sands, and organics.

FAp — **Fluvial sediments; active plain:** material laid transported and deposited by moderate streams; typically planar to gently sloping landforms mainly along valley bottoms; generally composed of silt and sand on floodplains and gravels along active channels and bars.

Fp — **Fluvial sediments; active plain:** material laid transported and deposited by streams in the floodplain above moderate channels; typically planar to gently sloping landforms mainly along valley bottoms; generally composed of silts, sands, and organics.

Ft — **Fluvial sediments; terrace:** material laid transported and deposited by streams and usually located adjacent to moderate streams; typically occurs as a planar landform with a conspicuous scarp along edge; generally composed of silts, sands, and organics.

Cv — **Colluvial sediments; veneer:** < 1 m thick; material that have been transported downslope through gravitational processes including freeze-thaw cycles, creep, solifluction, sloped wash and active-layer detachments; deposit roughly follows the surface of the underlying bedrock and is too thin to mask irregularities; generally composed of silts, sands, and gravels; may locally include larger clasts.

Cb — **Colluvial sediments; blanket:** > 1 m thick; material that have been transported downslope through gravitational processes including freeze-thaw cycles, creep, solifluction, sloped wash and active-layer detachments; deposit roughly follows the surface of the underlying bedrock and is thick enough to mask minor irregularities; generally composed of silts, sands, and gravels; may locally include larger clasts.

Cw — **Colluvial sediments; mantle of variable thickness:** typically 0 - 3 m thick; material that have been transported downslope through gravitational processes including freeze-thaw cycles, creep, solifluction, sloped wash and active-layer detachments; a layer or discontinuous layer that roughly follows the surface; may locally include larger clasts and gravels; may be locally inter mixed with fluvial deposits; generally composed of silts, sands, and gravels.

Ca — **Colluvial sediments; apron:** < 1 m thick; material that have been transported downslope through gravitational processes including freeze-thaw cycles, creep, solifluction, sloped wash and active-layer detachments; wedge-shaped landforms occurring on lower slope positions where sediments accumulate; may be locally inter mixed with fluvial deposits; generally composed of silts, sands, and gravels; may locally include larger clasts and organics.

Dv — **Bedrock, undifferentiated, weathered:** extensively weathered material laid derived directly from underlying bedrock without significant transportation; typically occurs on rounded summits and along broad and upland surfaces; generally composed of silt, sand, and gravel-sized regolith.

R — **Bedrock, undifferentiated:** moderate- to high-relief surface exposition; typically exposed in bluffs along ridges and in upper slope positions, in association with differential erosion of different sedimentary types typically gradational to weathered bedrock.

TEXTURE*

f - Matrix-dominated: deposit is composed nearly entirely of silts and clays, with minor sand.

m - Matrix-supported: deposit is a matrix-supported mixture of gravels, sands, silts, and minor clay.

c - Clast-supported: deposit is a clast-rich mixture of gravels, sands, and minor silts.

*Texture classes are applied to colluvium and weathered bedrock. Textures for other materials are characterized above in association with the landform definitions.

GEOMORPHOLOGICAL PROCESSES

I - Irregularly sinuous channel: a clearly defined main channel displaying irregular meanders bends.

S - Solifluction: slow, downslope gravitational movement of wet soil across a frozen (e.g. permafrost) impermeable substrate.

G - Gully erosion: formation of sub-parallel, narrow rarvines by concentrated surface runoff and mass exacerbated by fluvio-thermal erosion in areas of ice-rich permafrost.

X - Permafrost Processes:

-s - Sheetwash: areas where surface runoff flows as diffuse sheetflow, or in concentrated rrunnels (watershallow permafrost.

-f - Active-layer detachment: translational landslides along a shallow failure plane (also referred to as the typically result from the loss of strength at the contact between thawed (above) and frozen (below) rplane may be within or at base of active layer overlying permafrost.

-t - Thermokarst subsidence: ground-surface depressions created by the thawing of ice-rich permafrost soil subsidence; depressions commonly contain water (thaw pond); may be mapped as a lake in the base mapping.

-w - Patterned ground: polygonal surface expression of ice wedges in permafrost terrain; commonly thermokarst.

PERMAFROST CLASSIFICATION OVERLAY		ESTIMATED RELATIVE ICE CONTENT		
		Ice-poor: little to no excess ice; discontinuous ice; locally include segregated ice in thin seams; ice unlikely; most common condition in the study area	**Ice-moderate:** moderate amount of excess ice; continuous or locally segregated ice in seams and lenses; massive ice (e.g. ice wedges) possible locally	**Ice-rich:** large amount of excess ice; continuous ice; segregated ice in extensive seams and lenses; massive ice indicated (Xw), or likely (Xl)
ESTIMATED RELATIVE DEPTH	**Near-surface:** < 0.4 m; within or at the base of organics.	typically surface		
	Shallow: 0.4 - 1 m; relatively fine-grained, supported sediments; most common condition in the study area	commonly in matrix-dominated		
	Deep: > 1 m; typically relatively coarse-grained, supported sediments.	within clast-		

* *Excess ice refers to the volume of ice that exceeds the total voids (e.g. pore space) that would be present under natural, unfrozen conditions.*

*** Depth to permafrost and ice content classes are relative and inferred based on landform association with reference to limited field observations and secondary source information.*

Mapping Notes

Surficial geology mapping was completed at a scale of 1:20,000 using DAT/EM Summit software in combination with ESRI's ArcGIS. Interpretations were made based on continuous coverage of satellite imagery (2019) and aerial photography, and further refined using 1m resolution, LiDAR-derived (2019). Map units (polygons) were delineated based on surficial materials, expressions, active processes, and surface drainage in accordance with the Terrain Classification System for British Columbia (Kenk, 1997), with modifications for use in Yukon (Lipovsky and Bond, 2014) and to accommodate objectives. Under this system, up to two surficial materials may be identified in each polygon as either secondary materials, or in stratigraphic relation to each other. Polygons have been symbolized based on surficial material, discrete terrain features and geomorphic processes too small to be mapped as polygons. Permafrost stability and active-layer detachments, have been identified using point and line features. Interpretations were calibrated, in part, based on one week of helicopter-supported field reconnaissance in July, 2019.

SURFICIAL MATERIAL AND LANDFORM DEFINITIONS

A	**Anthropogenic deposits:** surficial material ials modified by human activities such that their or iginal physical properties have been significantly altered ed; applied to areas modified by excavation and construction activities; not applied to road networks.
Ov	**Organic deposits; veneer:** < 1 m thick; material ial derived from the accumulation of plant matter , generally consisting of peat (typically bog or fen) ; occurs on poorly drained, level to gently sloping shallow depressions; only included in map labels where accumulation is thicker than 20 cm.
Ob	**Organic deposits; blanket:** > 1 m thick; material ial derived from the accumulation of plant matter , generally consisting of peat (typically bog or fen) ; occurs on poorly drained, level to gently sloping shallow depressions.
FAv	**Fluvial sediments; active veneer:** < 1 m thick; material ial transported and deposited by stream s typically exhibiting inter mittent or presential flow; mainly occurs on gentle slopes within gullies at the headwaters of moder n streams; generally composed of silt, organics, and minor sands.
FAf	**Fluvial sediments; active fan:** materials transported and deposited by streams; typically occurs where tributary streams meet larger, lower angle river systems and deposited material is longitudinal in form slightly concave to slightly convex; generally composed of silt, sands, and organics.
FAp	**Fluvial sediments; active plain:** materials transported and deposited by moder n streams; typically planar to gently sloping landforms along valley bottoms; generally composed of silt and sand on floodplains and gravels along active channels and bars.
Fp	**Fluvial sediments; active plain:** materials transported and deposited by streams in the floodplain above moder n channels; typically planar to gently sloping landforms along valley bottoms; generally composed of silts, sands, and organics.
Ft	**Fluvial sediments; terrace:** materials transported and deposited by streams and usually located adjacent to moder n streams; typically occurs as a planar landform with a conspicuous scarp along edge; generally composed of silts, sands, and organics.
Cv	**Colluvial sediments; veneer:** < 1 m thick; materials that have been transported downslope through gravitational processes including freeze- thaw cycles, creep, solifluction, sloped wash and active detachments; deposits roughly follows the surface of the underlying bedrock and is too thin to mirror irregularities; generally composed of silts, sands, and gravels; may locally include larger clasts.
Cb	**Colluvial sediments; blanket:** > 1 m thick; materials that have been transported downslope through gravitational processes including freeze- thaw cycles, creep, solifluction, sloped wash and active detachments; deposits roughly follows the surface of the underlying bedrock and is too thick enough to mirror irregularities; generally composed of silts, sands, and gravels; may locally include larger clasts.
Cw	**Colluvial sediments; mantle of variable thickness:** typically 0 - 3 m thick; materials that have been transported downslope through gravitational processes including freeze- thaw cycles, creep, solifluction, sloped wash and active- layer detachments; a layer or discontinuous layer that roughly follows the surface expression of the underlying bedrock and fills or partly fills depressions in an irregular substrate; composed of silts, sands, and gravels; may locally include larger clasts.
Ca	**Colluvial sediments; apron:** < 1 m thick; materials that have been transported downslope through gravitational processes including freeze- thaw cycles, creep, solifluction, sloped wash and active detachments; wedge- shaped landforms occurring on lower slopes positions where sediments accumulate; may be locally inter mixed with fluvial deposits; generally composed of silts, sands, and gravels; locally include larger clasts and organics.
Dv	**Bedrock, undifferentiated, weathered:** extensively weathered materials derived directly from underlying bedrock without significant transport or ation; typically occurs on rounded summits and along broad and sloping surfaces; generally composed of silt, sand, and gravel- sized fragments.
R	**Bedrock, undifferentiated:** moder ate- to high- relief surface exposition; typically exposed in bluffs along ridges and in upper slope positions, in association with differential erosion of different sedimentary and typically gravitational to weather ed bedrock.

TEXTURE*

f - Matrix- dominated: deposit is composed nearly entirely of silts and clays, with minor sand.

m - Matrix- supported: deposit is a matrix- supported mixture of gravels, sands, silts, and minor clay.

c - Clast- supported: deposit is a clast- rich mixture of gravels, sands, and minor silts.

*Texture classes are applied to colluvium and weathered bedrock. Textures for other materials are characterized above in association with the landform definitions.

GEOMORPHOLOGICAL PROCESSES

I - Irregular ly sinuous channel: a clearly defined main channel displaying irregular meander bends.

S - Solifluction: slow, downslope gravitational movement of wet soil across a frozen (e.g. permafrost) impermeable substrate.

G - Gully erosion: formation of sub- parallel, narrow ravines by concentrated surface runoff and mass wasting exacerbated by fluvio- thermal erosion in areas of ice- rich permafrost.

X - Permafrost Processes:

-s - Sheetwash: areas where esurface runoff flows as diffuse sheetflow, or in concentrated runnels (watertracks) on shallow permafrost.

-f - Active- layer detachment: translational landslides along a shallow failure plane (also referred to as the typically result from the loss of strength at the contact between thawed (above) and frozen (below) material; the plane may be within or at base of active layer overlying permafrost.

-t - Thermokarst subsidence: ground- surface depressions created by the thawing of ice- rich permafrost soil subsidence; depressions commonly contain water (thaw pond) ; may be mapped as a lake in the base mapping.

-w - Patterned ground: polygonal surface expression of ice wedges in permafrost terrain; commonly thermokarst.

PERMAFROST CLASSIFICATION OVERLAY		ESTIMATED RELATIVE ICE CONTENT		
		Ice-poor: little to no excess ice, discontinuous, continuous pore space; generally ice is thin seams; most common ice unlikely; most condition in the study area	**Ice-moderate:** moderate excess ice, continuous pore space; generally ice is thin seams; massive ice possible locally.	**Ice-rich:** large amount of excess ice, continuous pore space; segregated ice extensive; generally ice in seams and lenses; massive ice indicated (Xw) ; inferred (Xi) ... or likely.
ESTIMATED RELATIVE DEPTH	**Near-surface:** < 0.4 m; within or at the base of organics.	locally surface		
	Shallow: 0.4 - 1 m; relatively fine- grained, supported by matrix- dominated sediments; most common condition in the study area.	commonly in matrix- dominated		
	Deep: > 1 m; typically relatively coarse- grained, supported sediments.	within clast-		

* Excess ice refers to the volume of ice that exceeds the total voids (e.g. pore space) that would be present under natural, unfrozen conditions.

** Depth to permafrost and ice content classes are relative and inferred based on landform association with reference to limited field observations and secondary source information.

Mapping Notes

Surficial geology mapping was completed at a scale of 1:20,000 using DAT/EM Summit software in combination with ESRI's ArcGIS. Interpretations were made based on continuous cover age of satellite imagery (2019) and aerial photographs, and further refined using 1m- resolution, LiDAR- (2019). Map units (polygons) were delineated based on surficial material ials, exposures, active processes, and surface drainage in accordance with the Terrain Classification System for British Columbia Kenk, 1997), with modifications for use in Yukon (Lipovsky and Bond, 2014) and to accommodate objectives. Under this system, up to two surficial materials may be identified in each polygon as either secondary materials, or in strategraphic relation to each other. Polygons have been symbolized based on surficial material, Quaternary terrain features and geomorphic processes too small to be mapped as polygons. Permafrost and active- layer detachments, have been identified using point and line features. In were calibrated, in part, based on one week of helicopter- supported field reconnaissance in July, 2019.

SURFICIAL MATERIAL AND LANDFORM DEFINITIONS

A	**Anthropogenic deposits:** surficial materials modified by human activities such that their original properties have been significantly altered, and applied to areas modified by excavation and construction activities; not applied to road networks.
Ov	**Organic deposits; veneer:** < 1 m thick; material derived from the accumulation of plant matter, generally consisting of peat (typically bog or fen); occurs on poorly drained, level to gently sloping shallow depressions; only included in map labels where accumulation is thicker than 2.0 cm.
Ob	**Organic deposits; blanket:** > 1 m thick; material derived from the accumulation of plant matter, generally consisting of peat (typically bog or fen); occurs on poorly drained, level to gently sloping shallow depressions.
FAv	**Fluvial sediments; active veneer:** < 1 m thick; material transported and deposited by streams typically exhibiting intermittent or perennial flow; mainly occurs on gentle slopes within gullies at the headwaters of moderate streams; generally composed of silt, organics, and minor sands.
FAf	**Fluvial sediments; active fan:** material laterally transported and deposited by streams; typically occurs where fluvial gradient steepens, most commonly at angular river systems and deposit material; longitudinal profile from slightly concave to slightly convex; generally composed of silt, sands, and organics.
FAp	**Fluvial sediments; active plain:** material laterally transported and deposited by moderate streams; typically planar to gently sloping landforms along valley bottoms; generally composed of silt and sand on floodplains and gravels along active channels and bars.
Fp	**Fluvial sediments; active plain:** material laterally transported and deposited by streams in the floodplain above moderate channels; typically planar to gently sloping landforms along valley bottoms; generally composed of silts, sands, and organics.
Ft	**Fluvial sediments; terrace:** material laterally transported and deposited by streams and usually located adjacent to moderate streams; typically occurs as a planar landform with a conspicuous scarp along edge; generally composed of silts, sands, and organics.
Cv	**Colluvial sediments; veneer:** < 1 m thick; material laterally that have been transported downslope through gravitational processes including freeze-thaw cycles, creep, solifluction, slopewash and active-layer detachments; deposit roughly follows the surface of the underlying bedrock and is too thin to mirror irregularities; generally composed of silts, sands, and gravels; may locally include larger clasts.
Cb	**Colluvial sediments; blanket:** > 1 m thick; material laterally that have been transported downslope through gravitational processes including freeze-thaw cycles, creep, solifluction, slopewash and active-layer detachments; deposit roughly follows the surface of the underlying bedrock and is thick enough to mirror irregularities; generally composed of silts, sands, and gravels; may locally include larger clasts.
Cw	**Colluvial sediments; mantle of variable thickness:** typically 0 - 3 m thick; material laterally that have been transported downslope through gravitational processes including freeze-thaw cycles, creep, solifluction, slopewash and active-layer detachments; a layer or discontinuous layer that roughly follows the expression of underlying bedrock and fills or partially fills depressions in an irregular substrate; composed of silts, sands, and gravels; may locally include larger clasts.
Ca	**Colluvial sediments; apron:** < 1 m thick; material laterally that have been transported downslope through gravitational processes including freeze-thaw cycles, creep, solifluction, slopewash and active-layer detachments; wedge-shaped landforms that occur ring on lower slope positions where sediments accumulate; may be locally inter mixed with fluvial deposits; generally composed of silts, sands, and gravels; locally include larger clasts and organics.
Dv	**Bedrock, undifferentiated, weathered:** extensively weathered material laterally derived directly from underlying bedrock without significant transportation; typically occurs on rounded summits and along broad and subdued s. generally composed of silt, sand, and gravel-sized regolith.
R	**Bedrock, undifferentiated:** moderate- to high-relief surface exposition; typically exposed in bluffs along ridges and in upper slope positions, in association with differentential erosion of different sedimentary typically gradational to weathered bedrock.

TEXTURE*

f - Matrix- dominated: deposit is composed nearly entirely of silts and clays, with minor sand.

m - Matrix- supported: deposit is a matrix- supported mixture of gravels, sands, silts, and minor clay.

c - Clast- supported: deposit is a clast- rich mixture of gravels, sands, and minor silts.

**Texture classes are applied to colluvium and weathered bedrock. Textures for other materials are characterized above in association with the landform definitions.*

GEOMORPHOLOGICAL PROCESSES

I - Irregularly sinuous channel: a clearly defined main channel displaying irregular meanders bends.

S - Solifluction: slow, downslope gravitational movement of wet soil across a frozen (e.g. permafrost) impermeable substrate.

G - Gully erosion: formation of sub- parallel, narrow ravines by concentrated surface runoff and mass exacerbated by fluvio- thermal erosion in areas of ice- rich permafrost.

X - Permafrost Processes:

-s - Sheetwash: areas where esurface runoff flows as diffuse sheetflow, or in concentrated runnels (watershallow permafrost.

-f - Active- layer detachment: translational landslides along a shallow failure plane (also referred to as thtypically resulting from the loss of strength at the contact between thawed (above) and frozen (belowmaterial may be within or at base of active layer overlying permafrost.

-t - Thermokarst subsidence: ground- surface depressions created by the thawing of ice- rich permafrost soil subsidence; depressions commonly contain water (thaw ponds); may be mapped as a lake in the base mapping.

-w - Patterned ground: polygonal surface expression of ice wedges in permafrost terrain; commonly thermokarst.

SURFICIAL MATERIAL AND LANDFORM DEFINITIONS

A — **Anthropogenic deposits:** surficial materials modified by human activities such that their original physical properties have been significantly altered, applied to areas modified by excavation and construction activities; not applied to road networks.

Ov — **Organic deposits; veneer:** <1 m thick; material ideally derived from the accumulation of plant matter, generally consisting of peat (typically bog or fen); occurs on poorly drained, level to gently sloping shallow depressions; only included in map labels where accumulation is thicker than 20 cm.

Ob — **Organic deposits; blanket:** >1 m thick; material ideally derived from the accumulation of plant matter, generally consisting of peat (typically bog or fen); occurs on poorly drained, level to gently sloping shallow depressions.

FAv — **Fluvial sediments; active veneer:** <1 m thick; material ideally transported and deposited by stream systems typically exhibiting intermittent or perennial flow; mainly occurs on gentle slopes within gullies at the headwaters of moderate streams; generally composed of silt, organics, and minor sands.

FAf — **Fluvial sediments; active fan:** material ideally transported and deposited by stream systems; typically occurs where tributary stream meets larger, lower angle river systems and deposit material ideally; longitudinal profile from slightly concave to slightly convex; generally composed of silt, sands, and organics.

FAp — **Fluvial sediments; active plain:** material ideally transported and deposited by modern stream systems; typically planar to gently sloping landforms along valley bottoms; generally composed of silt and sand on floodplains and gravels along active channels and bars.

Fp — **Fluvial sediments; active plain:** material ideally transported and deposited by streams in the floodplain above modern channels; typically planar to gently sloping landforms along valley bottoms; generally composed of silts, sands, and organics.

Ft — **Fluvial sediments; terrace:** material ideally transported and deposited by streams and usually located adjacent to modern streams; typically occurs as a planar landform with a consp icuous scarp along edge; generally composed of silts, sands, and organics.

Cv — **Colluvial sediments; veneer:** <1 m thick; material that have been transported and downslope through gravitational processes including freeze-thaw cycles, creep, solifluction, sloopewash and active-layer detachments; deposit roughly follows the surface of the underlying bedrock and is too thin to mirror regular ities; generally composed of silts, sands, and gravels; may locally include larger clasts.

Cb — **Colluvial sediments; blanket:** >1 m thick; material that have been transported and downslope through gravitational processes including freeze-thaw cycles, creep, solifluction, sloopewash and active-layer detachments; deposit roughly follows the surface of the underlying bedrock and is thick enough to minor irregular ities; generally composed of silts, sands, and gravels; may locally include larger clasts.

Cw — **Colluvial sediments; mantle of variable thickness:** typically 0-3 m thick; material that have been transported and downslope through gravitational processes including freeze-thaw cycles, creep, sloopewash and active-layer detachments; a layer or discontinuous layer that roughly follows the surface expression of underlying bedrock and fills or partially fills depressions in an irregular substrate; composed of silts, sands, and gravels; may locally include larger clasts.

Ca — **Colluvial sediments; apron:** <1 m thick; material that have been transported and downslope through gravitational processes including freeze-thaw cycles, creep, solifluction, sloopewash and active-layer detachments; wedge-shaped landforms occurring on lower slope positions where sediments accumulate; may be locally intermixed with fluvial deposits; generally composed of silts, sands, and gravels; locally include larger clasts and organics.

Dv — **Bedrock, undifferentiated, weathered:** extensively weathered material ideally derived directly from underlying bedrock without significant transportation; typically occurs on rounded summits and along broad and subdued ridges.

R — **Bedrock, undifferentiated:** moderate- to high-relief surface exposition; typically exposed in bluffs along ridges and in upper slope positions, in association with differential erosion of different sedimentary and typically gradational to weathered bedrock.

TEXTURE*

f - Matrix-dominated: deposit is composed nearly entirely of silts and clays, with minor sand.

m - Matrix-supported: deposit is a matrix-supported mixture of gravels, sands, silts, and minor clasts.

c - Clast-supported: deposit is a clast-rich mixture of gravels, sands, and minor silts.

*Texture classes are applied to colluvium and weathered bedrock. Textures for other materials are characterized above in association with the landform definitions.

GEOMORPHOLOGICAL PROCESSES

I - Irregularly sinuous channel: a clearly defined main channel displaying irregular meander bends.

S - Solifluction: slow, downslope gravitational movement of wet soil across a frozen (e.g. permafrost) impermeable substrate.

G - Gully erosion: formation of sub-parallel, narrow ravines by concentrated surface runoff and mass exacerbated by fluvio-thermal erosion in areas of ice-rich permafrost.

X - Permafrost Processes:

-s - Sheetwash: areas where surface runoff flows as diffuse sheetflow, or in concentrated runnels (watershallow permafrost.

-f - Active-layer detachment: translational landslides along a shallow failure plane (also referred to as the typically result from the loss of strength at the contact between thawed (above) and frozen (below) plane may be within or at base of active layer overlying permafrost.

-t - Thermokarst subsidence: ground-surface depressions created by the thawing of ice-rich permafrost soil subsidence; depressions commonly contain water (thaw pond); may be mapped as a lake in the base mapping.

SURFICIAL MATERIAL AND LANDFORM DEFINITIONS

A	**Anthropogenic deposits:** surficial materials modified by human activities such that their original properties have been significantly altered; applied to areas modified by excavation and construction activities; not applied to road network.
Ov	**Organic deposits; veneer:** <1 m thick; material ldeveloped from the accumulation of plant matter, generally consisting of peat (typically bog or fen); occurs on poorly drained, level to gently sloping shallow depressions; only included in map labels where accumulation is thicker than 20 cm.
Ob	**Organic deposits; blanket:** >1 m thick; material ldeveloped from the accumulation of plant matter, generally consisting of peat (typically bog or fen); occurs on poorly drained, level to gently sloping shallow depressions.
FAv	**Fluvial sediments; active veneer:** <1 m thick; material ltransported and deposited by streams typically exhibiting intermittent or perennial flow; mainly occurs on gentle slopes within gullies at the headwaters of moderate streams; generally composed of silt, organics, and minor sands.
FAf	**Fluvial sediments; active fan:** material ltransported and deposited by streams; typically occurs where fluvial systems meet flatter gradients; lower angle river systems and deposit material; longitudinal profile from slightly concave to slightly convex; generally composed of silt, sands, and organics.
FAp	**Fluvial sediments; active plain:** material ltransported and deposited by modern streams; typically planar to gently sloping landforms along valley bottoms; generally composed of silt and sand on floodplains and gravels along active channels and bars.
Fp	**Fluvial sediments; active plain:** material ltransported and deposited by streams in the floodplain above modern channels; typically planar to gently sloping landforms along valley bottoms; generally composed of silts, sands, and organics.
Ft	**Fluvial sediments; terrace:** material ltransported and deposited by streams and usually located adjacent to modern streams; typically occurs as a planar landform with a conspicuous scarp along edge; generally composed of silts, sands, and organics.
Cv	**Colluvial sediments; veneer:** <1 m thick; material that have been transported downslope through gravitational processes including freeze-thaw cycles, creep, solifluction, sloughwash and active-layer detachments; deposit roughly follows the surface of the underlying bedrock and is too thin to mask bedrock irregularities; generally composed of silts, sands, and gravels; may locally include large clasts.
Cb	**Colluvial sediments; blanket:** >1 m thick; material that have been transported downslope through gravitational processes including freeze-thaw cycles, creep, solifluction, sloughwash and active-layer detachments; deposit roughly follows the surface of the underlying bedrock and is thick enough to mask minor irregularities; generally composed of silts, sands, and gravels; may locally include large clasts.
Cw	**Colluvial sediments; mantle of variable thickness:** typically 0-3 m thick; material that have been transported downslope through gravitational processes including freeze-thaw cycles, creep, sloughwash and active-layer detachments; a layer or discontinuous layer that roughly follows the surface expression of underlying bedrock and fills or partly fills depressions in an irregular substrate; composed of silts, sands, and gravels; may locally include large clasts.
Ca	**Colluvial sediments; apron:** <1 m thick; material that have been transported downslope through gravitational processes including freeze-thaw cycles, creep, solifluction, sloughwash and active-layer detachments; wedge-shaped landforms occurring on lower slope positions where sediments accumulate; may be locally inter mixed with fluvial deposits; generally composed of silts, sands, and gravels; locally include large clasts and organics.
Dv	**Bedrock, undifferentiated, weathered:** extensively weathered material dominantly consisting of bedrock without significant transportation; typically occurs on rounded summits and along broad and spurs; generally composed of silt, sand, and gravel-sized fragments.
R	**Bedrock, undifferentiated:** moderate- to high-relief surface exposition; typically exposed in bluffs, ridges and in upper slope positions, in association with different erential erosion of different sedimentary; typically gradational to weathered bedrock.

TEXTURE*

f - Matrix-dominated: deposit is composed nearly entirely of silts and clays, with minor sand.

m - Matrix-supported: deposit is a matrix-supported mixture of gravels, sands, silts, and minor clay.

c - Clast-supported: deposit is a clast-rich mixture of gravels, sands, and minor silts.

**Texture classes are applied to colluvium and weathered bedrock. Textures for other materials are characterized above in association with the landform definitions.*

GEOMORPHOLOGICAL PROCESSES

I - Irregularly sinuous channel: a clearly defined main channel displaying irregular meanders bends.

S - Solifluction: slow, downslope gravitational movement of wet soil across a frozen (e.g. permafrost) impermeable substrate.

G - Gully erosion: formation of sub-parallel, narrow ravines by concentrated surface runoff and mass wasting exacerbated by fluvio-thermal erosion in areas of ice-rich permafrost.

X - Permafrost Processes:

-s - Sheetwash: areas where surface runoff flows as diffuse sheetflow, or in concentrated runnels (watertracks) shallow permafrost.

-f - Active-layer detachment: translational landslides along a shallow failure plane (also referred to as the typically result from the loss of strength at the contact between thawed (above) and frozen (below) material; plane may be within or at base of active layer overlying permafrost.

-t - Thermokarst subsidence: ground-surface depressions created by the thawing of ice-rich permafrost soil subsidence; depressions commonly contain water (thaw pond); may be mapped as a lake in the base mapping.

-w - Patterned ground: polygonal surface expression of ice wedges in permafrost terrain; commonly thermokarst.

Mapping Notes

Surficial geology mapping was completed at a scale of 1:20,000 using DAT/EM Summit software in combination with ESRI's ArcGIS. Interpretations were made based on continuous coverage of satellite imagery (2019) and aerial photographs, and further refined using 1m-resolution, LiDAR-derived (2019). Map units (polygons) were delineated based on surficial material, exposures, active processes, and surface drainage in accordance with the Terrain Classification System for British Columbia (Howes and Kenk, 1997), with modifications for use in Yukon (Lipovsky and Bond, 2014) and to accommodate project objectives. Under this system, up to two surficial materials may be identified in each polygon as either secondary material, or in strategraphic relation to each other. Polygons have been symbolized based on surficial material, dominant terrain features and geomorphic processes too small to be mapped as polygons. Permafrost, thermokarst deposits and active-layer detachments, have been identified using point and line features. In-field were calibrated, in part, based on one week of helicopter-supported field reconnaissance in July, 2019.

SURFICIAL MATERIAL AND LANDFORM DEFINITIONS

A	**Anthropogenic deposits:** surficial materials modified by human activities such that their original physical properties have been significantly altered, and applied to areas modified by excavation and construction activities; not applied to road network.
Ov	**Organic deposits; veneer:** < 1 m thick; material dominated from the accumulation of plant matter, generally consisting of peat (typically bog or fen); occurs on poorly drained, level to gently sloping shallow depressions; only included in map labels where accumulation is thicker than 20 cm.
Ob	**Organic deposits; blanket:** > 1 m thick; material dominated from the accumulation of plant matter, generally consisting of peat (typically bog or fen); occurs on poorly drained, level to gently sloping shallow depressions.
FAv	**Fluvial sediments; active veneer:** < 1 m thick; material that transported and deposited by streams typically exhibiting intermittent or perennial flow; mainly occurs on gentle slopes within gullies at the headwaters of moderate streams; generally composed of silt, organics, and minor sands.
FAf	**Fluvial sediments; active fan:** material laid transported and deposited by streams; typically occurs where a tributary stream meets larger, lower angle river systems and deposit material; longitudinal profile from slightly concave to slightly convex; generally composed of silt, sands, and organics.
FAp	**Fluvial sediments; active plain:** material laid transported and deposited by modern streams; typically a planar to gently sloping landform mainly along valley bottoms; generally composed of silt and sand on floodplains and gravels along active channels and bars.
Fp	**Fluvial sediments; active plain:** material laid transported and deposited by streams in the floodplain above modern channels; typically planar to gently sloping landform mainly along valley bottoms; generally composed of silts, sands, and organics.
Ft	**Fluvial sediments; terrace:** material laid transported and deposited by streams and usually located adjacent to modern streams; typically occurs as a planar landform with a conspicuous scarp along edge; generally composed of silts, sands, and organics.
Cv	**Colluvial sediments; veneer:** < 1 m thick; material laid that have been transported downslope through gravitational processes including freeze-thaw cycles, creep, solifluction, slopewash and active-layer detachments; deposit roughly follows the surface of the underlying bedrock and is too thin to mirror irregularities; generally composed of silts, sands, and gravels; may locally include larger clasts.
Cb	**Colluvial sediments; blanket:** > 1 m thick; material laid that have been transported downslope through gravitational processes including freeze-thaw cycles, creep, solifluction, slopewash and active-layer detachments; deposit roughly follows the surface of the underlying bedrock and is too thick enough to mirror irregularities; generally composed of silts, sands, and gravels; may locally include larger clasts.
Cw	**Colluvial sediments; mantle of variable thickness:** typically 0 - 3 m thick; material laid that have been transported downslope through gravitational processes including freeze-thaw cycles, creep, solifluction, slopewash and active-layer detachments; a layer or discontinuous layer that roughly follows the surface expression of the underlying bedrock and fills or partly fills depressions in an irregular substrate; composed of silts, sands, and gravels; may locally include larger clasts.
Ca	**Colluvial sediments; apron:** < 1 m thick; material laid that have been transported downslope through gravitational processes including freeze-thaw cycles, creep, solifluction, slopewash and active-layer detachments; wedge-shaped landforms occurring on lower slope positions where sediments accumulate; may be locally intermixed with fluvial deposits; generally composed of silts, sands, and gravels; locally include larger clasts and organics.
Dv	**Bedrock, undifferentiated, weathered:** extensively weathered material laid derived directly from underlying bedrock without significant transportation; typically occurs on rounded summits and along broad ridges and upslope positions, in association with different erosion of different sedimentary rocks; typically gravitational to weathered bedrock.
R	**Bedrock, undifferentiated:** moderate- to high-relief surface exposition; typically exposed in bluffs along ridges and in upper slope positions, in association with different erosion of different sedimentary rocks; typically gravitational to weathered bedrock.

TEXTURE*

f - Matrix-dominated: deposit is composed near-lyentirely of silts and clays, with minor sand.

m - Matrix-supported: deposit is a matrix-supported mixture of gravels, sands, silts, and minor clay.

c - Clast-supported: deposit is a clast-rich mixture of gravels, sands, and minor silts.

**Texture classes are applied to colluvium and weathered bedrock. Textures for other materials are characterized above in association with the landform definitions.*

GEOMORPHOLOGICAL PROCESSES

l - Irregularly sinuous channel: a clearly defined main channel displaying irregular meanders bends.

s - Solifluction: slow, downslope gravitational movement of wet soil across a frozen (e.g. permafrost) impermeable substrate.

g - Gully erosion: formation of sub-parallel, narrow ravines by concentrated surface runoff and mass exacerbated by fluvio-thermal erosion in areas of ice-rich permafrost.

X - Permafrost Processes:

-s - Sheetwash: areas where esurface runoff flows as diffuse sheetflow, or in concentrated runnels (watershallow permafrost.

-f - Active-layer detachment: translational landslides along a shallow failure plane (also referred to as thtypically resulting from the loss of strength at the contact between thawed (above) and frozen (belowplane may be within or at base of active layer overlying permafrost.

-t - Thermokarst subsidence: ground-surface depressions created by the thawing of ice-rich permafrost soil subsidence; depressions commonly contain water (thawponds); may be mapped as a lake in the base mapping.

-w - Patterned ground: polygonal surface expression of ice wedges in permafrost terrain; commther mokarst.

PERMAFROST CLASSIFICATION OVERLAY	ESTIMATED RELATIVE ICE CONTENT		
	Ice-poor: little to no excess ice; discontinuous to continuous pore ice; locally include segregated ice in thin seams, ice unlikely; most common condition in the study area	**Ice-moderate:** moderate amount of excess ice; continuous pore ice; segregated ice in seams and lenses, massive ice (e.g. ice wedges) may be possible locally	**Ice-rich:** large amount of excess ice; continuous pore ice; segregated ice; extensive in seams and lenses, massive ice indicated (Xw), ice wedges likely (Xi), or likely
Near-surface: < 0.4 m; within or at the base of organics.	typically surface		
Shallow: 0.4 - 1 m; relatively fine- grained, supported to matrix-dominated sediments; most common condition in the study area	commonly in coarser-grained, matrix-dominated sediments; most common.		
Deep: > 1 m; typically relatively coarse- grained, supported sediments.	within clast-	within clast-	within clast-

** Excess ice refers to the volume of ice that exceeds the total voids (e.g. pore space) that would be present under natural, unfrozen conditions.*
*** Depth to permafrost and ice content classes are relative and inferred based on landform association with reference to limited field observations and secondary source information.*

Mapping Notes

Surficial geology mapping was completed at a scale of 1:20,000 using DAT/EM Summit software in combination with ESRI's ArcGIS. Interpretations were made based on continuous coverage of satellite imagery (2019) and aerial photography, and further refined using 1 m resolution, LiDAR-(2019). Map units (polygons) were delineated based on surficial materials, expressions, active processes, and surface drainage in accordance with the Terrain Classification System for British Columbia Kenk, 1997), with modifications for use in Yukon (Lipovsky and Bond, 2014) to accommodate objectives. Under this system, up to two surficial materials may be identified in each polygon as either secondary material, or in strike aligned hydrologic relation to each other. Polygons have been symbolized based on surficial material. Discrete terrain features and geomorphic processes too small to be mapped as polygons ther mokarst depressions and active-layer detachments, have been identified using point and line features. In were calibrated, in part, based on one week of helicopter-supported field reconnaissance in July, 2019

SURFICIAL MATERIAL AND LANDFORM DEFINITIONS

A — **Anthropogenic deposits:** surficial materials modified by human activities such that their original properties have been significantly altered, or applied to areas modified by excavation and construction activities; not applied to road networks.

Ov — **Organic deposits; veneer:** < 1 m thick; material derived from the accumulation of plant matter, generally consisting of peat (typically bog or fen); occurs on poorly drained, level to gently sloping shallow depressions; only included in map labels where accumulation is thicker than 20 cm.

Ob — **Organic deposits; blanket:** > 1 m thick; material derived from the accumulation of plant matter, generally consisting of peat (typically bog or fen); occurs on poorly drained, level to gently sloping shallow depressions.

FAv — **Fluvial sediments; active veneer:** < 1 m thick; material and deposited by streams typically exhibiting intermittent or perennial flow; mainly occurs on gentle slopes within gullies at the headwaters of moderate streams; generally composed of silt, organics, and minor sands.

FAf — **Fluvial sediments; active fan:** material and deposited by streams; typically occurs where a tributary stream meets a larger, lower angle river systems and deposit material; landforms typically range from slightly concave to slightly convex; generally composed of silt, sands, and organics.

FAp — **Fluvial sediments; active plain:** material and deposited by moderate streams; typically a planar to gently sloping landform mantling along valley bottoms; generally composed of silt and sand on floodplains and gravels along active channels and bars.

Fp — **Fluvial sediments; active plain:** material and deposited by streams in the floodplain above moderate channels; typically a planar to gently sloping landform mantling along valley bottoms; generally composed of silts, sands, and organics.

Ft — **Fluvial sediments; terrace:** material and deposited by streams and usually located adjacent to moderate streams; typically occurs as a planar landform with a consp icuous scarp along edge; generally composed of silts, sands, and organics.

Cv — **Colluvial sediments; veneer:** < 1 m thick; material that have been transported downslope through gravitational processes including freeze- thaw cycles, creep, solifluction, slopewash and active-layer detachments; deposit roughly follows the surface of the underlying bedrock and is too thin to mirror irregularities; generally composed of silts, sands, and gravels; may locally include larger clasts.

Cb — **Colluvial sediments; blanket:** > 1 m thick; material that have been transported downslope through gravitational processes including freeze- thaw cycles, creep, solifluction, slopewash and active-layer detachments; deposit roughly follows the surface of the underlying bedrock and is thick enough to mirror irregularities; generally composed of silts, sands, and gravels; may locally include larger clasts.

Cw — **Colluvial sediments; mantle of variable thickness:** typically 0 - 3 m thick; material that have been transported downslope through gravitational processes including freeze- thaw cycles, creep, solifluction, slopewash and active- layer detachments; a discontinuous layer that roughly follows the expression of underlying bedrock and fills or partly fills depressions in an irregular substrate; composed of silts, sands, and gravels; may locally include larger clasts.

Ca — **Colluvial sediments; apron:** < 1 m thick; material that have been transported downslope through gravitational processes including freeze- thaw cycles, creep, solifluction, slopewash and active-layer detachments; wedge- shaped landforms occurring on lower slope positions where sediments accumulate; may be locally intermixed with fluvial deposits; generally composed of silts, sands, and gravels; locally include larger clasts and organics.

Dv — **Bedrock, undifferentiated, weathered:** extensively weathered material ideally derived directly from underlying bedrock without significant transportation; typically occurs on unconsolidated summits and along broad and sparsely; generally composed of silt, sand, and gravel- sized regolith.

R — **Bedrock, undifferentiated:** moderate- to high- relief surface exposition; typically exposed in bluffs along ridges and in upper slope positions, in association with differential erosion of different sedimentary types.

TEXTURE*

f - Matrix- dominated: deposit is composed nearly entirely of silts and clays, with minor sand.

m - Matrix- supported: deposit is a matrix- supported mixture of gravels, sands, silts, and minor clasts.

c - Clast- supported: deposit is a clast- rich mixture of gravels, sands, and minor silts.

*Texture classes are applied to colluvium and weathered bedrock. Textures for other materials are characterized above in association with the landform definitions.

GEOMORPHOLOGICAL PROCESSES

I - Irregularly sinuous channel: a clearly defined main channel displaying irregular meanders bends.

S - Solifluction: slow, downslope gravitational movement of wet soil across a frozen (e.g. permafrost) substrate.

G - Gully erosion: formation of sub- parallel, narrow ravines by concentrated surface runoff and mass wasting exacerbated by fluvio- thermal erosion in areas of ice- rich permafrost.

X - Permafrost Processes:

-s - Sheetwash: areas where surface runoff flows as diffuse sheetflow, or in concentrated runnels (watertracks) shallow permafrost.

-f - Active- layer detachment: translational landslides along a shallow failure plane (also referred to as the typically result from the loss of strength at the contact between thawed (above) and frozen (below) material; plane may be within or at base of active layer overlying permafrost.

-t - Thermokarst subsidence: ground- surface depressions created by the thawing of ice- rich permafrost soil subsidence; depressions commonly contain water (thaw pond); may be mapped as a lake in the base mapping.

-w - Patterned ground: polygonal surface expression of ice wedges in permafrost terrain; commonly thermokarst.

Exploration Development Suitability

Eagle Plains, Yukon

Road and Wellpad Suitability Classification

	Typical Description	Typical Implications
Very High	Moderately well to well drained, isolated topographic highs with deep or shallow, ice-poor permafrost. Generally considered to be stable terrain, and typically located along wide, rounded ridge crests.	Favourable conditions for access road and wellpad establishment through standard best management practices, with minimal expectation for maintenance requirements.
High	Generally moderately well to well drained areas with deep or shallow, ice-poor permafrost. Typically associated with ridges of weathered bedrock or shallow colluvium over convex topography.	Generally favourable conditions for access road and wellpad establishment through standard best management practices, with low to moderate expectation for maintenance requirements.
Moderate	Imperfectly to moderately well drained, colluvial slopes with deep to shallow permafrost, commonly with poor to moderate ice content; convex weathered bedrock bluffs, typically at moderate slope gradients; and fluvial terraces above the influence of modern stream processes.	Generally reasonable conditions for access road and wellpad establishment, where necessary employing mitigations to proactively manage natural concentrations of surface runoff and protect thaw-sensitive permafrost, with moderate expectation for maintenance requirements. Field reconnaissance would help inform route/site selection and mitigation requirements.
Low	Poorly to imperfectly drained, thick colluvial slopes with shallow, ice-rich or ice-moderate permafrost; and imperfectly drained fluvial fans and veneers. Sheetwash, gully erosion, and ice-wedge polygons are common; surface runoff becomes concentrated.	Generally unfavourable conditions for access road and wellpad establishment, except through mitigations to proactively manage natural concentrations of surface runoff and protect thaw-sensitive permafrost, with moderate to high expectation for maintenance requirements. Field reconnaissance necessary to inform route/site selection and mitigation requirements.
Very Low	Very poorly to imperfectly drained areas with shallow or near-surface, ice-rich or ice-moderate permafrost, commonly in association with floodplains, as well as steep bedrock scarps. Thermokarst subsidence and ice-wedge polygons are common; surface runoff and slopes may be subjected to mass movements including solifluction and active-layer detachments.	Unfavourable conditions for access road and wellpad establishment. Any necessary crossings will require comprehensive mitigations to protect thaw-sensitive permafrost and manage surface runoff and fine-grained sediments. Widespread shallow or near-surface of permafrost within overburden. Road construction through steep bedrock scarps would require earthworks and potentially localized blasting. Regardless, maintenance expectations would be high. Field reconnaissance critical to inform route/site selection and mitigation requirements.

Mix-Bury-Cover Disposal Suitability Classification*

Potentially Suitable: level or near-level, elevated areas with minimal or no receipt of surface runoff (i.e., 'shedding sites'). Generally areas are located along broad to rounded ridge crests and knolls that are set back from significant watercourses.

Probably Unsuitable: moderate to steep slopes, areas with ice-rich permafrost, and/or areas exhibiting evidence of instability (e.g, fluvial erosion, thermokarst subsidence, solifluction, active-layer detachments).

**Field investigations necessary to evaluate suitability at a site-specific level.*

Mapping Notes

The exploration development suitability (EDS) maps represent the general suitability of distinct areas for the construction and maintenance of access roads and wellpads, as well as the suitability for disposal of drill cuttings using mix-bury-cover (MBC) techniques. The EDS classification was derived from the 1:20,000-scale surficial geology interpretations and is specific to the project area. Map units (polygons) were categorized into five road and wellpad suitability classes and two MBC disposal suitability classes based on interpretations of texture, material genesis, geomorphological processes, drainage, and permafrost characteristics. A lower rating does not necessarily mean suitable terrain is not present in the map unit; localized portions of these polygons may be found to be suitable for exploration development or MBC disposal based on site-specific terrain characteristics. Similarly, a higher rating does not necessarily mean the entire polygon is suitable for exploration development or MBC disposal.

Road and wellpad suitability has been primarily classified based on terrain characteristics, site drainage, and permafrost conditions. Isolated topographic highs and moderately to well drained ridges are generally ice poor and favourable for development of exploration infrastructure. Conversely, lower valley terrain such as floodplains and fine grained colluvial aprons are generally prone to higher ice content, and active permafrost and periglacial processes, including active-layer detachments, solifluction, thermokarst, and sheetwash. Construction and maintenance of exploration infrastructure typically requires greater effort and more complex management solutions as road and wellpad suitability decreases. The MBC disposal suitability serves to highlight regions of the study area potentially suitable for MBC disposal of drill cuttings. This classification highlights ice poor, gently sloping, and geomorphologically isolated regions of the landscape set back from significant watercourses as potentially suitable for MBC disposal. Site specific investigations are recommended to confirm the suitability classifications.

Road and Wellpad Suitability Classification

	Typical Description	Typical Implications
Very High	Moderately well to well drained, isolated topographic highs with deep or shallow, ice-poor permafrost. Generally considered to be stable terrain, and typically located along wide, rounded ridge crests.	Favourable conditions for access road and wellpad establishment through standard best management practices, with minimal expectation for maintenance requirements.
High	Generally moderately well to well drained areas with deep or shallow, ice-poor permafrost. Typically associated with ridges of weathered bedrock or shallow colluvium over convex topography.	Generally favourable conditions for access road and wellpad establishment through standard best management practices, with low to moderate expectation for maintenance requirements.
Moderate	Imperfectly to moderately well drained, colluvial slopes with deep to shallow permafrost, commonly with poor to moderate ice content; convex weathered bedrock bluffs, typically at moderate slope gradients; and fluvial terraces above the influence of modern stream processes.	Generally reasonable conditions for access road and wellpad establishment, where necessary employing mitigations to proactively manage natural concentrations of surface runoff and protect thaw-sensitive permafrost, with moderate expectation for maintenance requirements. Field reconnaissance would help inform route/site selection and mitigation requirements.
Low	Poorly to imperfectly drained, thick colluvial slopes with shallow, ice-rich or ice-moderate permafrost; and imperfectly drained fluvial fans and veneers. Sheetwash, gully erosion, and ice-wedge polygons are common; surface runoff becomes concentrated.	Generally unfavourable conditions for access road and wellpad establishment, except through mitigations to proactively manage natural concentrations of surface runoff and protect thaw-sensitive permafrost, with moderate to high expectation for maintenance requirements. Field reconnaissance necessary to inform route/site selection and mitigation requirements.
Very Low	Very poorly to imperfectly drained areas with shallow or near-surface, ice-rich or ice-moderate permafrost, commonly in association with floodplains, as well as steep bedrock scarps. Thermokarst subsidence and ice-wedge polygons are common; surface runoff and slopes may be subjected to mass movements including solifluction and active-layer detachments.	Unfavourable conditions for access road and wellpad establishment. Any necessary crossings will require comprehensive mitigations to protect thaw-sensitive permafrost and manage surface runoff and fine-grained sediments. Road construction in areas underlain of permafrost within overburden. Road construction through steep bedrock scarps would require earthworks and potentially localized blasting. Regardless, maintenance expectations would be high. Field reconnaissance critical to inform route/site selection and mitigation requirements.

Mix-Bury-Cover Disposal Suitability Classification*

Potentially Suitable: level or near-level, elevated areas with minimal or no receipt of surface runoff (i.e., 'shedding sites'). Generally areas are located along broad to rounded ridge crests and knolls that are set back from significant watercourses.

Probably Unsuitable: moderate to steep slopes, areas with ice-rich permafrost, and/or areas exhibiting evidence of instability (e.g. fluvial erosion, thermokarst subsidence, solifluction, active-layer detachments).

**Field investigations necessary to evaluate suitability at a site-specific level.*

Road and Wellpad Suitability Classification

	Typical Description	Typical Implications
Very High	Moderately well to well drained, isolated topographic highs with deep or shallow, ice-poor permafrost. Generally considered to be stable terrain, and typically located along wide, rounded ridge crests.	Favourable conditions for access road and wellpad establishment through standard best management practices, with minimal expectation for maintenance requirements.
High	Generally moderately well to well drained areas with deep or shallow, ice-poor permafrost. Typically associated with ridges of weathered bedrock or shallow colluvium over convex topography.	Generally favourable conditions for access road and wellpad establishment through standard best management practices, with low to moderate expectation for maintenance requirements.
Moderate	Imperfectly to moderately well drained, colluvial slopes with deep to shallow permafrost, commonly with poor to moderate ice content; convex weathered bedrock bluffs, typically at moderate slope gradients; and fluvial terraces above the influence of modern stream processes.	Generally reasonable conditions for access road and wellpad establishment, where necessary employing mitigations to proactively manage natural concentrations of surface runoff and protect thaw-sensitive permafrost, with moderate expectation for maintenance requirements. Field reconnaissance would help inform route/site selection and mitigation requirements.
Low	Poorly to imperfectly drained, thick colluvial slopes with shallow, ice-rich or ice-moderate permafrost; and imperfectly drained fluvial fans and veneers. Sheetwash, gully erosion, and ice-wedge polygons are common; surface runoff becomes concentrated.	Generally unfavourable conditions for access road and wellpad establishment, except through mitigations to proactively manage and vehicles. Thaw-sensitive permafrost and slopes may be subjected to mass movements including solifluction and active-layer detachments.
Very Low	Very poorly to imperfectly drained areas with shallow or near-surface, ice-rich or ice-moderate permafrost, commonly in association with floodplains, as well as steep bedrock scarps. Thermokarst subsidence and ice-wedge polygons are common; surface runoff and slopes may be subjected to mass movements including solifluction and active-layer detachments.	Unfavourable conditions for access road and wellpad establishment. Any necessary crossings will require comprehensive mitigations to protect thaw-sensitive permafrost and manage surface runoff and fine-grained sediments. Road construction in areas underlain by permafrost within overburden. Road construction through steep bedrock scarps would require earthworks and potentially localized blasting. Regardless, maintenance expectations would be high. Field reconnaissance critical to inform route/site selection and mitigation requirements.

Mix-Bury-Cover Disposal Suitability Classification*

Potentially Suitable: level or near-level, elevated areas with minimal or no receipt of surface runoff (i.e., 'shedding sites'). Generally areas are located along broad to rounded ridge crests and knolls that are set back from significant watercourses.

Probably Unsuitable: moderate to steep slopes, areas with ice-rich permafrost, and/or areas exhibiting evidence of instability (e.g. fluvial erosion, thermokarst subsidence, solifluction, active-layer detachments).

**Field investigations necessary to evaluate suitability at a site-specific level.*

Mapping Notes

The exploration development suitability (EDS) maps represent the general suitability of distinct areas for the construction and maintenance of access roads and wellpads, as well as the suitability for disposal of drill cuttings using mix-bury-cover (MBC) techniques. The EDS classification was derived from the 1:20,000-scale surficial geology interpretations and is specific to the project area. Map units (polygons) were categorized into five road and wellpad suitability classes and two MBC disposal suitability classes based on interpretations of texture, material genesis, geomorphological processes, drainage, and permafrost characteristics. A lower rating does not necessarily mean suitable terrain is not present in the map unit; localized portions of these polygons may be found to be suitable for exploration development or MBC disposal based on site-specific terrain characteristics. Similarly, a higher rating does not necessarily mean the entire polygon is suitable for exploration development or MBC disposal.

Road and wellpad suitability has been primarily classified based on terrain characteristics, site drainage, and permafrost conditions. Isolated topographic highs and moderately to well drained ridges are generally ice poor and favourable for development of exploration infrastructure. Conversely, lower valley terrain such as floodplains and fine grained colluvial aprons are generally prone to higher ice content, and active permafrost and periglacial processes, including active-layer detachments, solifluction, thermokarst, and sheetwash. Construction and maintenance of exploration infrastructure typically requires greater effort and more complex management solutions as road and wellpad suitability decreases. The MBC disposal suitability serves to highlight regions of the study area potentially suitable for MBC disposal of drill cuttings. This classification highlights ice poor, gently sloping, and geomorphologically isolated regions of the landscape set back from significant watercourses as potentially suitable for MBC disposal. Site specific investigations are recommended to confirm the suitability classifications.

Road and Wellpad Suitability Classification

	Typical Description	Typical Implications
Very High	Moderately well to well drained, isolated topographic highs with deep or shallow, ice-poor permafrost. Generally considered to be stable terrain, and typically located along wide, rounded ridge crests.	Favourable conditions for access road and wellpad establishment through standard best management practices, with minimal expectation for maintenance requirements.
High	Generally moderately well to well drained areas with deep or shallow, ice-poor permafrost. Typically associated with ridges of weathered bedrock or shallow colluvium over convex topography.	Generally favourable conditions for access road and wellpad establishment through standard best management practices, with low to moderate expectation for maintenance requirements.
Moderate	Imperfectly to moderately well drained, colluvial slopes with deep to shallow permafrost, commonly with poor to moderate ice content; convex weathered bedrock bluffs, typically at moderate slope gradients; and fluvial terraces above the influence of modern stream processes.	Generally reasonable conditions for access road and wellpad establishment, where necessary employing mitigations to proactively manage natural concentrations of surface runoff and protect thaw-sensitive permafrost, with moderate expectation for maintenance requirements. Field reconnaissance would help inform route/site selection and mitigation requirements.
Low	Poorly to imperfectly drained, thick colluvial slopes with shallow, ice-rich or ice-moderate permafrost; and imperfectly drained fluvial fans and veneers. Sheetwash, gully erosion, and ice-wedge polygons are common; surface runoff becomes concentrated.	Generally unfavourable conditions for access road and wellpad establishment, except through mitigations to proactively manage natural concentrations of surface runoff and protect thaw-sensitive permafrost, with moderate to high expectation for maintenance requirements. Field reconnaissance necessary to inform route/site selection and mitigation requirements.
Very Low	Very poorly to imperfectly drained areas with shallow or near-surface, ice-rich or ice-moderate permafrost, commonly in association with floodplains, as well as steep bedrock scarps. Thermokarst subsidence and ice-wedge polygons are common; surface runoff and seeps may be subjected to mass movements including solifluction and active-layer detachments.	Unfavourable conditions for access road and wellpad establishment. Any necessary crossings will require comprehensive mitigations to protect thaw-sensitive permafrost and manage surface runoff and fine-grained sediments. Widespread shallow ice-rich terrain and slopes may be subjected to mass movements during construction through steep bedrock scarps would require earthworks and potentially localized blasting. Regardless, maintenance expectations would be high. Field reconnaissance critical to inform route/site selection and mitigation requirements.

Field reconnaissance necessary to inform route/site selection and mitigation requirements.
Very Low	Very poorly to imperfectly drained areas with shallow or near-surface, ice-rich or ice-moderate permafrost, commonly in association with floodplains, as well as steep bedrock scarps. Thermokarst subsidence and ice-wedge polygons are common; surface runoff ponds and slopes may be subjected to mass movements including solifluction and active-layer detachments.	Unfavourable conditions for access road and wellpad establishment. Any necessary crossings will require comprehensive mitigations to protect thaw-sensitive permafrost and manage surface runoff and fine-grained sediments. Thick deposits of ice-rich fine-grained and organic material within overburden. Road construction through steep bedrock scarps would require earthworks and potentially localized blasting. Regardless, maintenance expectations would be high. Field reconnaissance critical to inform route/site selection and mitigation requirements.

Mix-Bury-Cover Disposal Suitability Classification*

Potentially Suitable: level or near-level, elevated areas with minimal or no receipt of surface runoff (i.e., 'shedding sites'). Generally areas are located along broad to rounded ridge crests and knolls that are set back from significant watercourses.

Probably Unsuitable: moderate to steep slopes, areas with ice-rich permafrost, and/or areas exhibiting evidence of instability (e.g. fluvial erosion, thermokarst subsidence, solifluction, active-layer detachments).

**Field investigations necessary to evaluate suitability at a site-specific level.*

Mapping Notes

The exploration development suitability (EDS) maps represent the general suitability of distinct areas for the construction and maintenance of access roads and wellpads, as well as the suitability for disposal of drill cuttings using mix-bury-cover (MBC) techniques. The EDS classification was derived from the 1:20,000-scale surficial geology interpretations and is specific to the project area. Map units (polygons) were categorized into five road and wellpad suitability classes and two MBC disposal suitability classes based on interpretations of texture, material genesis, geomorphological processes, drainage, and permafrost characteristics. A lower rating does not necessarily mean suitable terrain is not present in the map unit; localized portions of these polygons may be found to be suitable for exploration development or MBC disposal based on site-specific terrain characteristics. Similarly, a higher rating does not necessarily mean the entire polygon is suitable for exploration development or MBC disposal.

Road and wellpad suitability has been primarily classified based on terrain characteristics, site drainage, and permafrost conditions. Isolated topographic highs and moderately to well drained ridges are generally ice poor and favourable for development of exploration infrastructure. Conversely, lower valley terrain such as floodplains and fine grained colluvial aprons are generally prone to higher ice content, and active permafrost and periglacial processes, including active-layer detachments, solifluction, thermokarst, and sheetwash. Construction and maintenance of exploration infrastructure typically requires greater effort and more complex management solutions as road and wellpad suitability decreases. The MBC disposal suitability serves to highlight regions of the study area potentially suitable for MBC disposal of drill cuttings. This classification highlights ice poor, gently sloping, and geomorphologically isolated regions of the landscape set back from significant watercourses as potentially suitable for MBC disposal. Site specific investigations are recommended to confirm the suitability classifications.

Road and Wellpad Suitability Classification

	Typical Description	Typical Implications
Very High	Moderately well to well drained, isolated topographic highs with deep or shallow, ice-poor permafrost. Generally considered to be stable terrain, and typically located along wide, rounded ridge crests.	Favourable conditions for access road and wellpad establishment through standard best management practices, with minimal expectation for maintenance requirements.
High	Generally moderately well to well drained areas with deep or shallow, ice-poor permafrost. Typically associated with ridges of weathered bedrock or shallow colluvium over convex topography.	Generally favourable conditions for access road and wellpad establishment through standard best management practices, with low to moderate expectation for maintenance requirements.
Moderate	Imperfectly to moderately well drained, colluvial slopes with deep to shallow permafrost, commonly with poor to moderate ice content; convex weathered bedrock bluffs, typically at moderate slope gradients; and fluvial terraces above the influence of modern stream processes.	Generally reasonable conditions for access road and wellpad establishment, where necessary employing mitigations to proactively manage natural concentrations of surface runoff and protect thaw-sensitive permafrost, with moderate expectation for maintenance requirements. Field reconnaissance would help inform route/site selection and mitigation requirements.
Low	Poorly to imperfectly drained, thick colluvial slopes with shallow, ice-rich or ice-moderate permafrost; and imperfectly drained fluvial fans and veneers. Sheetwash, gully erosion, and ice-wedge polygons are common; surface runoff becomes concentrated.	Generally unfavourable conditions for access road and wellpad establishment, except through mitigations to proactively manage natural concentrations of surface runoff and protect thaw-sensitive permafrost, with moderate to high expectation for maintenance requirements. Field reconnaissance necessary to inform route/site selection and mitigation requirements.
Very Low	Very poorly to imperfectly drained areas with shallow or near-surface, ice-rich or ice-moderate permafrost, commonly in association with floodplains, as well as steep bedrock scarps. Thermokarst subsidence and ice-wedge polygons are common; surface runoff and slopes may be subjected to mass movements including solifluction and active-layer detachments.	Unfavourable conditions for access road and wellpad establishment. Any necessary crossings will require comprehensive mitigations to protect thaw-sensitive permafrost and manage surface runoff and fine-grained sediments. Road construction in areas of permafrost within overburden. Road construction through steep bedrock scarps would require earthworks and potentially localized blasting. Regardless, maintenance expectations would be high. Field reconnaissance critical to inform route/site selection and mitigation requirements.

Mix-Bury-Cover Disposal Suitability Classification*

Potentially Suitable: level or near-level, elevated areas with minimal or no receipt of surface runoff (i.e., 'shedding sites'). Generally areas are located along broad to rounded ridge crests and knolls that are set back from significant watercourses.

Probably Unsuitable: moderate to steep slopes, areas with ice-rich permafrost, and/or areas exhibiting evidence of instability (e.g. fluvial erosion, thermokarst subsidence, solifluction, active-layer detachments).

Appendix D

Glossary

D1. Glossary of Terms
D2. Acronyms & Abbreviations

Glossary of Terms

Term	Definition
Active Layer	The top layer of ground above the permafrost table that is subject to annual thawing and freezing.
Active Layer Detachment	Shallow slope failure in which the thawed or thawing active layer and vegetation mat detach from the underlying frozen material. Common on colluvial slopes in areas of fine-grained, ice-rich deposits.
Apron	Coalesced fans which occur at foot of bluffs, escarpments, or steep slopes. They are formed by materials transported from the steeper slope and form wedge-shaped deposits with concave to planar surfaces. Deposition of materials typically occurs during extreme storm or runoff events.
Blanket	A mantle of surficial materials thicker than about one metre, which reflects the topography of the bedrock or older surficial materials upon which it rests, although minor details of the topography may be masked.
Colluvial Deposits/Colluvium	Materials deposited by downslope movements due to gravity, such as rockfall, soil creep, and debris flows, including talus slopes and mantles of weathered bedrock. Colluvial deposits are composed of rock fragments of all sizes derived from the local bedrock and reworked loess, as well as finer textured material derived from in place weathering of the rock fragments. These deposits are generally poorly sorted and poorly consolidated.
Creep	The imperceptibly slow downward movement of soil or rock on slopes or slow deformation of frozen ground; caused by gravity or long-term application of a stress too small to produce failure in the frozen material.
Cryoturbation	Heaving, churning, and sorting of soil and surficial materials due to repeated freezing and thawing; results in the development of convoluted and flame- like structures in the soil and patterned ground.
Debris Flow	A sudden and destructive landslide where loose material on a slope, with more than 50% of particles larger than sand size, is mobilized by saturation and flows down a channel or canyon. The flow contains a combination of or all of the following: soil, surficial materials, bedrock, and plant material. Whether saturated or dry, a debris flow behaves much like a viscous fluid when moving.
Dendritic	Surface drainage pattern where streams branch out in an irregular tree-like fashion.
Drunken Forest	A stand of trees rotated from their normal vertical alignment due to frost heaving
Earth Hummocks	A hummock having a core of silty and clayey mineral soil which may show evidence of cryoturbation. Earth hummocks are a type of non-sorted circle (see patterned ground) commonly found in the zone of continuous permafrost. They develop in materials of a high silt and clay content and/or of high ice content.
Excess Ice	The volume of ice in the ground that exceeds the total pore volume that the ground would have under natural unfrozen conditions.
Fluvial Deposits	Sediments transported and deposited by streams and rivers, including floodplain deposits, river terraces, and fluvial fans. “Alluvial” is an older term meaning the same.
Fluvial Fan	A fan-shaped deposit built by streams, usually located at the mouth of a tributary valley. The sediment flows start at the apex of the fan, and over time move to occupy many positions on the

Term	Definition
	fan surface. Sediments generally consist of sand and gravel, and are formed by a combination of stream flood and debris flow activity. Fluvial fans typically have gradients of less than 10%.
Frost Heave	The upward or outward movement of the ground surface (or objects on, or in, the ground) caused by the formation of ice in the soil.
Glaciofluvial Deposits	Sediments formed by meltwater issuing from, or within, a glacier. The deposits are stratified and may form outwash plains, or terraces.
Ground Ice	Ice in pores, cracks, and other openings in surface sediments or rock, which forms in permafrost terrain. A general term referring to all types of ice formed in freezing or frozen ground.
Gully	A channel caused by erosion and the concentrated but intermittent flow of water during and immediately after heavy rains or ice/snow melt; generally V-shaped; larger than a rill and smaller than a ravine.
Ice Wedge	A massive, generally wedge-shaped body of ground ice with its apex pointing downward, composed of foliated or vertically banded, commonly white, ice; forms in permafrost environments.
Massive Ice	Large masses of ground ice, including ice wedges, pingo ice, buried ice, and large ice lenses, with a minimum thickness of 0.3 m. Ice layers less than 0.3 m in thickness are better termed ice lenses.
Packstone	A grain-supported carbonate rock with a muddy matrix.
Patterned Ground	Any ground surface exhibiting a discernibly ordered, more or less symmetrical, morphological pattern and, where present, vegetation, including non-sorted and sorted circles, nets, polygons, steps, and stripes, and solifluction features. In permafrost regions, ice-wedge polygon and non-sorted circles are most common.
Peat	Unconsolidated compressible material consisting largely of undecomposed, or slightly decomposed, organic matter accumulated under water-saturated conditions. Peat is commonly formed by the slow decay of successive layers of aquatic and semi-aquatic plants in swampy or water-logged areas, where oxygen is absent.
Permafrost	Ground (soil or rock) that remains at or below 0ºC for at least two consecutive years.
Physiography	The physical nature of the land; it includes topography (the relief and contours of the land), elevation, aspect, slope, surface pattern of landforms, and drainage.
Retrogressive Thaw Flow Slide	A slope failure resulting from thawing of ice-rich permafrost. The head scarp commonly continues to grow in a headward direction as new permafrost is exposed to thaw.
Segregated Ice	Ice in discrete layers or ice lenses, formed by ice segregation; commonly occurs in alternating layers of ice and soil. Segregated ice layers can range from hairline to more than 10 m in thickness.
Slopewash	Fine sediments on or at the foot of hillsides that have been moved by downslope by water saturation, groundwater flow and freeze/thaw processes.
Soil	The upper portion of a surficial deposit that has been affected by soil-forming processes such as eluviation
Solifluction	Slow downslope movement of saturated unfrozen (in non-permafrost regions) or thawed (associated with frozen ground) earth materials across a frozen substrate.
Spiculite	A siliceous rock composed predominantly of sponge spicules, with a porosity greater than 50%.

Term	Definition
Thermokarst	The process by which characteristic landforms result from the thawing of ice rich permafrost or the melting of massive ice.
Terrain	The surficial geology and landforms that make up a particular region
Veneer	A cover of surficial material with a thickness less than 1 meter.

EXECUTIVE SUMMARY

The Eagle Plains Project (the Project) is an oil and gas exploration program in north-central Yukon, approximately 605 km north of Whitehorse along the Dempster Highway. Chance Oil and Gas Ltd. intends to conduct exploratory activities over a 10-year period to confirm the quality, quantity, and areal extent of hydrocarbons. Project activities will include seismic exploration and exploratory wells supported by an expanded winter road network. The Project's Regional Study Area (RSA) is approximately 2,386 km² (238,566 ha) and is spatially bounded by the Peel River and Ogilvie River to the south and the northern reaches of Chance Creek to the north. The Project is within the Eagle Plains ecoregion, an intermontane basin underlain by sedimentary rock. The regional land cover comprises subarctic coniferous forest with mixed forest and arctic/alpine tundra while also lying within a continuous permafrost zone.

EDI Environmental Dynamics Inc. (EDI) was retained by Chance Oil and Gas in 2019 to provide a surface water quality and hydrology baseline report to inform background characteristics of surface water within the RSA. This report is intended to support the Chance Oil and Gas submission to the Yukon Environmental Socio-Economic Board for Executive Committee screening and guide any of their anticipated or intended water resource requirements.

This report was developed using historical data available from Environment and Climate Change Canada (ECCC), Yukon Government Water Resources Branch (YG WRB) and the Water Survey of Canada (WSC). In August 2019 and March 2020, EDI collected additional water quality data from the RSA and the broader adjacent area to support this baseline water quality assessment.

Water quality data are framed within the Canadian Council of Ministers of the Environment (CCME) guidelines for protecting freshwater 'aquatic life.' Key characteristics including general chemistry, major ions, nutrients, trace metals and hydrocarbons are analyzed to understand water quality as it exists within the RSA.

Water quality was similar across the RSA, with neutral to slightly acidic, brown stained water. Variable turbidity and total suspended sediment concentrations were likely associated with melting permafrost and resulting slumping banks that continuously deposit material into the water columns. The dominant ions reflect local geology and included bicarbonate, calcium, and sulphate. Nutrient concentrations were generally low to moderate, and total phosphorus concentrations indicated that streams were oligotrophic to mesotrophic. Metals including aluminum, cadmium, copper, iron, and manganese were present throughout the RSA at concentrations that exceeded the CCME guidelines for protecting freshwater aquatic life (CCME-FAL) guidelines.

Additionally, some other metals were present at concentrations above the CCME-FAL in isolated samples from each watershed area, including arsenic from Chance and Dalglish creek sites, and selenium from McParlon, Eagle and Dalglish creek sites. Volatile organic carbons were not present at or above laboratory detection limits at any of the sample locations. Common polycyclic aromatic hydrocarbons in the RSA included naphthalene, biphenyl, phenanthrene, and retene; these compounds are associated with naturally occurring oil and gas deposits and by-products of forest fires.

The hydrometric conditions in the RSA and surrounding region are snowmelt-dominated annual discharges, representative of a hydrologic regime of a northern climate. The highest flows occur in spring, driven by warming events and rainfall, which release water stored in the snowpack. The magnitude of the peak discharge during freshet is generally proportional to the contributing area of the snowpack. Over the summer, as snowmelt volume declines, stream discharge decreases, and flows are sustained by rainfall inputs, characterized by short-term peaks in discharge. Tributary watercourses, including first to third-order streams that originate within the RSA, are also snowmelt driven, but have flashier responses to precipitation events relative to watercourses with larger catchment areas. Stream discharges continue to decline into the fall as precipitation begins to be stored as snowpack and the active permafrost layer begins to refreeze. With no inputs to support baseflow during the winter, tributary channels tend to de-water or freeze to the bed over winter between October and November and do not resume discharge until the following freshet, typically beginning in April or early May. Thick continuous permafrost prevents interaction between aquifers and surface water, and limits groundwater interactions to perched seasonal suprapermafrost groundwater in the thin active layer. Watercourses with larger catchment areas (i.e., higher-order streams and rivers) do not reach zero flow winter conditions due to larger contributing areas and shorter periods where the active layer is frozen. In the larger watercourses, flows continue to decline through the winter, with the lowest discharge reported in February and March. In some third and fourth-order streams, water was found in residual pools in March. However, the water contained low dissolved oxygen. These conditions indicate zero or very low flow rates and are lower than minimum levels to support overwintering fish.

1 INTRODUCTION

The Eagle Plains Project (the Project) is a proposed oil and gas exploration operation spanning approximately 2,500 km² in the Eagle Plains region in northern Yukon. The Project will consist of seismic exploration and up to 30 test wells; both supported via a winter road network. All exploration activities will occur in winter; however, year-round monitoring may be conducted at a subset of the well sites depending on exploration results.

The Regional Study Area (RSA) overlaps three Yukon First Nations Traditional Territories; these are the Na-cho Nyäk Dun (NND), Vuntut Gwitchin (VG), and the Tetlit Gwich'in Council (Secondary Use Area; TGC). The proposed Project is also within the boundaries of the North Yukon and Peel Planning Regions and is subject to Land Use Plans developed for both regions.

The Eagle Plains Ecoregion is in the Taiga Cordillera Ecozone, characterized by subarctic coniferous forest (90 %) and mixed forest and Arctic/alpine tundra (5% each; Yukon Ecoregions Working Group 2004). Black spruce woodlands dominate this Ecoregion, with black spruce-tussock tundra at lower elevations and shrub-tundra above 800 m (Yukon Ecoregions Working Group 2004). The area is characterized by long winters, generally extending from October to May, with a mean annual temperature of −7.5°C (average −28°C in January and 13°C in July). The Eagle Plains Ecoregion has extensive permafrost throughout the whole Ecoregion, approximately 89 m in depth, with the active layer in the top one metre (i.e., thaws in summer and refreezes in the winter). However, as was previously noted in the water quality baseline developed for this area in 2018, permafrost monitoring along the Dempster Highway since 2013 indicated that permafrost degradation is actively occurring in the Eagle Plains area (Idrees et al. 2015, Golder Associates Ltd. 2018).

Watercourses in active permafrost regions range from permanent to intermittent flow, which are seasonally timed. The annual discharge in streams in watersheds like those in the RSA are snowmelt driven, with peak flows during the spring and low flows during the winter. The lower order streams are more likely to be seasonally intermittent as inputs from precipitation decrease and permafrost re-freezes. Ice build-up in watercourses alters flow behaviour in all these watercourses from the beginning of freeze-up until spring thaw is complete. In the case of the smaller streams, the channel may fully freeze in early winter. There are four Water Survey of Canada (WSC) and two Yukon Geological Survey (YGS) hydrometric stations collecting discharge data on watercourses relevant to the RSA, collecting discharge data over variable periods of record from 2004, and all stations are currently operating. The Yukon Government Water Resources Branch (YG WRB) received funding via the Yukon Environmental and Socio-Economic Assessment Act (YESAA) to collect seasonal water quality samples in the Eagle Plains area in anticipation of further funding resource development in the area. They collected water quality data from 2012 through 2017; data relevant to this Project was collected from 2013 to 2016. These data were used to develop a water quality and sediment baseline for the Eagle Plains area in 2018 (Golder Associates Ltd. 2018) and their findings are reflected in this report.

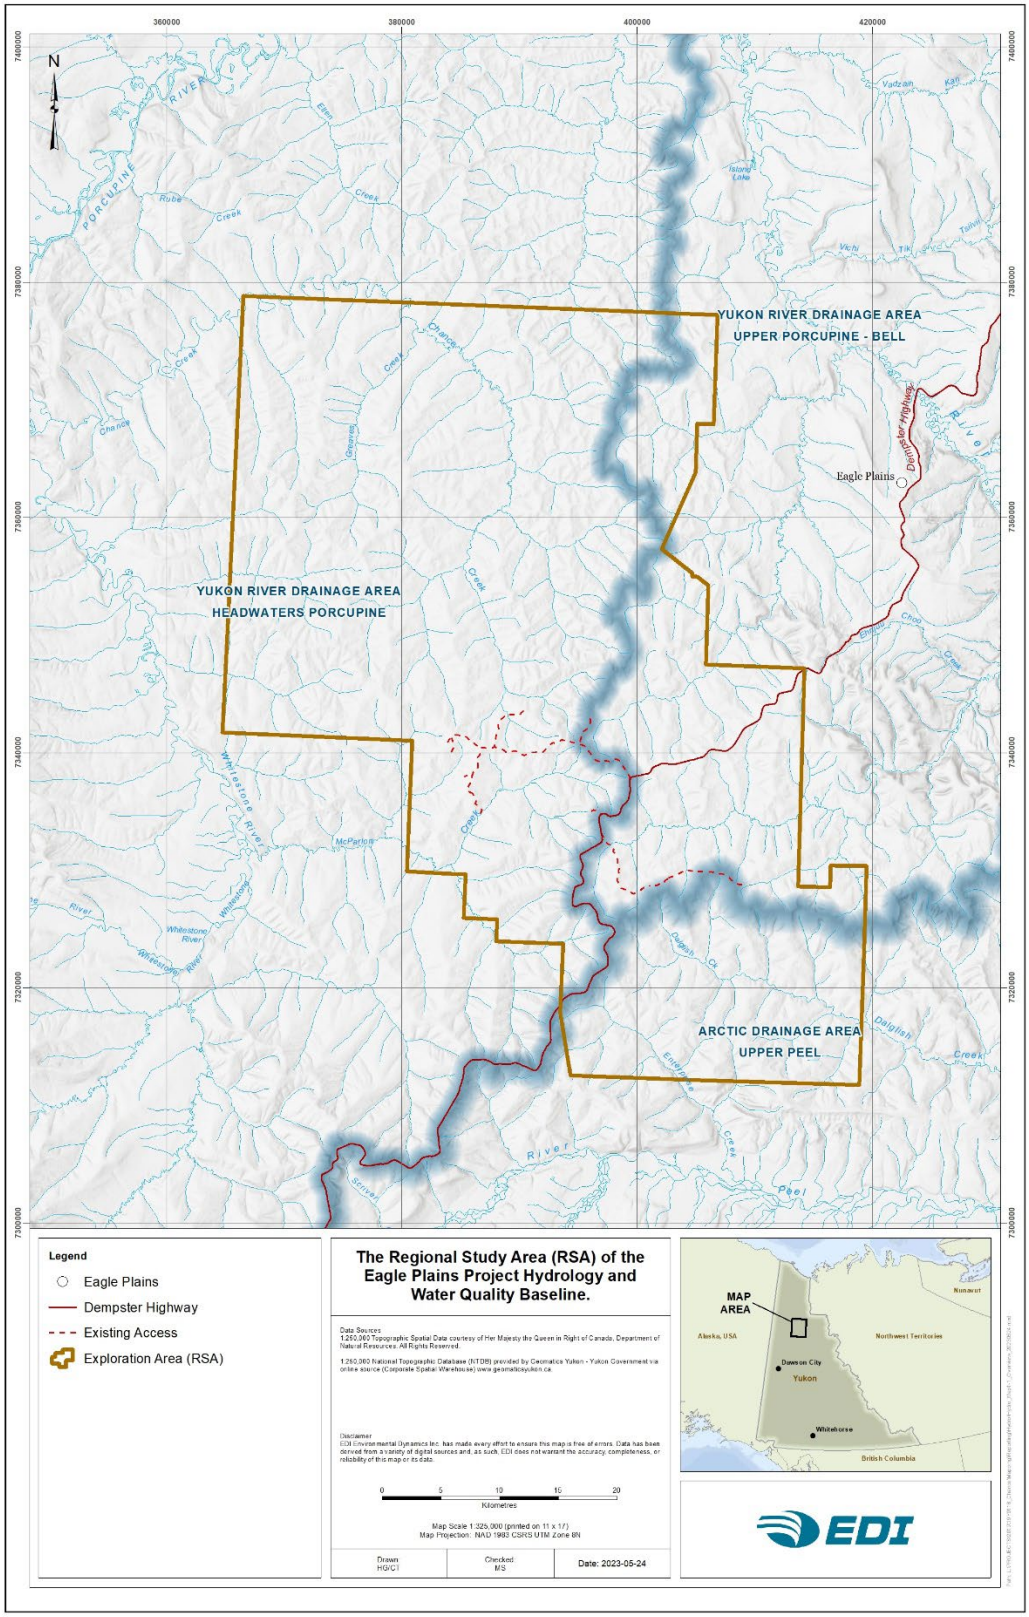
The major drainages within and adjacent to the RSA include the Porcupine and Peel river watersheds, with the subdrainages of the Eagle and Whitestone rivers entering the Porcupine drainage and the Ogilvie River

entering the Peel drainage (Map 1-1). The largest drainages within the RSA include Chance (Porcupine), McParlon (Porcupine), Dalglish (Peel), and Enterprise (Peel) creeks. The proposed Project would use winter roads that may include stream crossings. Thus, there was a need to understand the RSA's water quality and hydrology values, including seasonal and temporal trends. This report describes the baseline surface water resources conditions throughout the RSA.

1.1 PROGRAM OVERVIEW AND OBJECTIVES

This study aimed to document baseline information on surface water quality and hydrology within the RSA. This information could then be used to assess the Project's potential effects on water in the permit proposal to Yukon Environmental Socio-Economic Board and support management measures to mitigate potential effects.

Historical surface water quality and hydrology data, collected by various government and industry organizations are available for the RSA. EDI Environmental Dynamics Inc. (EDI) also conducted a modest surface water quality data collection program during the summer 2019 and winter 2020 to supplement the available water quality data with broader geographic sampling across the RSA, focusing on lower-order tributary streams, which were poorly represented in the historical data. This combination of historical and recent data was used to define the baseline surface water quality and quantity in the RSA.



Map 1-1. The Regional Study Area (RSA) of the Eagle Plains Project Hydrology and Water Quality Baseline.

2 METHODS

2.1 WATER QUALITY

The RSA was divided into four catchments to describe baseline water quality: McParlon, Chance, Eagle River Tributaries to the north and south, and Dalglish. Within each micro watershed, multiple sampling locations were established, including data historical collected by YG WRB from 2013 to 2016 (Section 2.1.1) and new surveys by EDI in August 2019 and March 2020 (Section 2.1.2; both summarized in Table 2-1). Water quality data at these sites represent water quality within and downstream of the RSA.

Table 2-1. Water quality monitoring sites, organized by catchment, moving from upstream to downstream.

Site Code	Site Name	YG WRB Data Collection Range	YG WRB Sample Frequency	EDI Sampling

DALG-002	Dalglish Creek, just upstream from Ogilvie River	2014, 2015	Quarterly	August 2019 March 2020

2.1.1 HISTORICAL DATA COMPILATION

The Yukon Government Water Resources Branch collected water quality data in the area surrounding the RSA between 2013 and 2016; this sampling was funded by the Yukon Environmental and Socio-Economic Assessment Act implementation funding in anticipation of further resource development in the area (Table 2-1). The frequency of data collection was quarterly (seasonal) at most sites, but only periodically at upper Chance Creek (CHNC-003) and in the small tributary to Chance Creek (CHNC-t-002), generally owing to winter conditions. Winter samples were not regularly collected at all sites as many small streams were dry or frozen to the substrate through the winter season.

Water quality samples were collected and analyzed for inorganics, metals, nutrients, organics, and physical parameters. These historical data are publicly available from the Yukon Environment website (www.env.gov.yk.ca/air-water-waste/hydrogeology.php). EDI accessed and downloaded this data to review for the development of this baseline (A-1). These data were reviewed and described in a baseline data report drafted for the Yukon Government (Golder Associates Ltd. 2018).

2.1.2 PROJECT-SPECIFIC FIELD SAMPLING

After reviewing the existing data, additional water quality data were collected from ten sites; five sites within the RSA and the other five sites downstream of streams and rivers contained within the RSA (Table 2-1, Table 2-2, Map 2-1). Eight of these sites fall within or downstream of the RSA and were previously sampled by YG WRB; these were resampled to such that more recent data could be added to evaluate any recent changes to water quality in the RSA. Two sites were added to expand coverage of the RSA and downstream areas; these included EAGL-t-003, a tributary to the Eagle River that drains the RSA to the northeast, and DALG-003, located on the upstream reaches of Dalglish Creek, within the Project footprint (Table 2-1, Table 2-2, Map 2-1). All water quality samples were analyzed for inorganics, metals, nutrients, organics, and physical parameters.

Table 2-2. Record of EDI sampling conducted for the Project in August 2019 and March 2020.

Site Code	August 2019	March 2020

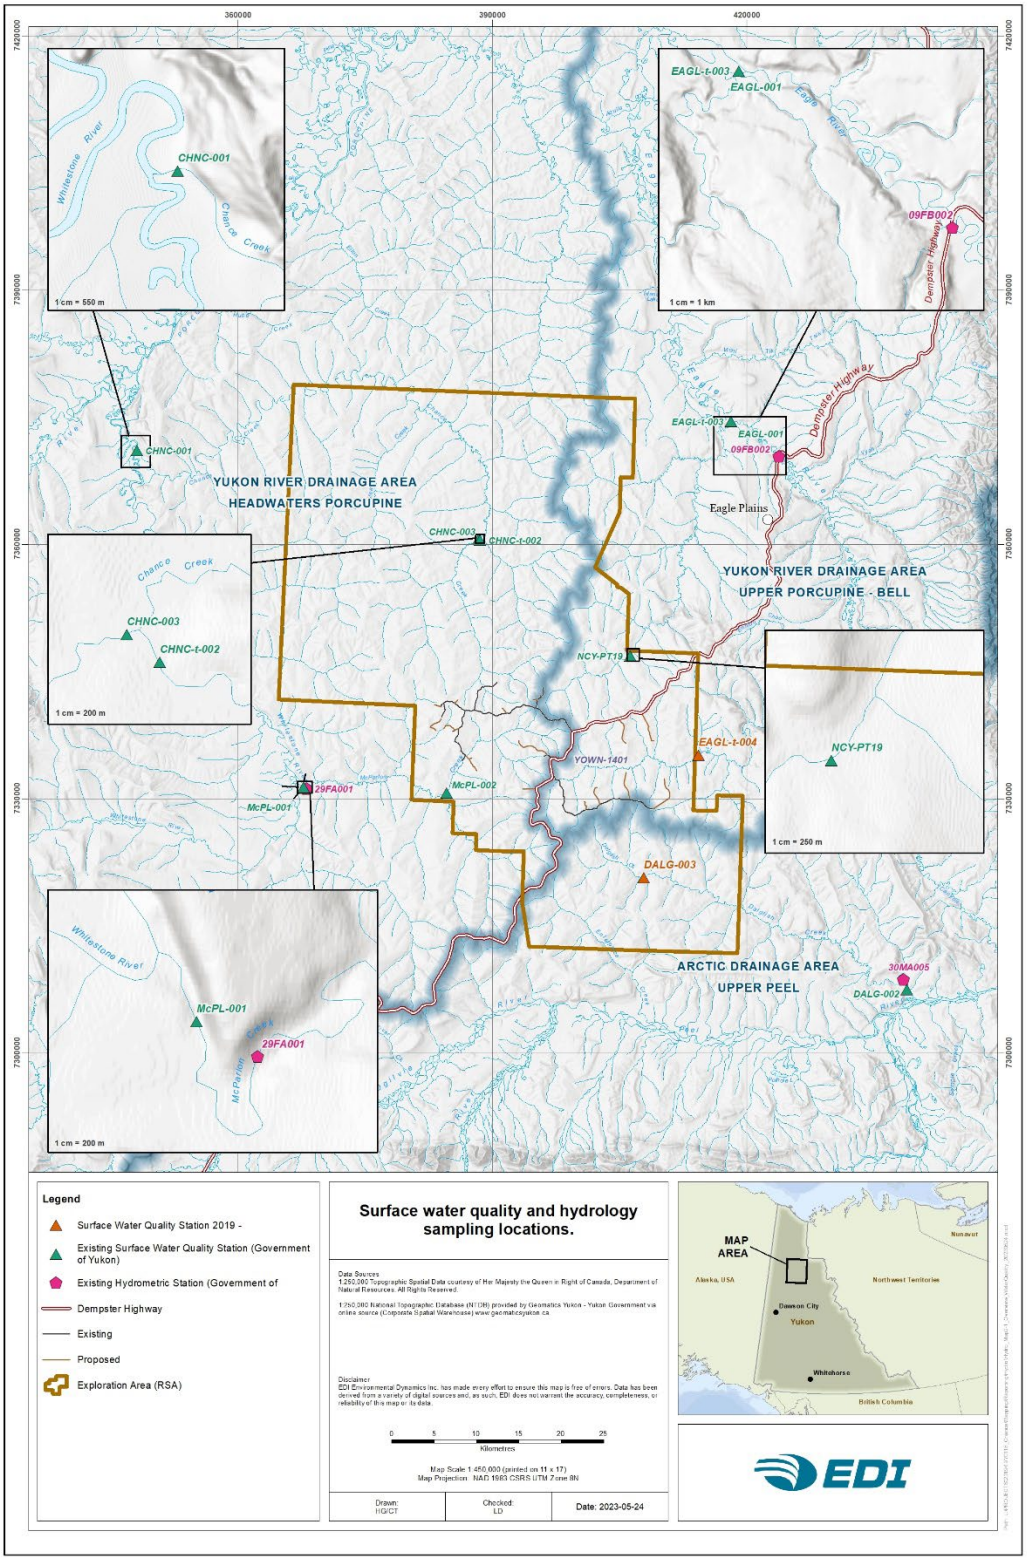

Map 2-1. Surface water quality and hydrology sampling locations.

2.1.3 FIELD SAMPLING METHODS

Field staff used a YSI ProPlus multi-meter to measure in-situ water temperature (degrees Celsius [°C]), pH (pH units), specific conductivity (SPC; microSiemens per centimetre [µS/cm]), oxidation-reduction potential (ORP; millivolts [mV]) and dissolved oxygen (DO; milligrams per litre [mg/L]). The YSI meter was calibrated on the first day of each trip, performed a 'bump test' to verify data at the end of each field sampling day and re-calibrated as required in the field. Staff used an Oakton T100 turbidity meter to collect in-situ turbidity (nephelometric turbidity units [NTU]) calibrated monthly in the office, according to instrument specifications and bump-tested pre- and post-trip.

Field staff recorded data on standard field data forms (either on an iPad tablet or hard copy datasheets). This information included station name, sample date and time, location (GPS coordinates), water temperature, SPC, pH, DO, ORP, turbidity, and photo numbers. Site conditions were also recorded, including flow stage (low, moderate, high), turbidity (clear, light, moderate, high), and any other qualitative observations.

In addition to in-situ data, water samples were collected from each monitoring site. Staff filled laboratory-cleaned bottles using clean techniques (i.e., nitrile gloves, appropriate bottle handling) and samples were filtered and preserved on site, as per instructions from the accredited lab. Samples were stored in coolers, with lab-supplied ice packs, when necessary, to maintain sample temperatures at approximately 4°C. On the final day of each sampling event, staff delivered the samples with laboratory Chain of Custody forms to Air North in Whitehorse for delivery to an analytical laboratory. Efforts were made to meet all sample holding times despite the remote location of the Project site.

2.1.4 LABORATORY ANALYSIS

Laboratory analysis consisted of routine physical chemistry, anions, nutrients, dissolved organic carbon, total and dissolved metals, extractable hydrocarbons, and volatile organic carbons.

2.1.5 QUALITY ASSURANCE / QUALITY CONTROL

The water quality field program included collecting quality assurance/quality control (QA/QC) samples, including replicate samples, field blanks, and travel blanks. Replicate samples are sample duplicates collected at the same date, time, and location as the regular sample. Sampling methodology is the same for the collection of both regular and replicate samples. Field staff collected replicates from randomly selected sites during each trip. The total number of replicates represented approximately 10% of the total sites sampled. The replicate samples determine the accuracy and precision of the laboratory analysis; they also provide a measure of variability in water quality at a site for a given time.

Field blank samples comprised one complete bottle set filled on-site with deionized water during the sampling trip. Sampling methodology is the same as if sampling from a stream, with filtering and preserving as required. Field blanks assist in identifying any contamination introduced to the sample during the act of field sampling (i.e., sample filling/handling, exposure to questionable air quality) or via the supplies (filter, syringe, bottle, or preservative). The analytical lab supplied the travel blank, which EDI field crews carry to and from the site

during the fieldwork. Field staff do not open the travel blank at any time during the trip. Travel blanks assist in the identification of any sample contamination caused during transportation or storage.

2.1.6 DATA MANAGEMENT AND ANALYSIS

Once field crews returned from the field, they reviewed and entered all in-situ data and site condition notes recorded on the field data forms (either a table export file or hard copy datasheets) into a Microsoft Excel template and updated the project water quality database (data available in Attachment B).

Upon receipt, laboratory data were reviewed and appended to the project database. As part of the data review, we compare the results with the Canadian Council of Ministers of the Environment (CCME) guidelines to protect freshwater 'aquatic life' (CCME-FAL; CCME 2015; Table 2-3). Water quality characteristics such as hardness and nutrient concentrations will be evaluated against accepted scales (Table 2-4 and Table 2-5).

Table 2-3. Canadian Council of the Ministers of the Environment Guidelines for the Protection of Freshwater Aquatic Life (CCME-FAL) guidelines (CCME 2015).

Water Quality Parameter	CCME FAL Guideline	Comments
Aluminum	0.1 mg/L	Guideline is 0.1 at pH ≥ 6.5; if pH is lower than 6.5, guideline is set at 0.005 mg/L.
Ammonia	Variable	Guideline is temperature and pH dependent. Guidelines are for pH ranging from 6 to 10. For pH below 6, guideline is set as if pH was 6.
Arsenic	0.005 mg/L	-
Boron	1.5 mg/L	-
Cadmium	Variable	Guideline is hardness dependent; the guideline is 0.04 µg/L when water hardness is >0 to <17 mg/L. At hardness >280 mg/L, the guideline is 0.37 µg/L. At hardness ≥17 to ≤280 mg/L, the guideline in µg/L is calculated using the following equation: Hardness Adjusted Guideline = $10^{[0.83(\log[\text{hardness}])-2.46]}$
Chloride	120 mg/L	-
Chromium – trivalent	0.0089 mg/L	Interim guideline
Copper	Variable	Guideline is hardness dependent; the guideline is 2 µg/L for water hardness between 0 to <82 mg/L. At hardness >180 mg/L, the guideline is 4 µg/L. At hardness ≥82 to ≤180 mg/L, the guideline in µg/L is calculated using the following equation: Hardness Adjusted Guideline = $e^{0.8545\ (\text{LN}[\text{hardness}]-1.465*0.2}$
Dissolved oxygen	9.5 mg/L	Lowest acceptable dissolved oxygen concentration for cold water biota in early life stages.
Fluoride	0.120 mg/L	Interim guideline
Iron	0.3 mg/L	-
Lead	Variable	Guideline is hardness dependent; the guideline is 0.003 mg/L for a hardness of 100 mg/L. When hardness is 0 to ≤60 mg/L, the guideline is 0.001 mg/L. At hardness >180 mg/L, the guideline is 0.007 mg/L. At hardness >60 to ≤180 mg/L, the guideline in µg/L is calculated using the following equation: Hardness Adjusted Guideline = $e^{[1.273\ (\text{LN}[\text{hardness}]-4.705]}$

Water Quality Parameter	CCME FAL Guideline	Comments
Manganese	Variable	Guideline is pH and hardness dependent. Resulting guideline can be determined using a look up table/Canadian Water Quality Guideline (CWQG) calculator available at: http://ceqg-rcqe.ccme.ca/download/en/361
Mercury	0.000026 mg/L	-
Molybdenum	0.073 mg/L	-
Nickel	Variable	Guideline is hardness dependent; the guideline is 0.1 mg/L for a hardness of 100 mg/L. When hardness is 0 to ≤60 mg/L, the guideline is 25 µg/L. At hardness >180 mg/L, the guideline is 150 µg/L. At hardness >60 to ≤180 mg/L, the guideline in µg/L is calculated using the following equation: Hardness Adjusted Guideline = $e^{[0.76\ (LN[hardness]+1.06]}$
Nitrate (as NO_3-N)	13 mg/L	-
Nitrite (as NO_2-N)	0.06 mg/L	-
pH	6.5 - 9.0	-
Selenium	0.001 mg/L	-
Silver	0.00025 mg/L	-
Thallium	0.0008 mg/L	-
Uranium	0.015 mg/L	-
Zinc (dissolved)	Variable	Guideline is hardness and dissolved organic carbon (DOC) dependent; the short-term benchmark is for dissolved zinc in mg/L and is calculated using the following equation: Hardness and DOC Adjusted Guideline = $\exp^{(0.833[\ln(\text{hardness mg/L})] + 0.240[\ln(\text{DOC mg/L})] + 0.526)}$ At hardness (as $CaCO_3$) of 50 mg/L and DOC of 0.5 mg/L, the guideline value is 0.037 mg/L. The benchmark equation is valid for hardness between 13.8 and 250.5 mg/L and DOC between 0.3 and 17.3 mg/L. When hardness or DOC values are outside these limits, the nearest applicable limit is used in the equation.

Table 2-4. Qualitative scale of water hardness adapted from McNeely et al. 1979.

Hardness Category	Hardness (mg/L as $CaCO_3$)
Very soft	0 – 30
Soft	31 – 75
Moderately soft	76 – 120
Hard	121 – 180
Very Hard	>180

Table 2-5. General relationship of surface water productivity to total phosphorus.

Trophic Status	Total Phosphorus (mg/L)	
	Waterbodies [1]	Watercourses [2]
Ultra-oligotrophic (very nutrient-poor)	<0.004	N/A
Oligotrophic (nutrient-poor)	0.004 – 0.01	<0.025
Mesotrophic (containing a moderate concentration of nutrients)	0.01 – 0.02	0.025 – 0.075
Meso-eutrophic (containing moderate to high concentration of nutrients)	0.02 – 0.035	N/A
Eutrophic (nutrient rich)	0.035 – 0.1	>0.075
Hypereutrophic (very nutrient rich)	>0.1	N/A

2.1.7 RISKS AND LIMITATIONS

Due to the number of streams within the RSA (n = 1,467), the length of time needed to access and sample sites, and the cost associated with laboratory analysis of samples, only a very small proportion of streams were sampled as part of this program (~2.5%). However, past data are available, including a recent baseline water quality program administered by the YG WRB. The YG WRB program was designed to characterize the baseline water quality of the area, including that encompassed by the Project. This report incorporated that data, combined with the additional sampling in 2019 and 2020, to provide adequate, current baseline water quality conditions. In some historical data collected by YG WRB it appears that for some metals, including iron and manganese, the dissolved fraction is higher than the total fraction; given that only some metals exhibit this pattern, it is unlikely that this is a sampling error. Instead, it is an indication that most of the total metals are present in the dissolved form. Differences in concentrations are a result of laboratory methods.

2.2 HYDROLOGY

Hydrological data in this report are based solely on historical information. EDI did not collect supplemental hydrological data as part of this study.

2.2.1 ENVIRONMENT AND CLIMATE CHANGE CANADA HYDRO-CLIMATE DATA

Environment and Climate Change Canada (ECCC) operates a meteorological station near the Eagle Plains hotel (Table 2-6). The historical climate data collected at that station are available from the ECCC website (https://climate.weather.gc.ca/historical_data/search_historic_data_e.html). Rainfall and snowpack data recorded by this station were used to analyze precipitation and snowmelt trends and support flow regime data.

Table 2-6. Environment and Climate Change Canada meteorological records used for baseline analysis.

Station Code	Site Name/ID	Record Date Range	Coordinates
2100468	Eagle Plains – 2100468	1998–2005, 2007–2008	66° 22' 10" N 136° 43' 03" W

2.2.2 WATER SURVEY OF CANADA REGIONAL DATA

Surface water in the RSA flows into four major watercourses in the region: Eagle, Peel, Ogilvie, and Porcupine Rivers. The Water Survey of Canada (WSC) operates and maintains continuous hydrometric monitoring stations on these watercourses and provides real-time and historic discharge records to the public. The WSC discharge data are developed using rating curves maintained by WSC using regular field discharge measurements, stage elevation surveys, and continuous water level logger data. These records are computed based on active rating curves and revised by WSC for final publication following a detailed review of water level and discharge field measurement records. These data are available on-demand from the WSC website (https://wateroffice.ec.gc.ca/index_e.html). Table 2-7 outlines the discharge records used to establish regional baseline flow trends. The rationale for the records chosen was based on the destination of outgoing flow from the RSA, geographic proximity to the RSA and completeness of records.

Table 2-7. Water Survey of Canada discharge records used for baseline analysis.

Station Code	Site Name	Record Date Range	Coordinates
09FB002	Eagle River at Dempster Highway Bridge	2013–2020	66° 26’ 36” N 136° 42’ 33” W
10MA001	Peel River Above Canyon Creek	2006–2020	65° 53’ 33” N 136° 02’ 17” W
10MA002	Ogilvie River at Kilometre 197.9 Dempster Highway	2016–2020	65° 21’ 45” N 138° 17’ 50” W
09FD003	Porcupine River Below Old Crow River	2004–2020	67° 34’ 05” N 139° 50’ 03” W

2.2.3 YUKON GOVERNMENT WATER RESOURCES BRANCH DATA

Yukon Government Water Resource Branch operates two continuous hydrometric monitoring stations on McParlon and Dalglish Creeks (Map 2-1). These tributaries originate within the RSA and feed into the Porcupine and Peel Rivers, respectively. The flow data are available upon request from YG WRB (water.resources@gov.yk.ca) and the YG WRB data catalogue is available at the YG WRB website (http://yukonwater.ca/monitoring-yukon-water/water-data-catalogue). The YG-WRB discharge data are developed using rating curves maintained by YG WRB using regular field discharge measurements, stage elevation surveys and continuous water level logger data. Table 2-8 outlines the discharge records used to analyze site-specific flow trends. The McParlon and Dalglish Creek flow records were the only records available for watercourses originating within the RSA.

Table 2-8. Yukon Government Water Resources Branch discharge records used for baseline analysis.

Station Code	Site Name	Record Date Range	Coordinates
30MA004	Dalglish Creek - Lower	2013–2014	65° 52' 56" N 136° 20' 15" W
29FA001	McParlon Creek	2013–2017	66° 4' 24" N 137° 54' 57" W

2.2.4 QUALITY ASSURANCE / QUALITY CONTROL

EDI performed independent QA/QC on all data used for hydrology and meteorological baseline analysis. Data records averaged across the complete annual and partial year records were not included in the analysis. As such, annual averages are calculated across different year ranges based on the records available.

ECCC performs data review before incorporation into their database and retroactively updates historical data records. Data include quality flags defined by ECCC in each data file, and where data was flagged as "Missing," data points are displayed as gaps in this report. No other data flags were present in the date ranges used for this report. The "Missing" flag is about data that were never collected due to power outages, equipment failure, or station maintenance. All meteorological data are subject to a disclaimer for meteorological information, which can be viewed at the ECCC website (https://climate.weather.gc.ca/climate_data/data_quality_e.html).

Historical data records for watercourses originating from within the RSA are incomplete, with varying degrees of data quality. The YG WRB grades and approves all hydrometric data and provides grade and approval descriptions upon request. Where data were graded as "Unusable," "Water Level Below Sensor," or "Ice," data points were rejected and displayed as gaps in this report. Data graded at these levels were primarily found to occur between September and April. The remaining gaps present in the data were blank cells in raw data files provided by YG WRB and were rejected during the internal approval process. The YG WRB monitoring stations on McParlon Creek and Dalglish Creek are subject to overwinter de-watering, adversely impacting water level logger data and low flow rating curve development. The review of the data records, data gaps and flags, suggests that the McParlon and Dalglish Creeks reach zero-flow levels during mid to late October. Additionally, these creeks experience more rapid hydromorphic change, such as banks caving in or sediment transport due to their small size and drastic flow fluctuations. Thus, long-term data are incomplete where stations have been required to be relocated or discontinued.

The WSC data records for regional watercourses were complete and of moderate to high quality. No provisional data were included in this analysis. The WSC monitoring stations on the Eagle, Peel, Ogilvie, and Porcupine Rivers are in watercourses that exhibit some flow year-round and do not de-water or freeze to bed during winter months. For these reasons, WSC records cover a greater period with complete over-winter flow data. Gaps present in the data were blank cells in raw data files provided by WSC and were rejected during the WSC internal approval process. All flow data provided by WSC are subject to a disclaimer for hydrometric information, which can be viewed at the WSC website (https://wateroffice.ec.gc.ca/disclaimer_info_e.html).

3 RESULTS

3.1 WATER QUALITY

3.1.1 MCPARLON CREEK

McParlon Creek drains the RSA to the west, emptying into the Whitestone River (Map 2-1). Available water quality data are from two sites in the McParlon watershed:

1. McPL-002, which lies in the upstream reaches of McParlon Creek (Photo 3-1); and,
2. McPL-001, which is located just upstream of the Whitestone River (Photo 3-2).

Water quality data were collected from McPL-001 periodically starting in July 2013, in spring and fall 2014, 2015 and 2016, in winter, spring and fall in 2017, and later winter 2018. Data were collected from McPL-002 from 2013 through 2016. EDI collected samples from both sites in the summer of 2019. While a sample was collected from McPL-001 in March 2020, McPL-002 was frozen to the substrate. McParlon Creek is a wide, shallow, slow-moving stream that freezes to substrate in the winter months. The YG WRB attempts to sample in March during all sampling years found either no water (as EDI also found in 2020), or only standing water, as was found in 2016.

Photo 3-1 Overview of site McPL-002.

Photo 3-2 Upstream view from site McPL-001.

3.1.1.1 General Chemistry and Major Ions

Water in McParlon Creek was circumneutral to slightly acidic. Conductivity ranged widely with the seasons from between 50 to 100 µS/cm in early summer during freshet to a high of 1,200 µS/cm recorded in later winter when the water is dominated by basal, groundwater-sourced flow. Water was generally characterized as 'very to moderately soft' during the open water season with available hardness data ranging from 25 to

63 mg/L (as $CaCO_3$), and 'hard to very hard' during the under-ice months, with hardness as high as 270 mg/L (Table 2-4).

Water was brown stained in colour, and turbidity ranged from very low during the under-ice period, to close to 100 NTUs at other times of the year. Aside from low turbidity under ice, turbidity showed no seasonal pattern and may have been influenced by precipitation events and bank material periodically entering the water column as melting permafrost resulting in slumping banks. The suspended sediment load was generally low, ranging from <1 mg/L (below detection) to 23 mg/L; however, like turbidity, there were some spikes to approximately 100 mg/L in samples collected at various open water times of the which were likely associated with precipitation events year, and melting permafrost. Major ions were predominantly comprised of bicarbonate, calcium and sulphate (Figure 3-1) and showed no variation with seasons and little difference among the two sites.

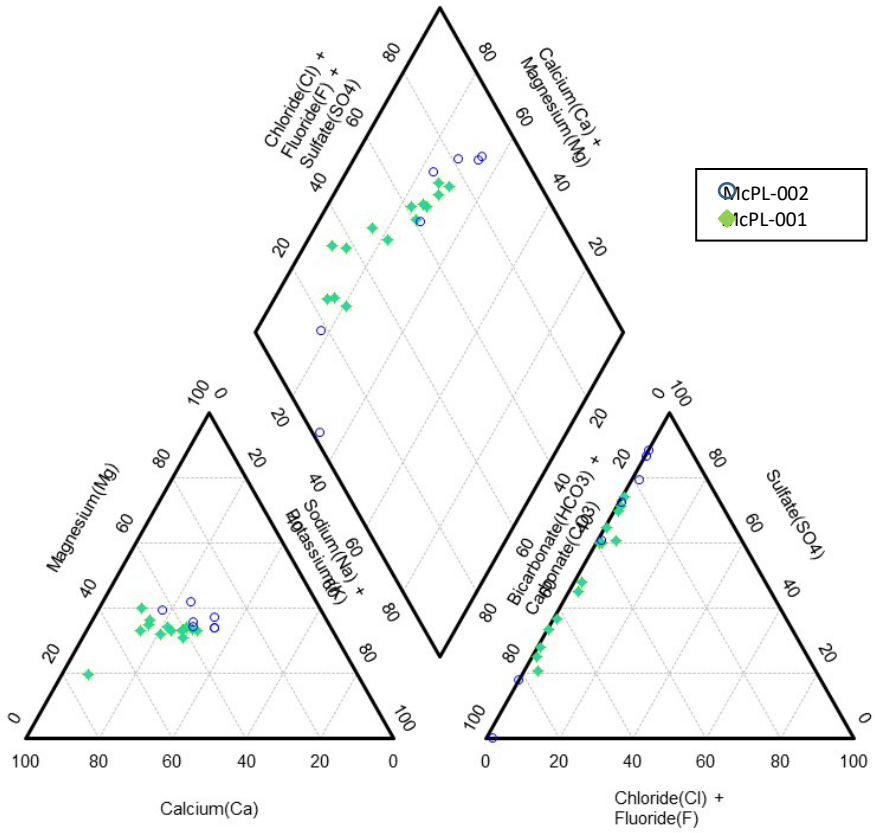

Figure 3-1. Piper plot showing major ion composition of waters in the McParlon watershed in % meq/kg.

3.1.1.2 Nutrients

Nutrient concentrations in McParlon Creek at both sampling sites were low. Concentrations of nitrate, nitrite, nitrate+nitrite, and total ammonia were below applicable guidelines for surface water. Total Kjeldahl Nitrogen (TKN), which is the total concentration of organic nitrogen and ammonia, ranged from 0.85 to 1.19 mg/L. Total phosphorus concentrations ranged from <0.050 (March 2020 at McPL-001) through 0.086 (July 2013 at McPL-001) mg/L, indicating oligotrophic to mesotrophic trophic status (Table 2-5).

3.1.1.3 Trace Metals

Aluminum, cadmium, copper, iron, manganese, and selenium in the McParlon Creek watershed occurred at concentrations that regularly exceeded the CCME-FAL concentrations (Table 2-3). Total aluminum exceeded the CCME-FAL guideline in nearly all samples from both sites; however, the dissolved fraction of aluminum in nearly all samples was below the CCME-FAL guideline (Figure 3-2 and Figure 3-3). Therefore, most of the aluminum in the water column was bound to suspended sediment. Total and dissolved cadmium, copper, iron, and manganese regularly exceeded their respective CCME-FAL guidelines (Figure 3-4 through Figure 3-11). Total selenium exceeded the CCME-FAL in three samples associated with under-ice sampling; dissolved fractions were below the guideline (Figure 3-12 and Figure 3-13).

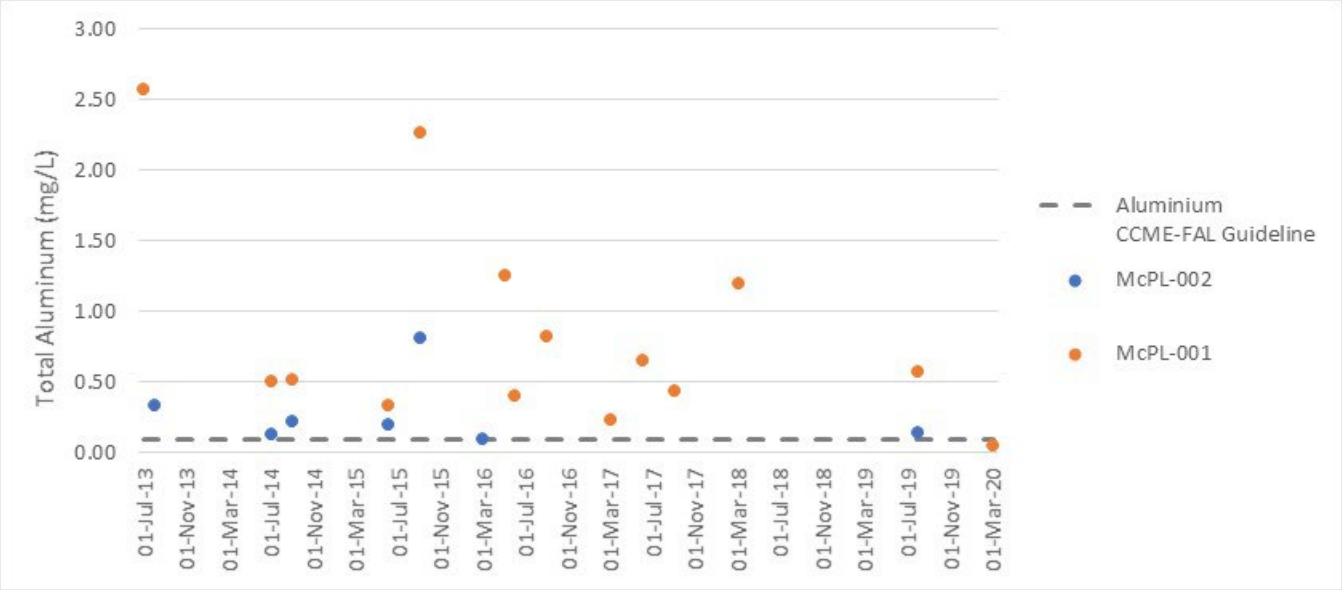

Figure 3-2. Total aluminum concentrations in McParlon Creek sites between July 2013 and March 2020.

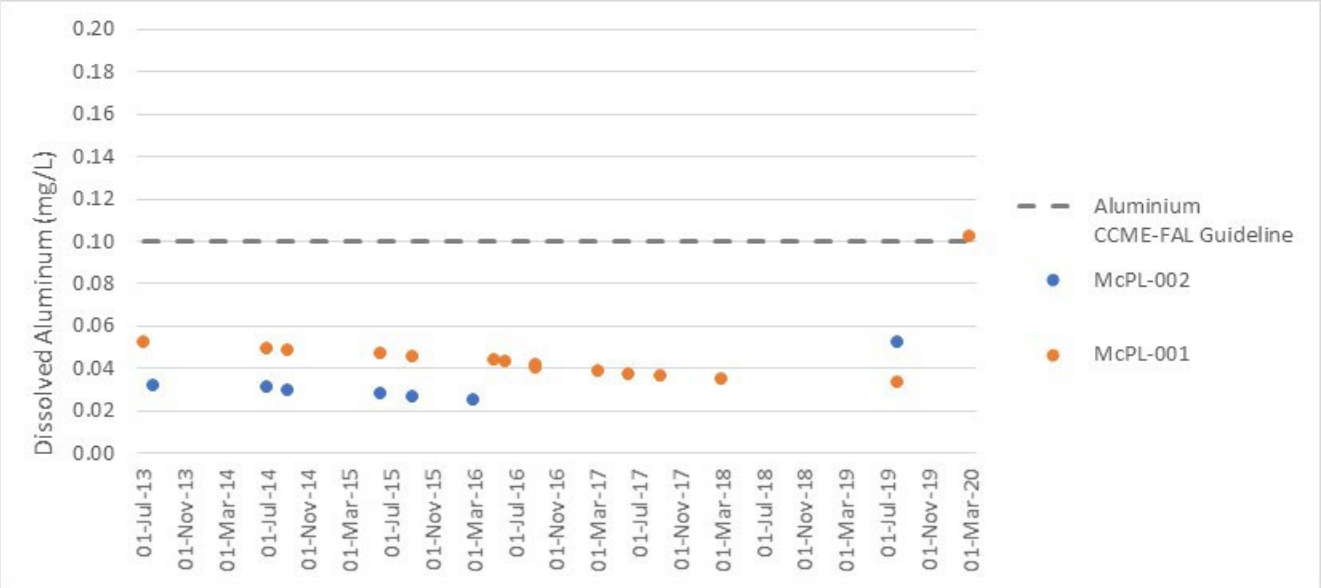

Figure 3-3. Dissolved aluminum concentrations in McParlon Creek sites between July 2013 and March 2020.

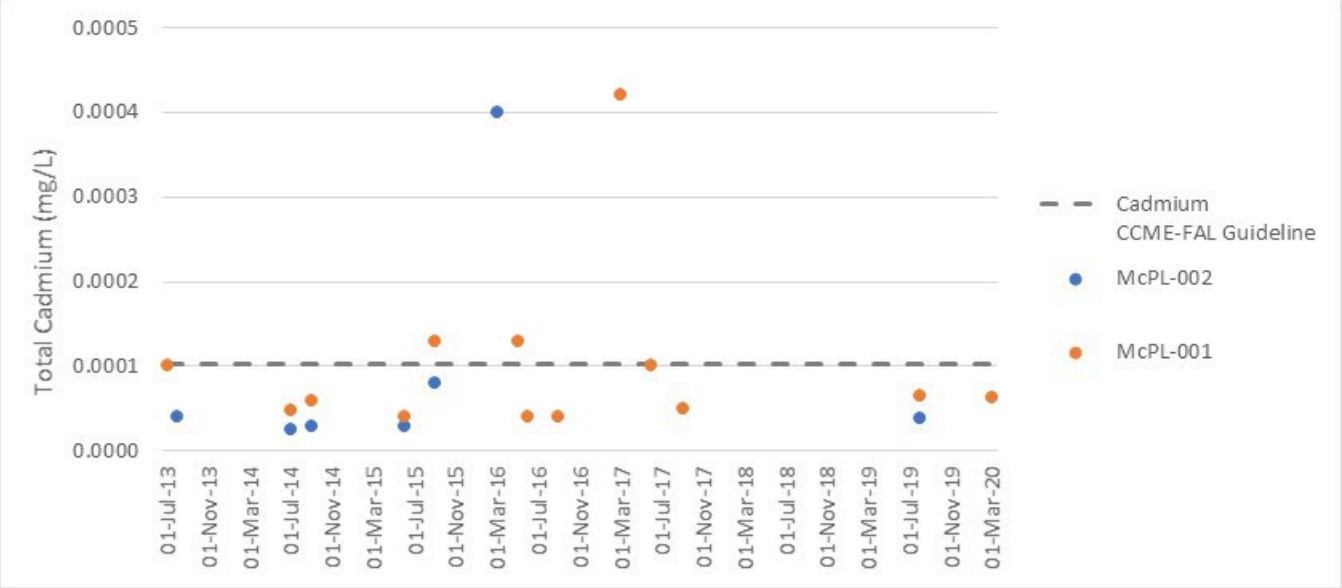

Figure 3-4. Total cadmium concentrations in McParlon Creek sites between July 2013 and March 2020.

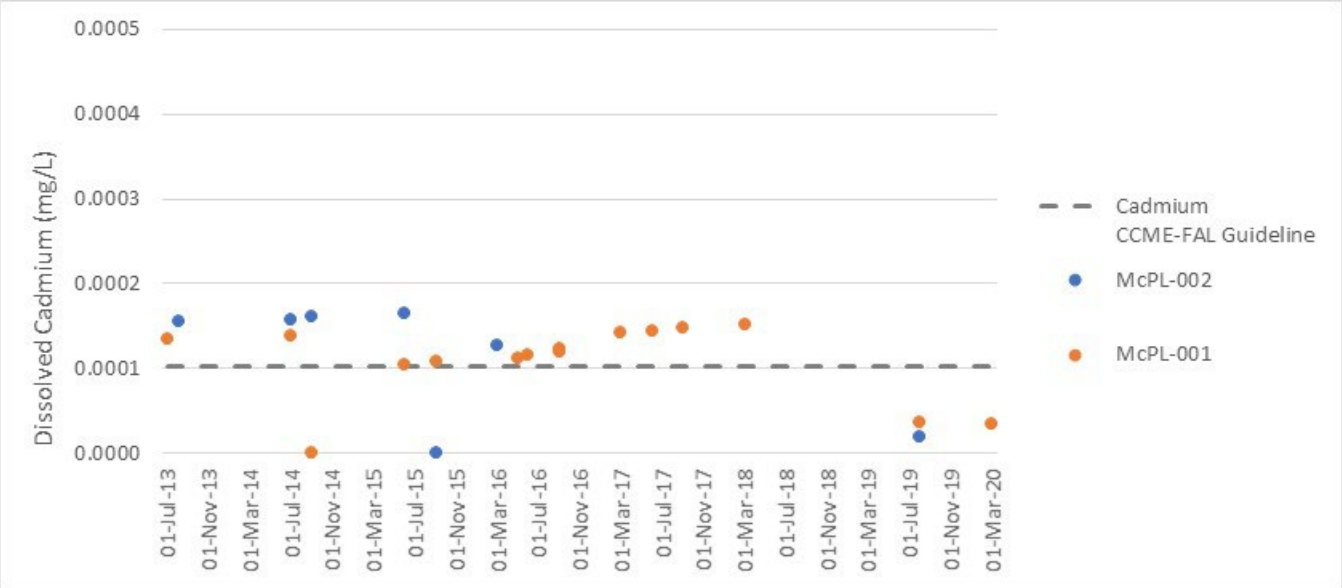

Figure 3-5. Dissolved cadmium concentrations in McParlon Creek sites between July 2013 and March 2020.

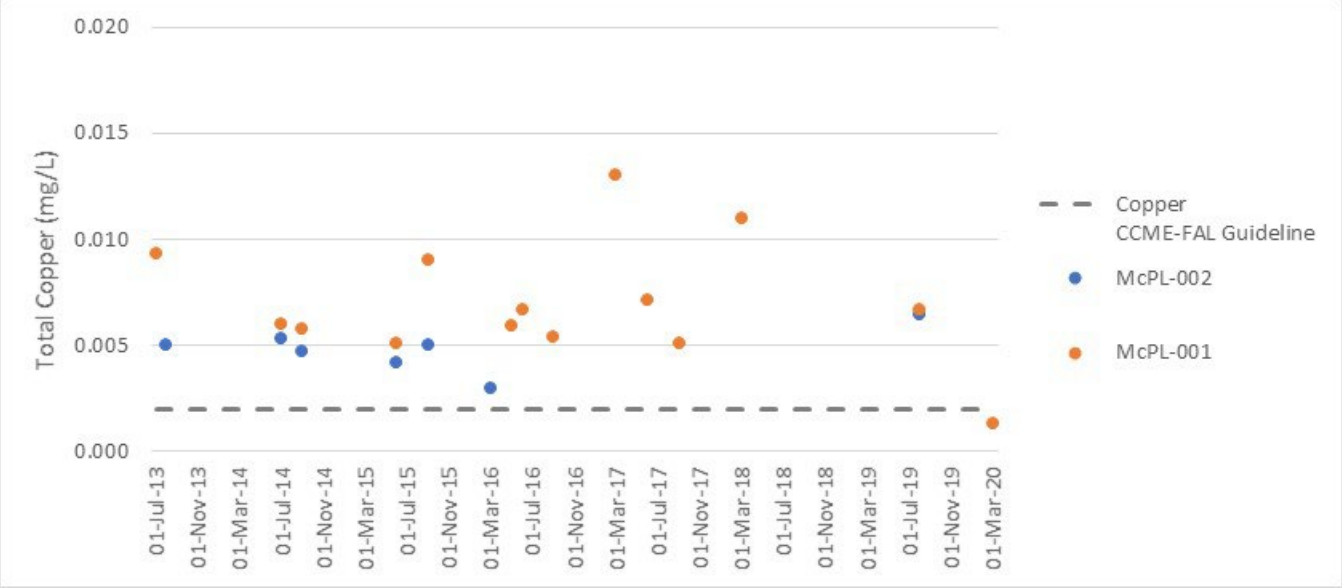

Figure 3-6. Total copper concentrations in McParlon Creek sites between July 2013 and March 2020.

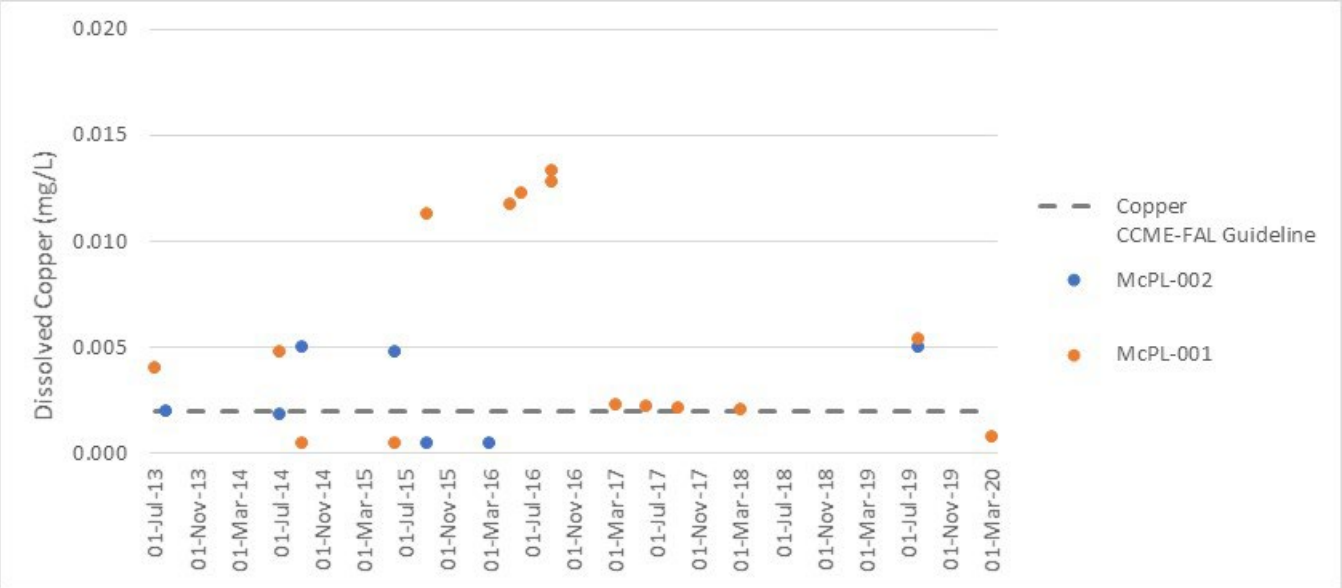

Figure 3-7. Dissolved copper concentrations in McParlon Creek sites between July 2013 and March 2020.

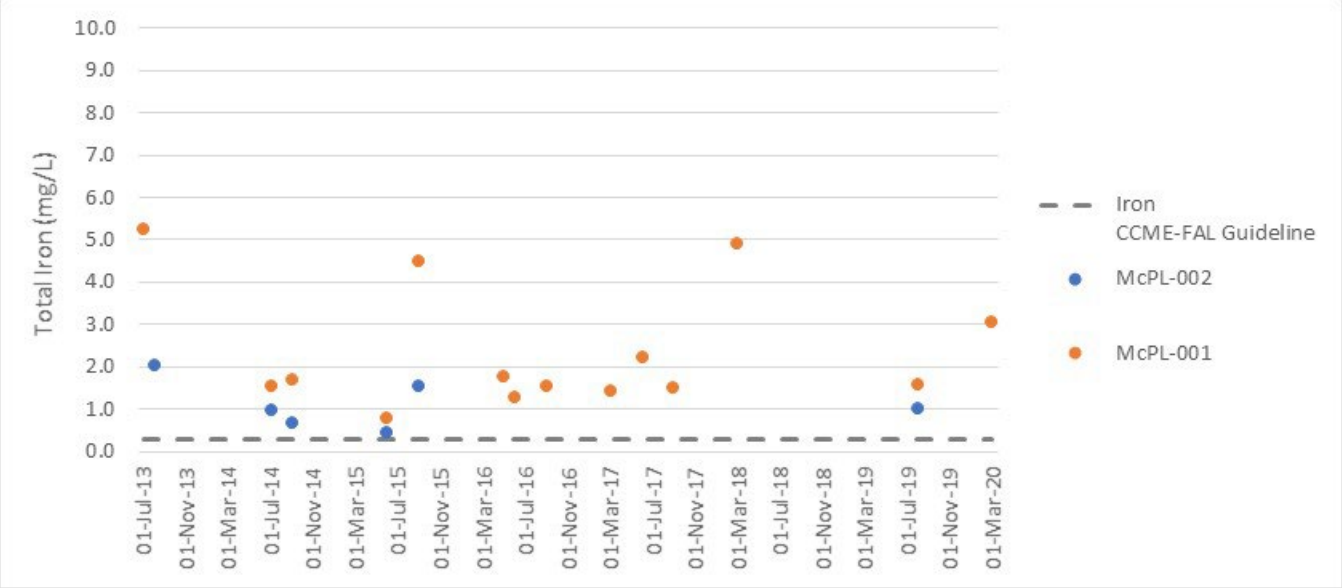

Figure 3-8. Total iron concentrations in McParlon Creek sites between July 2013 and March 2020.

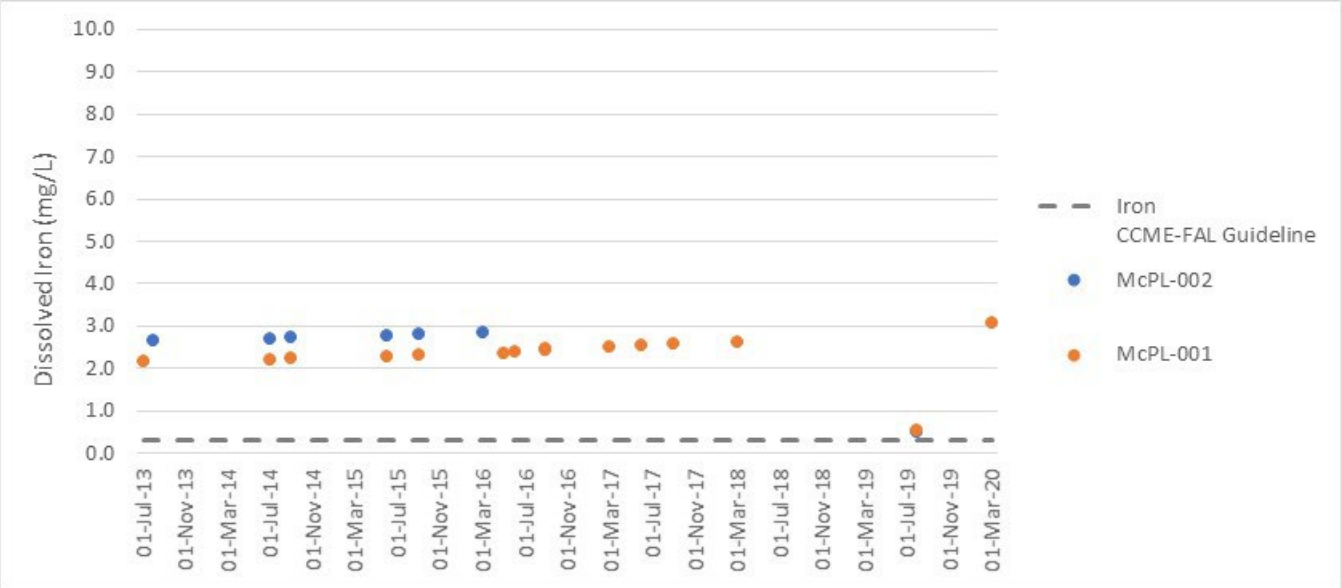

Figure 3-9. Dissolved iron concentrations in McParlon Creek sites between July 2013 and March 2020.

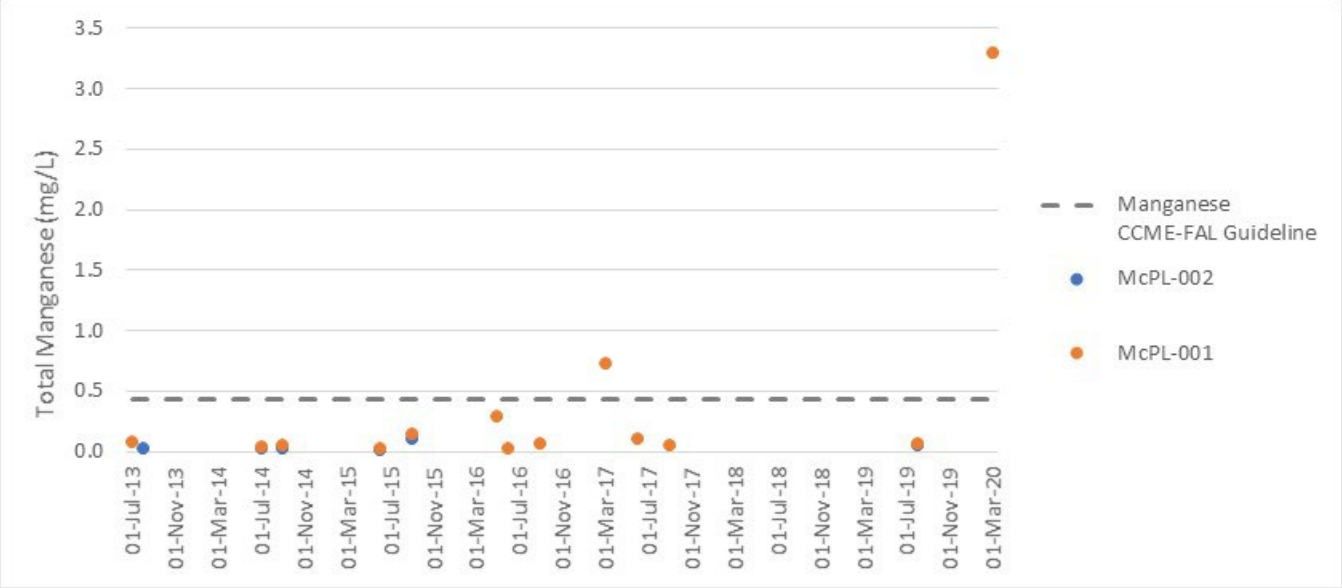

Figure 3-10. Total manganese concentrations in McParlon Creek sites between July 2013 and March 2020.

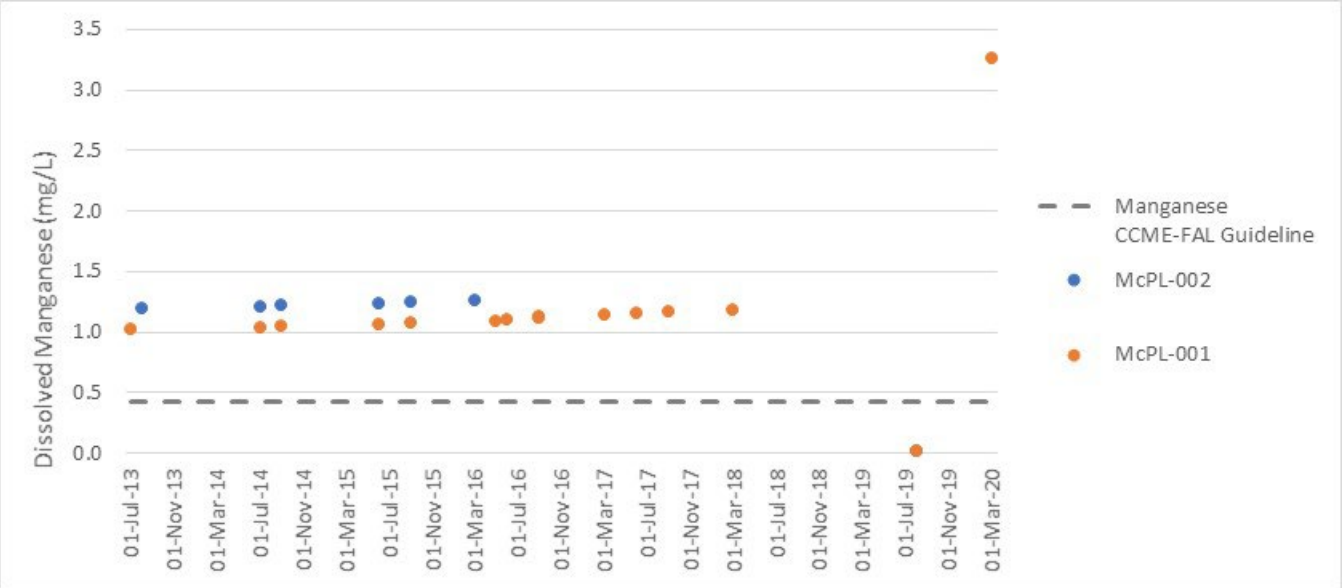

Figure 3-11. Dissolved manganese concentrations in McParlon Creek sites between July 2013 and March 2020.

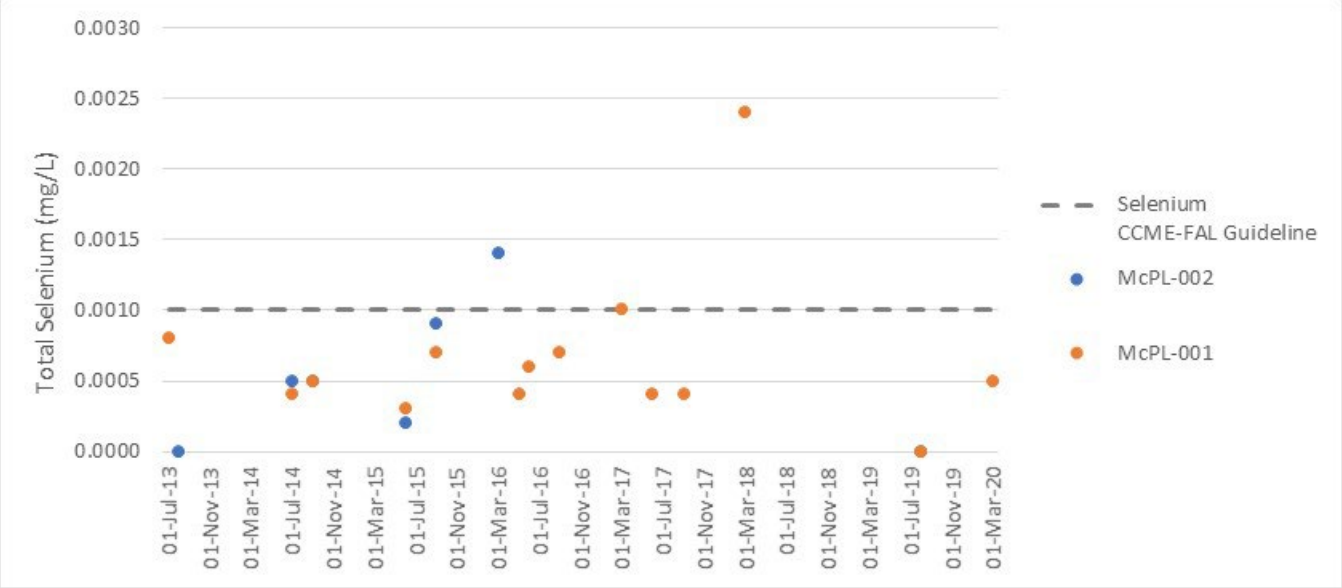

Figure 3-12. Total selenium concentrations in McParlon Creek sites between July 2013 and March 2020.

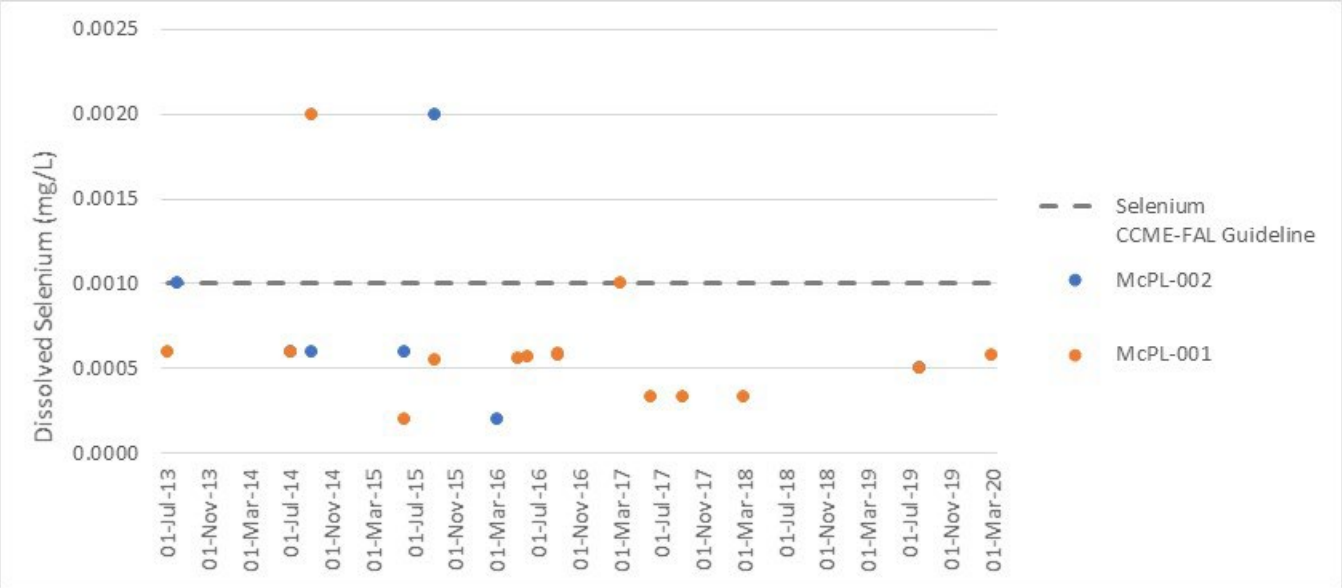

Figure 3-13. Dissolved selenium concentrations in McParlon Creek sites between July 2013 and March 2020.

3.1.1.4 Hydrocarbons

Hydrocarbons in the McParlon Creek sites were the lowest in the RSA. Hydrocarbons including volatile hydrocarbons (VHs), volatile petroleum hydrocarbons (VPHs), and volatile organic carbons (VOCs) were undetectable throughout the McParlon Creek sample sites. In general, naphthalene, biphenyl, phenanthrene, and retene were the major polycyclic aromatic hydrocarbons (PAHs) found at the McParlon Creek sites (Figure 3-14 and Figure 3-15).

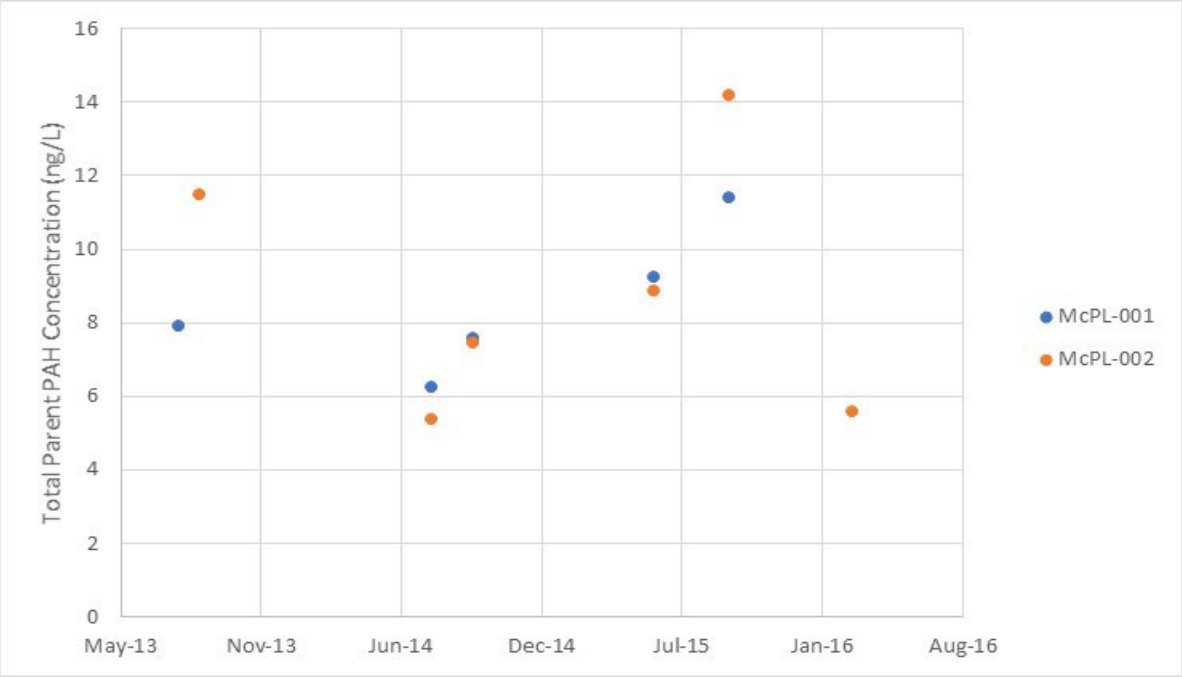

Figure 3-14. Total parent PAH concentrations in McParlon Creek sites from July 2013 through March 2016.

Note: Results that were below detection were treated as 0 ng/L.

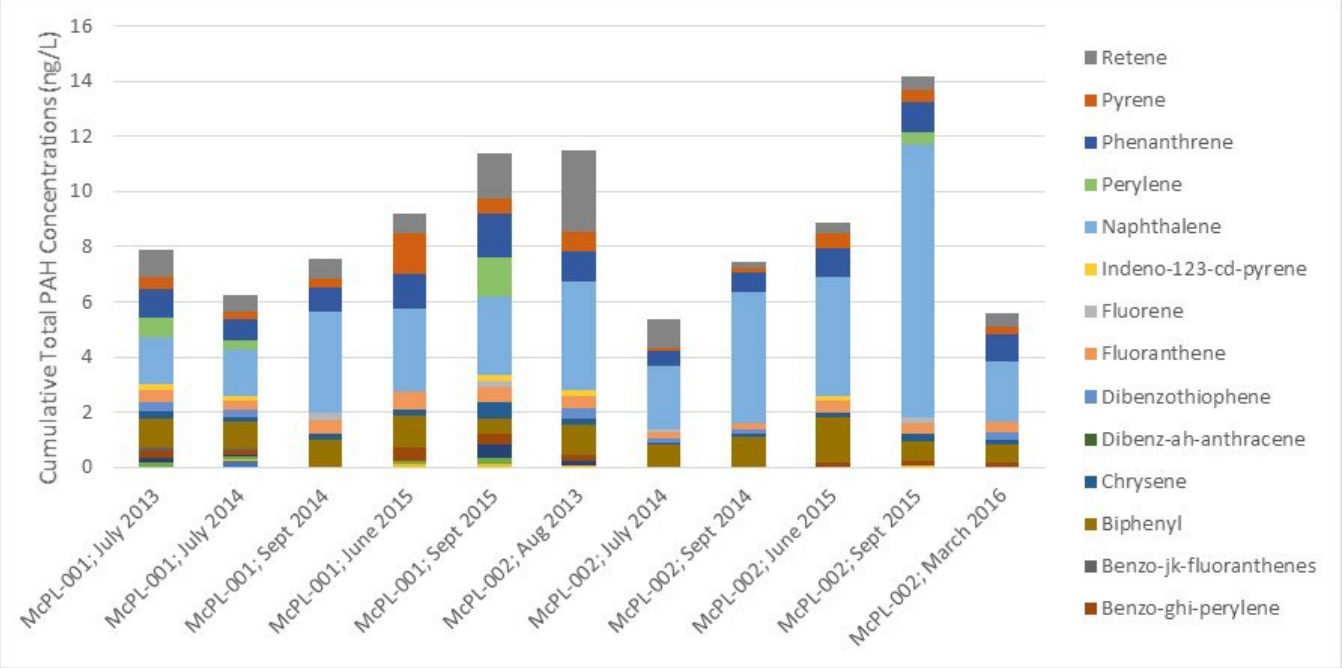

Figure 3-15. Cumulative parent PAH compounds in McParlon Creek sites from July 2013 through March 2016.

Note: Results that were below detection were treated as 0 ng/L.

3.1.2 CHANCE CREEK

The Chance Creek system is in the north of the RSA. It drains to the west, flowing first into the Whitestone River, and ultimately the headwaters of the Porcupine River. Data are available from three sites in the Chance Creek watershed:

1. CHNC-003, located in the upper reaches of Chance Creek, upstream of CHNC-t-002 (Photo 3-3);
2. CHNC-t-002, which is a small tributary to Chance Creek (Photo 3-4); and,
3. CHNC-001, which is just upstream from the Whitestone River (Photo 3-5).

Water quality data were collected from all sites periodically from July/August 2013 through March 2016 at CHNC-t-002, June 2017 at CHNC-003, and through March 2018 at CHNC-001. Chance Creek, which has brown stained water, is a wide, slow-moving stream. While some year-to-year variability is expected, many section of this stream and its tributaries within the RSA freeze to substrate during the winter months.

Photo 3-3. Downstream view from CHNC-003.

Photo 3-4. Upstream view from site CHNC-t-002.

Photo 3-5. Downstream view from CHNC-001.

3.1.2.1 General Chemistry and Major Ions

Water in Chance Creek and its tributary was circumneutral to slightly acidic. The headwaters of Chance Creek and the tributary sampled at CHNC-t-002 were more acidic and pH moved toward neutral by the CHNC-001 sample site. Conductivity in the Chance headwaters ranged from 28.5 to 58 µS/cm at CHNC-003 and from 24.5 to 50 µS/cm at CHNC-t-002, with one outlier at 285 µS/cm, collected in March 2016. At CHNC-001, the conductivity range was greater at 28 to 507 µS/cm. Water can be generally characterized as 'very to moderately soft' during the open water season and 'hard to very hard' during the under-ice months (Table 2-4).

Water was brown stained in colour, and turbidity ranged from very low during the under-ice period, to close to 100 NTUs at other times of the year. Aside from low turbidity under ice, turbidity showed no seasonal pattern and may be influenced by precipitation events. The suspended sediment load is generally low, ranging from <1 mg/L (below detection) to 88 mg/L; however, like turbidity, there are some spikes to approximately 245 mg/L in samples collected at various open water times of the year that were likely associated with precipitation events. Major ions were predominantly comprised of bicarbonate, calcium, and sulphate (Figure 3-16); the headwaters had higher proportions of magnesium in comparison with CHNC-001, and the sulfate increased with distance downstream.

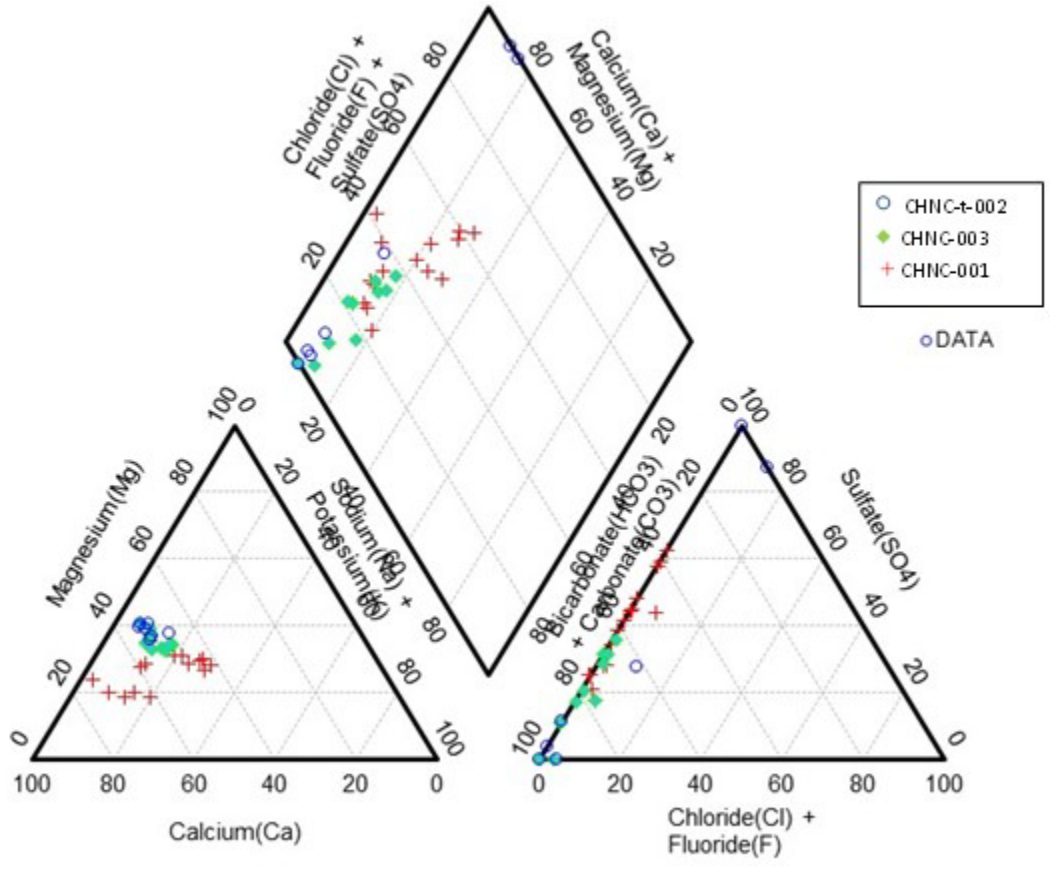

Figure 3-16. Piper plot showing major ion composition of waters in the C hance Creek watershed in % meq/kg.

3.1.2.2 Nutrients

Nutrient concentrations in the Chance Creek sites were low. Concentrations of nitrate, nitrate+nitrite, and total ammonia were below applicable guidelines in surface water. One nitrite sample, collected from CHNC-001 in March 2016, had a concentration of 0.11 mg/L, which exceeded the CCME-FAL of 0.06 mg/L; all other nitrite concentrations ranged from <0.010 mg/L (below detection) to 0.06 mg/L. Total Kjeldahl Nitrogen ranged from 0.85 to 1.19 mg/L.

Total phosphorus concentrations generally ranged from 0.020 through 0.085 mg/L, indicating that the trophic status generally ranged from oligotrophic to mesotrophic (Table 2-5); one sample, collected from CHNC-003 in March 2020, had a concentration of 0.218 mg/L.

3.1.2.3 Trace Metals

Aluminum, arsenic, copper, iron, and manganese in the Chance Creek watershed occurred in concentrations that regularly exceeded the CCME-FAL guideline. Total aluminum exceeded the CCME-FAL guideline in nearly all samples from both sites; however, most of the aluminum in the water column is likely bound to suspended sediment as the dissolved fraction of aluminum in nearly all samples was below the CCME-FAL guideline (Figure 3-17 and Figure 3-18). Total arsenic exceeded the CCME-FAL in two samples, both associated with under-ice sampling; dissolved fractions were below the guideline (Figure 3-19 and Figure 3-20). Total and dissolved copper, iron, and manganese regularly exceeded their respective CCME-FAL guidelines (Figure 3-21 through Figure 3-26).

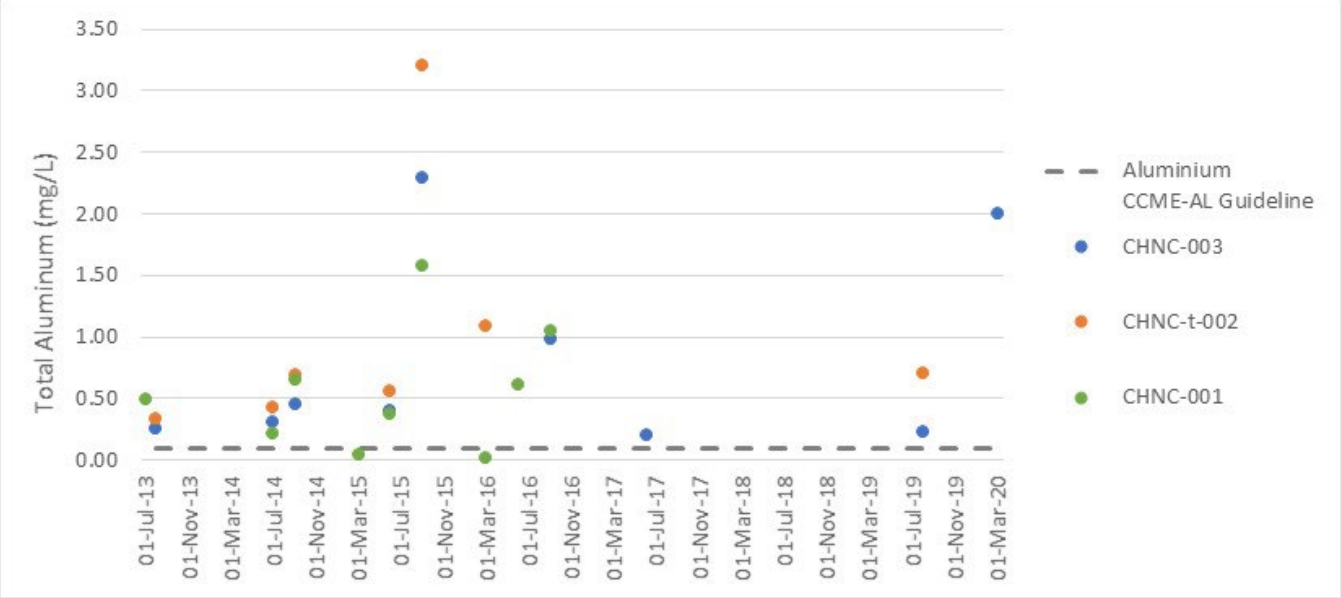

Figure 3-17. Total aluminum concentrations in Chance Creek sites between July 2013 and March 2020.

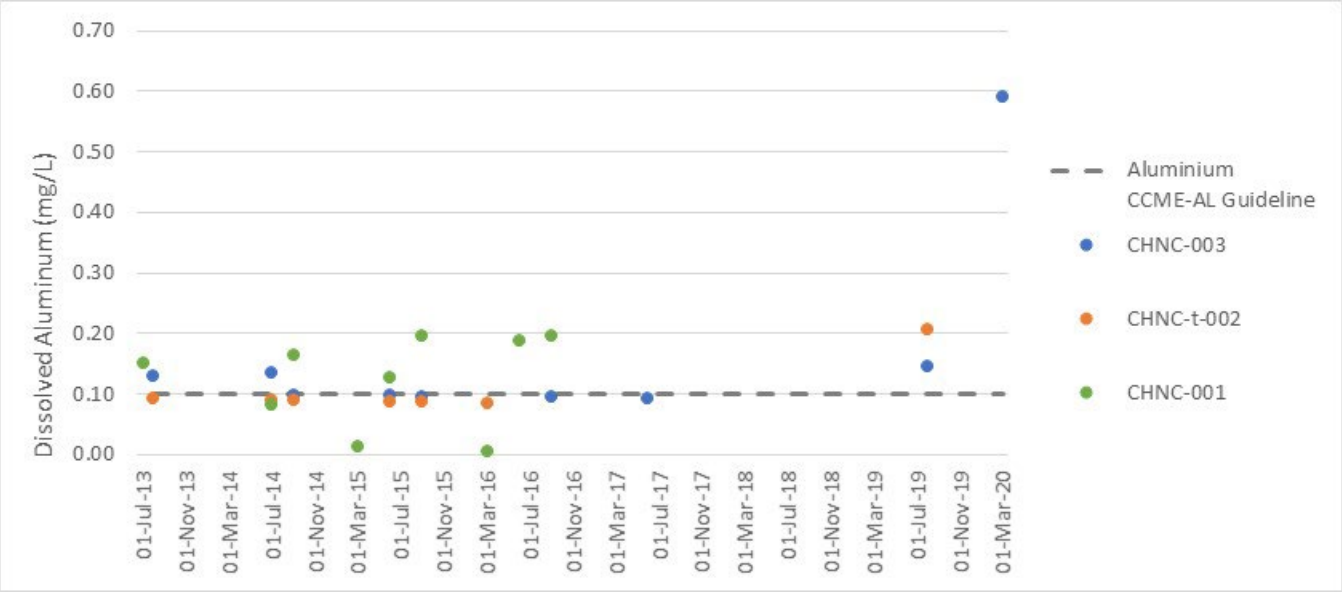

Figure 3-18. Dissolved aluminum concentrations in Chance Creek sites between July 2013 and March 2020.

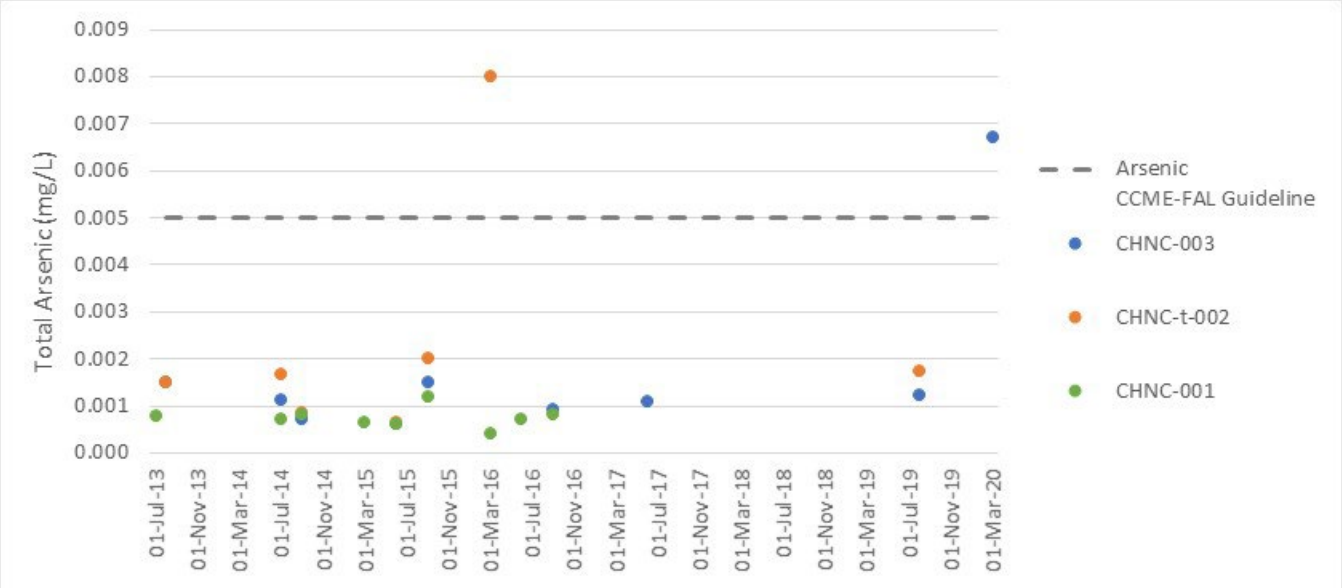

Figure 3-19. Total arsenic concentrations in Chance Creek sites between July 2013 and March 2020.

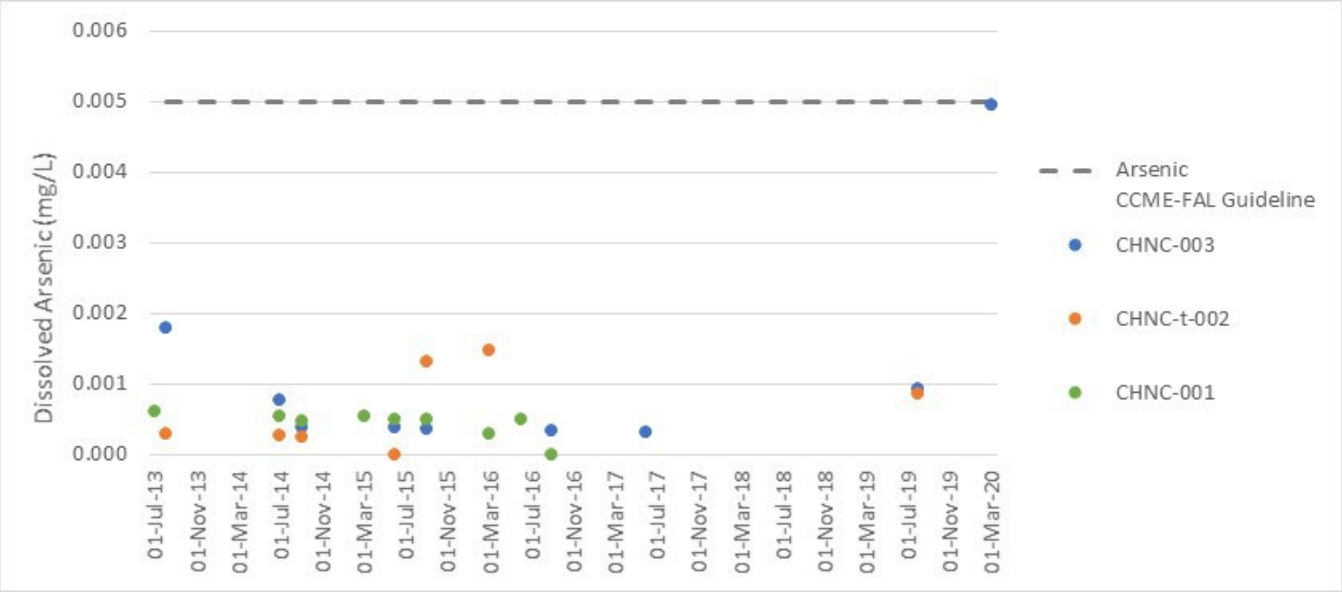

Figure 3-20. Dissolved arsenic concentrations in Chance Creek sites between July 2013 and March 2020.

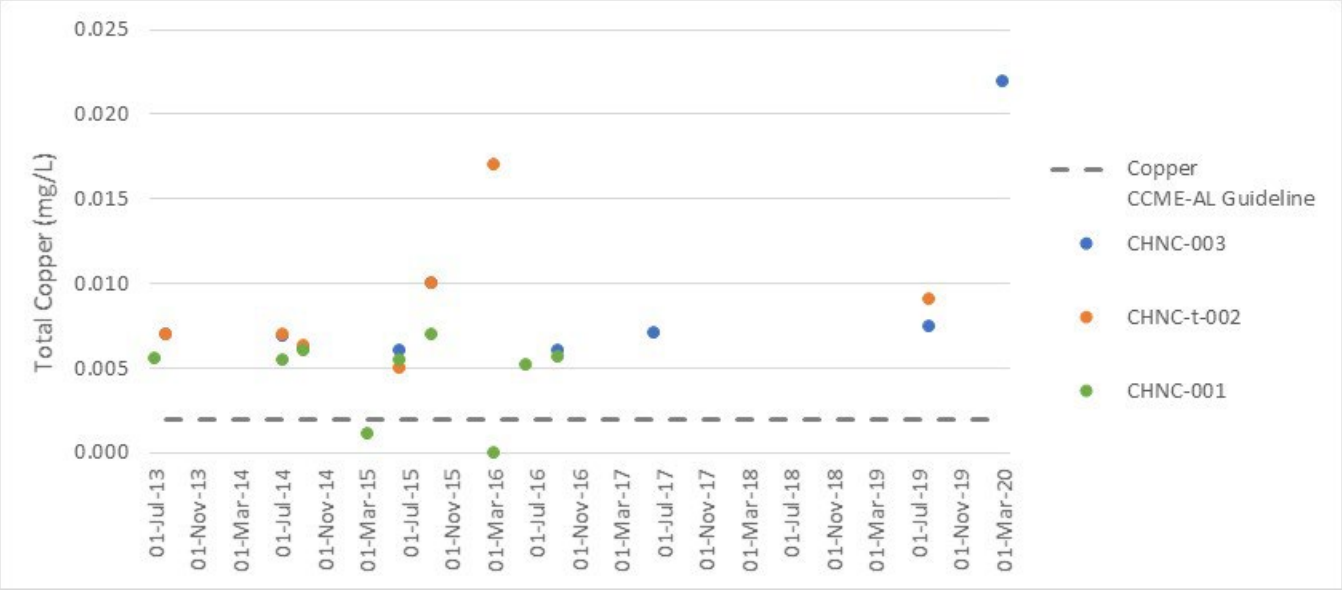

Figure 3-21. Total copper concentrations in Chance Creek sites between July 2013 and March 2020.

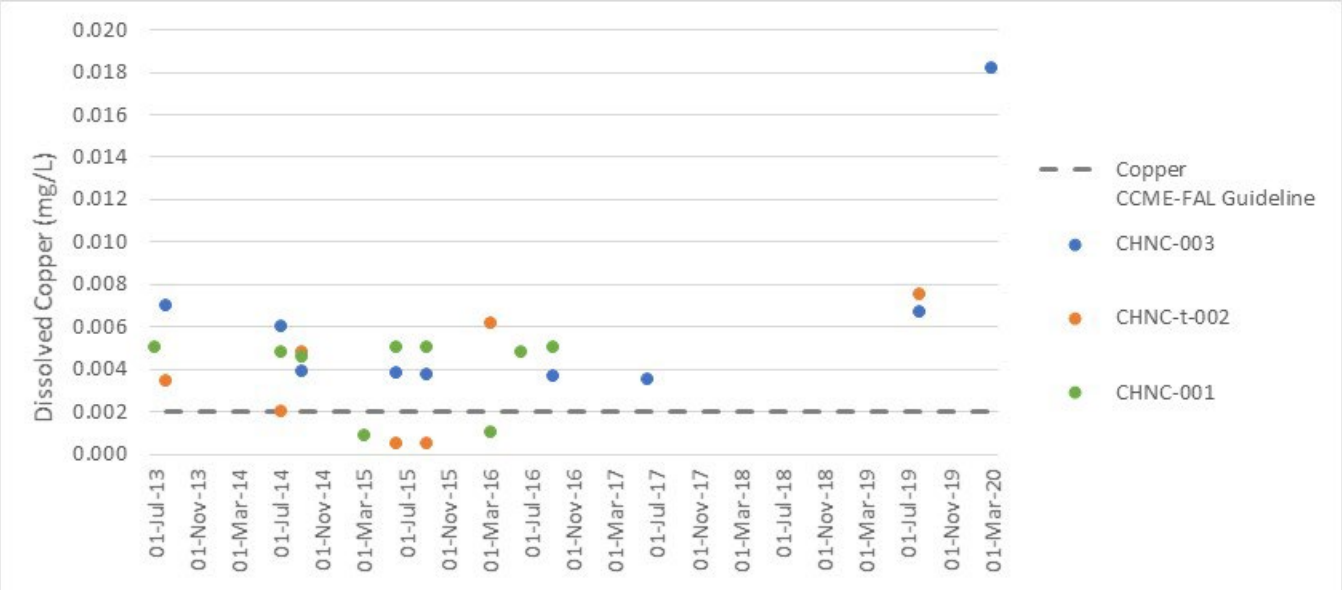

Figure 3-22. Dissolved copper concentrations in Chance Creek sites between July 2013 and March 2020.

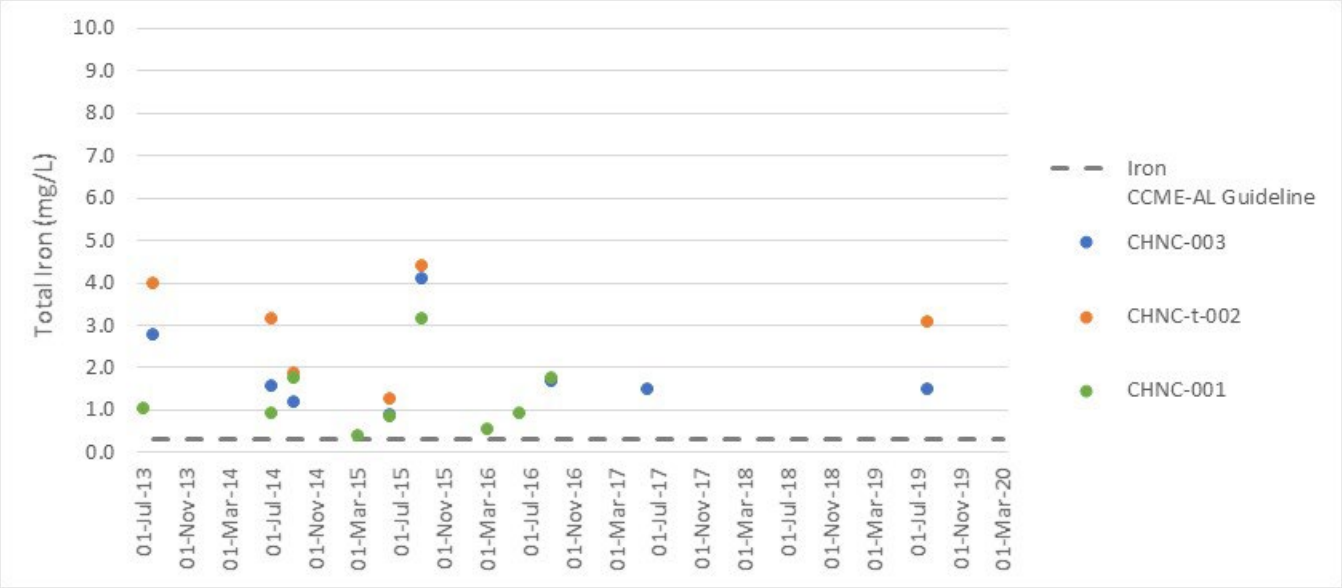

Figure 3-23. Total iron concentrations in Chance Creek sites between July 2013 and March 2020.

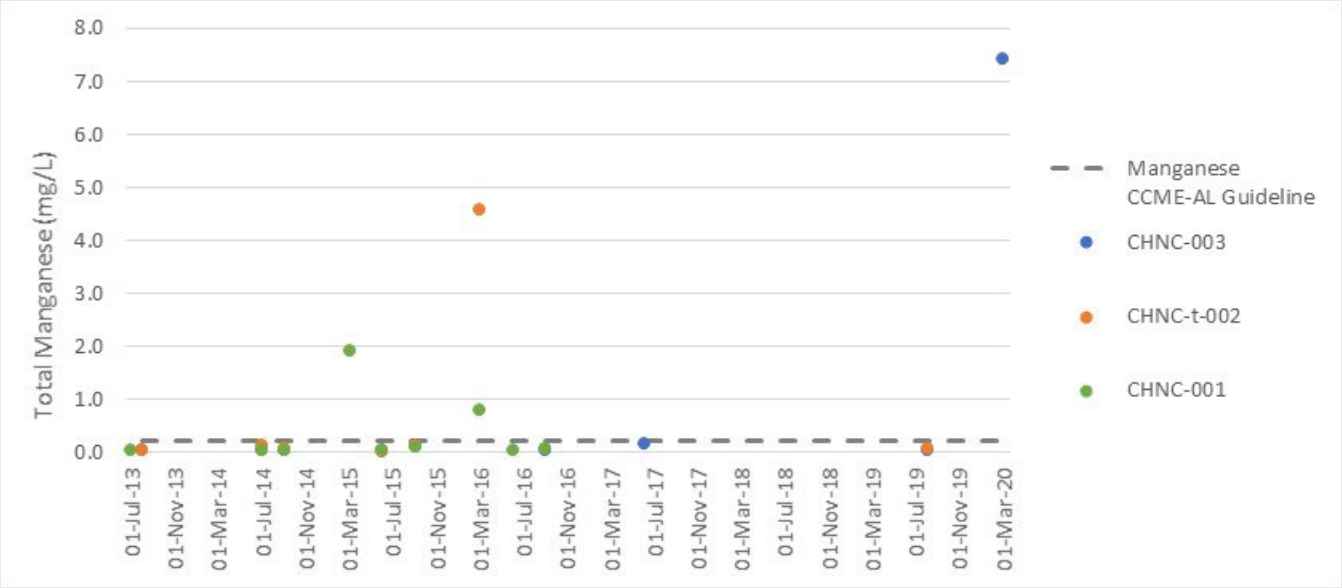

Figure 3-25. Total manganese concentrations in Chance Creek sites between July 2013 and March 2020.

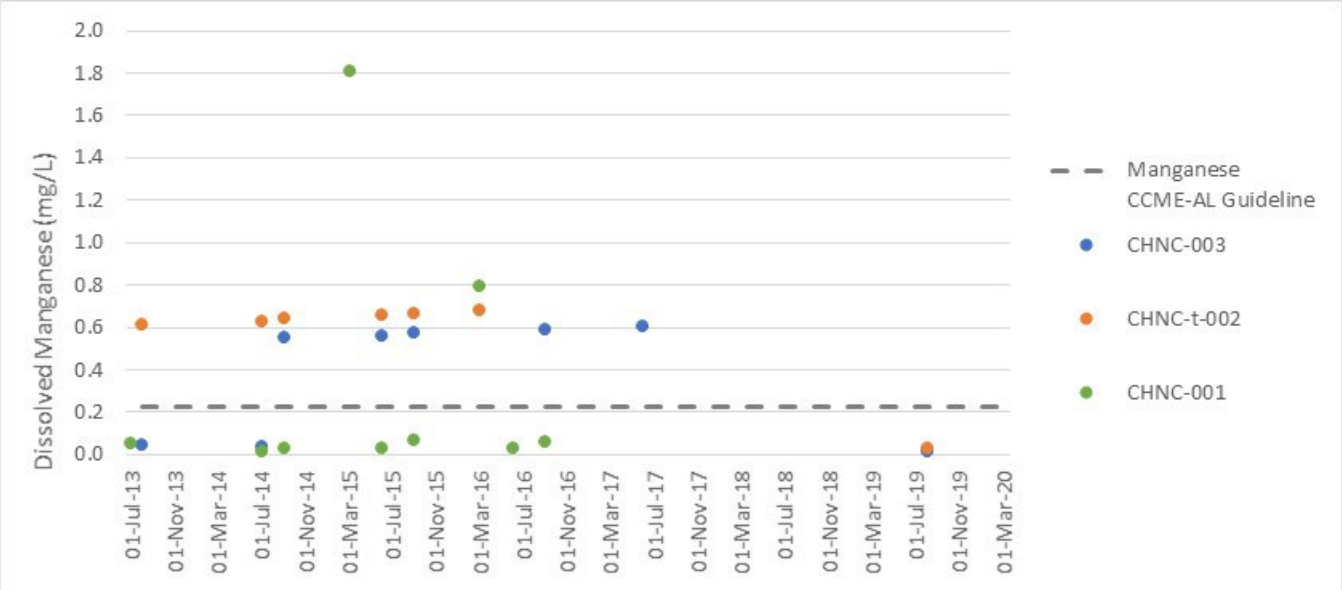

Figure 3-26. Dissolved manganese concentrations in Chance Creek sites between July 2013 and March 2020.

3.1.2.4 Hydrocarbons

Hydrocarbon concentrations in water from the Chance Creek sites including VHs, VPHs, and VOCs were undetectable throughout the Chance Creek sample sites. In general, PAH concentrations were higher in Chance Creek than in McParlon Creek. No pattern in total PAH concentration was identified among the Chance Creek sample sites (Figure 3-27). The PAHs that comprised most total parent PAHs at the Chance Creek sites included naphthalene and retene (Figure 3-28). The sample collected from CHNC-001 in March 2015 had significantly higher PAH concentrations, particularly naphthalene, than all other samples from all sites, indicating that this sample may have been contaminated (Figure 3-27).

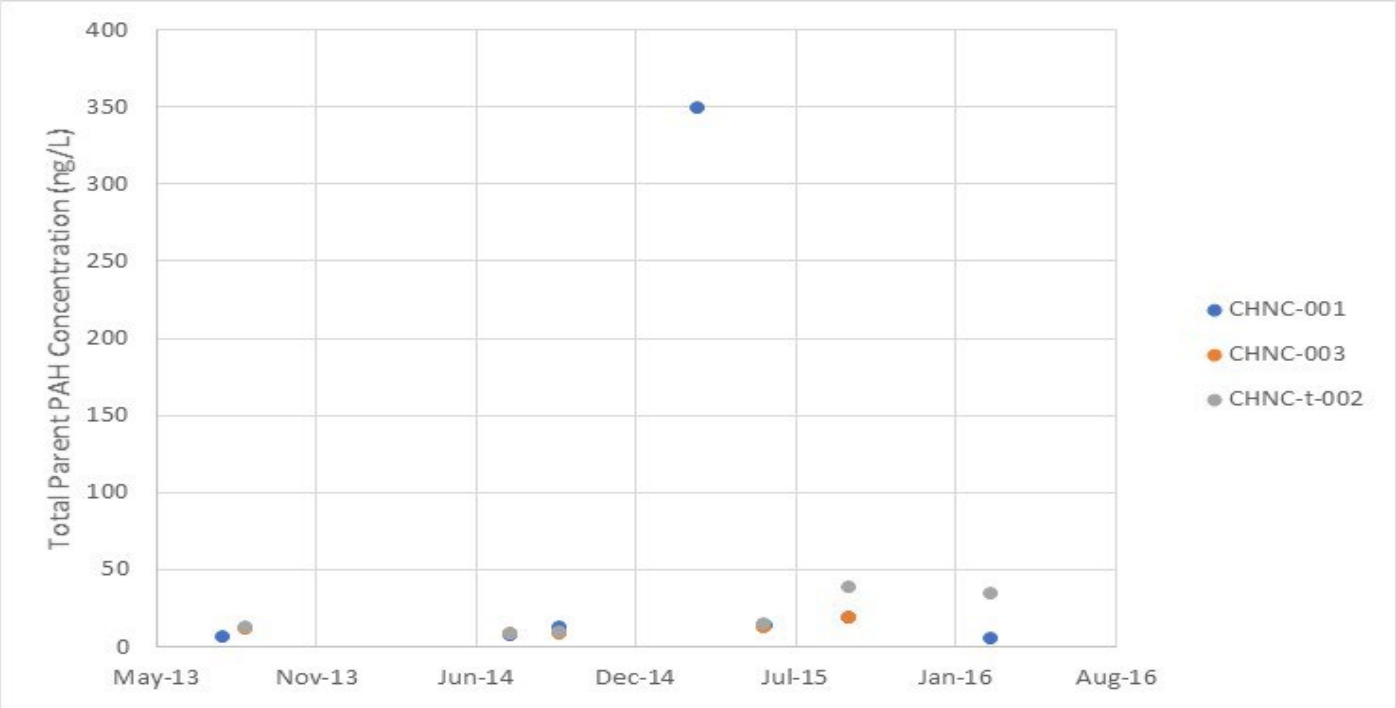

Figure 3-27. Total parent PAH concentrations in Chance Creek sites from July 2013 through March 2016.

Note: Results that were below detection were treated as 0 ng/L.

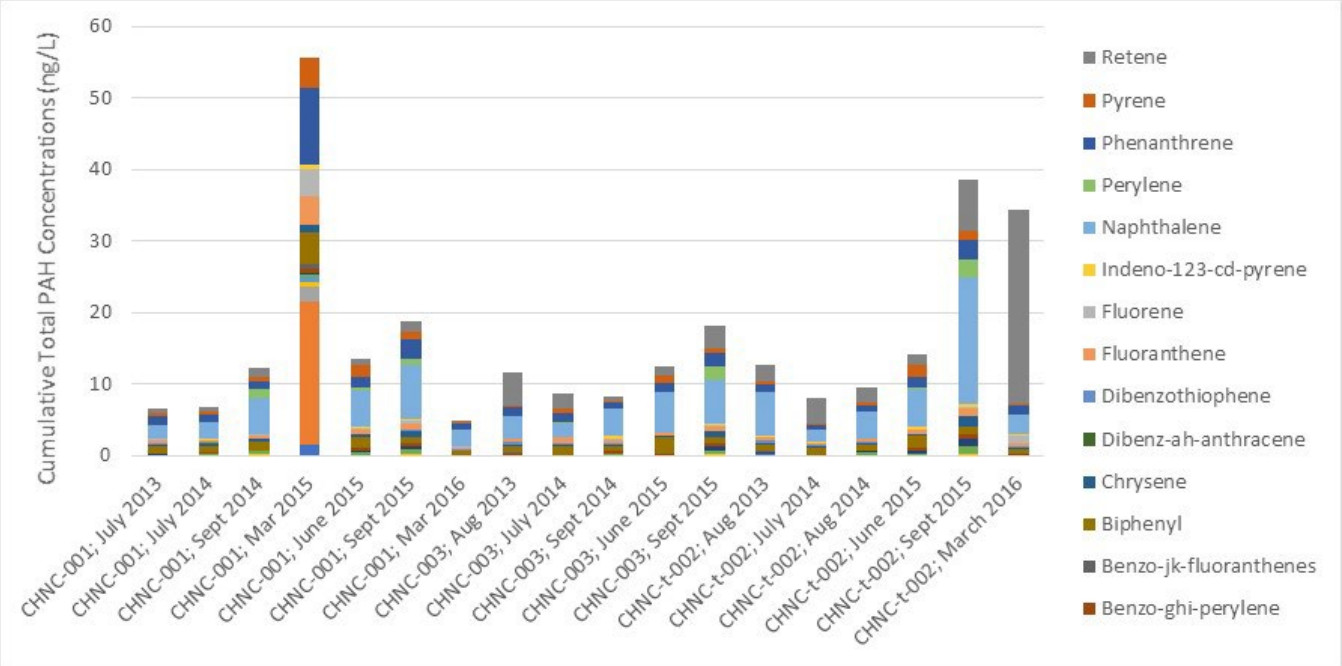

Figure 3-28. Cumulative parent PAH compounds in Chance Creek sites from July 2013 through March 2016.

Note: Results that were below detection were treated as 0 ng/L. The naphthalene at CNHC-001 in March 2015 result was removed from the bar chart due to suspected contamination error (294 ng/L).

3.1.3 EAGLE RIVER TRIBUTARIES, NORTH AND SOUTH

Water quality sampling took place in three tributaries to Eagle River, which ultimately drains into the headwaters of Porcupine River (Map 2-1):

1. NCY-PT19, an unnamed tributary that drains north from the RSA to the Eagle River (Photo 3-6);
2. EAGL-t-003, located in a tributary to the Eagle River, downstream of NCY-PT19 and EAGLE-t-002, and just upstream from the Eagle River (Photo 3-7); and,
3. EAGL-t-004, a tributary that drains the RSA south, to the Eagle River (Photo 3-8).

Water quality data were collected by YG WRB periodically at NCY-PT19 from August 2013 through September 2015. The longest sampling record in this catchment comes from EAGL-t-003, which YG WRB sampled from August 2013 through March 2018. EDI collected samples from all three sites in August 2019 and March 2020.

Photo 3-6. Upstream view from NCY-PT19.

Photo 3-7. Upstream view from site EAGL-t-003.

Photo 3-8. Downstream view from EAGL-t-004.

3.1.3.1 General Chemistry and Major Ions

Water in Eagle River tributaries (Eaglet north and south drainage) was circumneutral to slightly acidic. Conductivity was higher than noted in other RSAs, ranging from 142 to 626 µS/cm. Water hardness can be generally characterized as 'moderately hard' during the open water season and 'hard to very hard' during the under-ice months, with hardness concentrations generally greater than 60 mg/L (as $CaCO_3$).

Water was brown stained in colour, and turbidity was generally low. Turbidity showed no seasonal pattern and may be influenced by precipitation events and sampling. The suspended sediment load was generally low, ranging from <1 mg/L (below detection) to 39 mg/L; however, like turbidity, there are some spikes to approximately 182 mg/L in samples collected at various open water times of the year, which were likely associated with precipitation events or permafrost melt-related bank slumping. Major ions predominantly included bicarbonate, calcium, sodium, and sulphate (Figure 3-29); the furthest downstream site, EAGL-t-003 showed lower amounts of magnesium and higher amounts of calcium when compared with NCY-PT19.

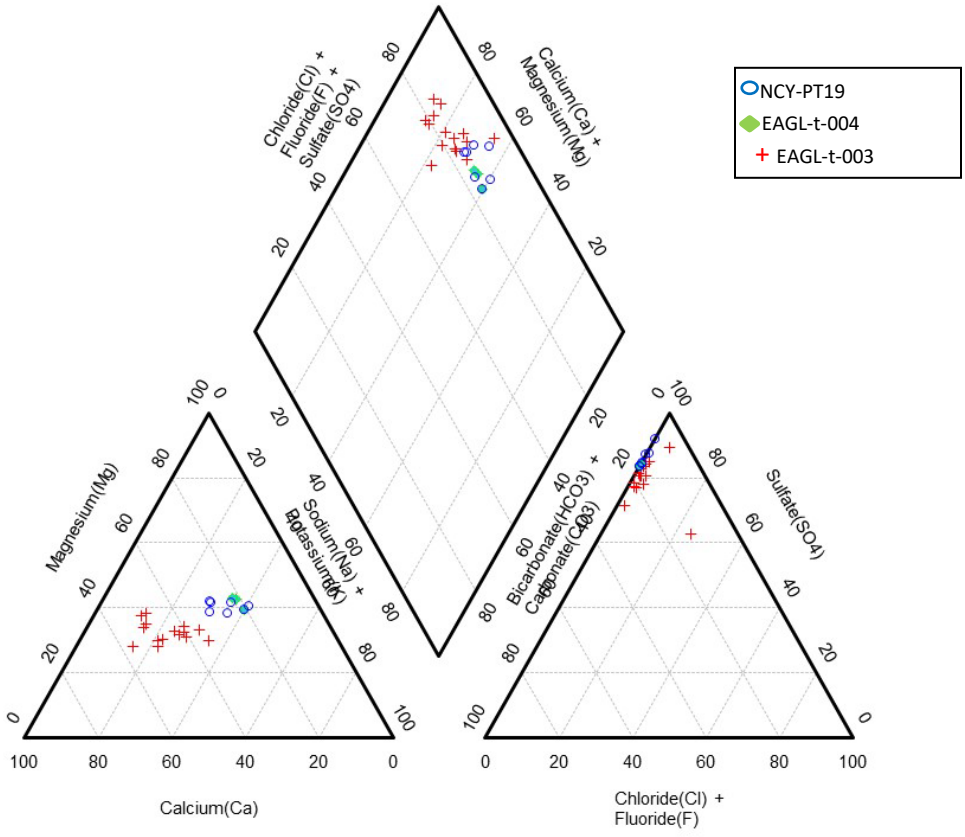

Figure 3-29. Piper plot showing major ion composition of waters in the Eaglet north and south watersheds in % meq/kg.

3.1.3.2 Nutrients

Nutrient concentrations in the Eagle Creek tributary sites were low; nitrate, nitrite, nitrate+nitrite, and total ammonia were below applicable guidelines in surface water. Total Kjeldahl Nitrogen ranged from 0.48 to 1.00 mg/L (NCY-PT19 in July 2014). Total phosphorus concentrations ranged from 0.014 to 0.05 mg/L, indicating mesotrophic trophic status (Table 2-5).

3.1.3.3 Trace Metals

Aluminum, cadmium, copper, iron, manganese, and selenium in the Eagle Creek tributary sites occurred in concentrations that regularly exceeded the CCME-FAL guideline. Total aluminum exceeded the CCME-FAL guideline in nearly all samples from all sites; however, the dissolved fraction of aluminum was below the CCME-FAL guideline in all but one sample (Figure 3-30 and Figure 3-31). Total and dissolved cadmium and selenium exceeded the CCME-FAL, a small number of samples associated with under-ice sampling (Figure 3-32, Figure 3-33, Figure 3-40, and Figure 3-41). Total and dissolved copper, iron, and manganese regularly exceeded their respective CCME-FAL guidelines (Figure 3-34 to Figure 3-38).

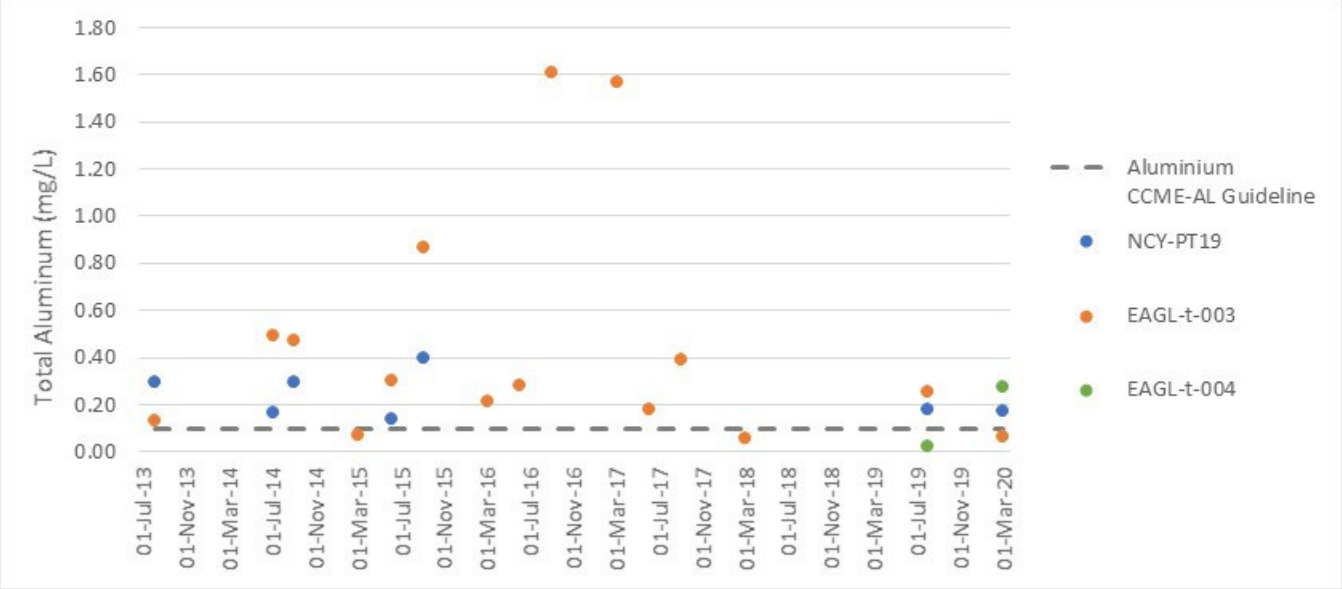

Figure 3-30. Total aluminum concentrations in Eagle Creek tributary sites between July 2013 and March 2020.

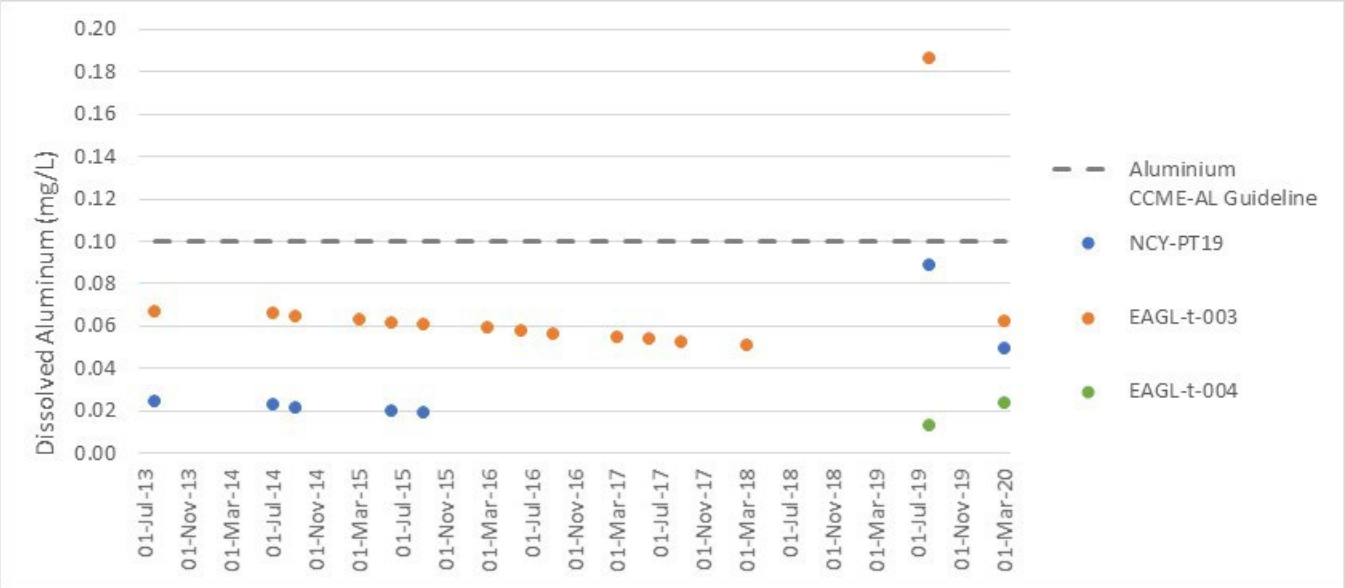

Figure 3-31. Dissolved aluminum concentrations in Eagle Creek tributary sites between July 2013 and March 2020.

3.1.3.4 Hydrocarbons

As in McParlon Creek, hydrocarbons including VHs, VPHs, and (VOCs were undetectable throughout the Eagle Creek sample sites. The PAH concentrations were higher at EAGL-t-003 than at NCY-PT19 (Figure 3-42). The PAHs that comprised the majority of total parent PAHs at the Eagle Creek tributary included naphthalene, phenanthrene, and biphenyl (Figure 3-43).

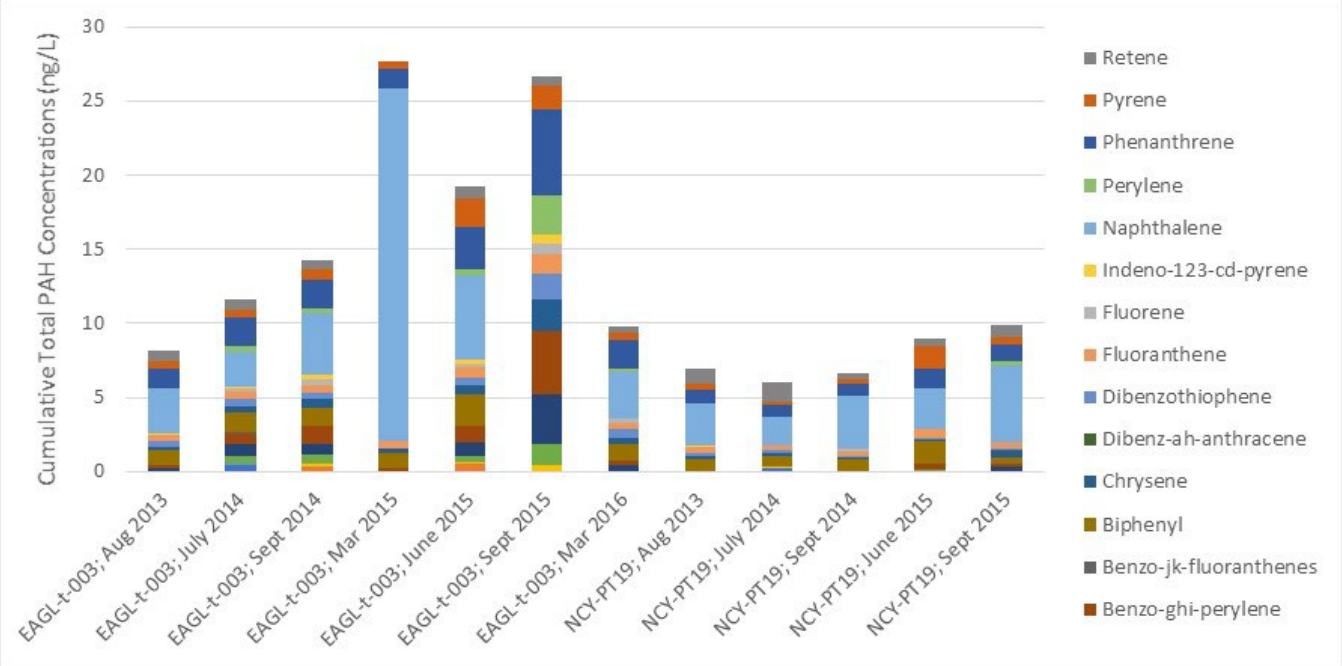

Figure 3-43. Cumulative parent PAH compounds in Eagle Creek tributaries from August 2013 through March 2016.

Note: Results that were below detection were treated as 0 ng/L.

3.1.4 DALGLISH CREEK

Dalglish Creek drains the RSA to the south, emptying into the Peel River. Water quality data were collected from two locations:

1. DALG-003, located on Dalglish Creek, in the upper reaches of the tributary (Photo 3-9); and,
2. DALG-002, located on Dalglish Creek, just upstream of the Peel River (Photo 3-10).

Water quality data were collected by YG WRB periodically at DALG-002 from September 2014 through March 2018. DALG-003 was sampled by EDI in August 2019 but was frozen to bed in March 2020.

Photo 3-9. Upstream view from DALG-003.

Photo 3-10. Upstream view from site DALG-002.

3.1.4.1 General Chemistry and Major Ions

Water in Dalglish Creek was circumneutral to slightly acidic. Conductivity was higher than noted in other areas, ranging from 61 to 886 µS/cm. Water hardness can be generally characterized as 'soft to moderately soft' during the open water season and 'very hard' during the under-ice months (Table 2-4).

Water was brown stained in colour, and turbidity was generally low. The suspended sediment load was variable throughout the year, with higher total suspended solids (TSS) samples likely associated with freshet and other rainfall events; it is suspected that elevated TSS in under-ice samples was associated with the sampling event itself, as the augur may have disturbed bottom sediments. Major ions predominantly comprised bicarbonate, calcium, magnesium, and sulphate (Figure 3-44).

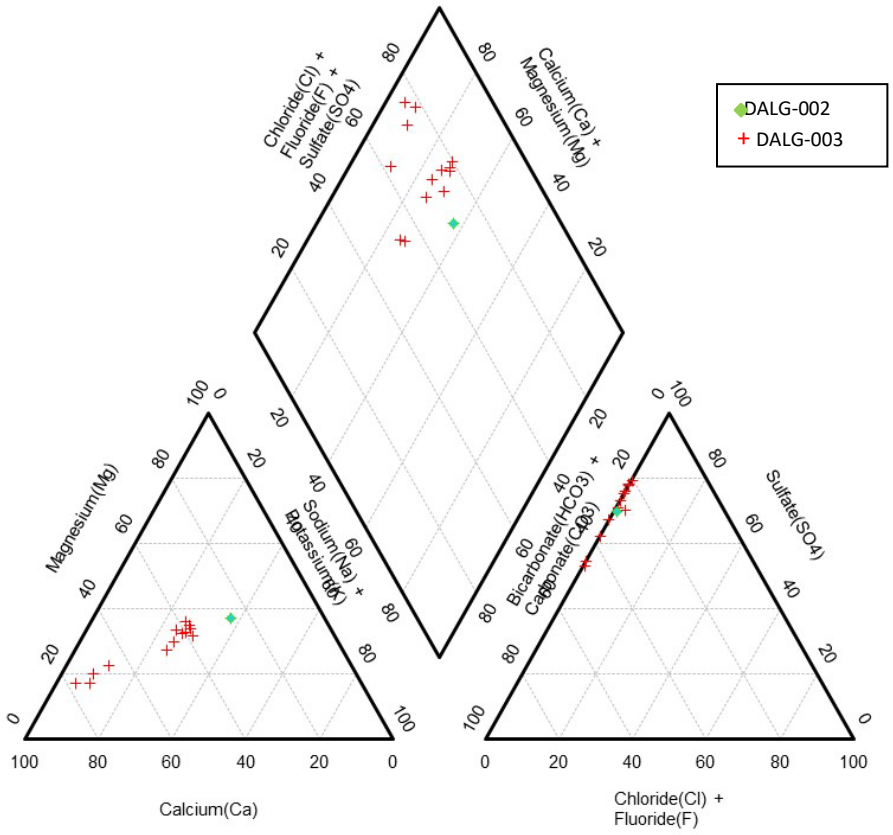

Figure 3-44. Piper plot showing major ion composition of waters in the Dalglish watershed in % meq/kg.

3.1.4.2 Nutrients

Nutrient concentrations in the Dalglish Creek sites were low; nitrate, nitrite, nitrate+nitrite, and total ammonia were below applicable guidelines in surface water. Total phosphorus concentrations ranged from 0.017 to 0.11 mg/L, indicating mesotrophic to oligotrophic trophic status (Table 2-5).

3.1.4.3 Trace Metals

Aluminum, copper, iron, and manganese in the Dalglish Creek sites occurred at concentrations that regularly exceeded the CCME-FAL guideline. Total aluminum exceeded the CCME-FAL guideline in nearly all samples from both sites; however, the dissolved fraction of aluminum was below the CCME-FAL guideline in all samples (Figure 3-45 and Figure 3-46). Total and dissolved copper, iron, and manganese regularly exceeded their respective CCME-FAL guidelines (Figure 3-47 through Figure 3-52). Total arsenic, cadmium and selenium exceeded the hardness-specific guideline in only one sample, an under-ice sample from March 2017, when there was no visible flow at the sampling time.

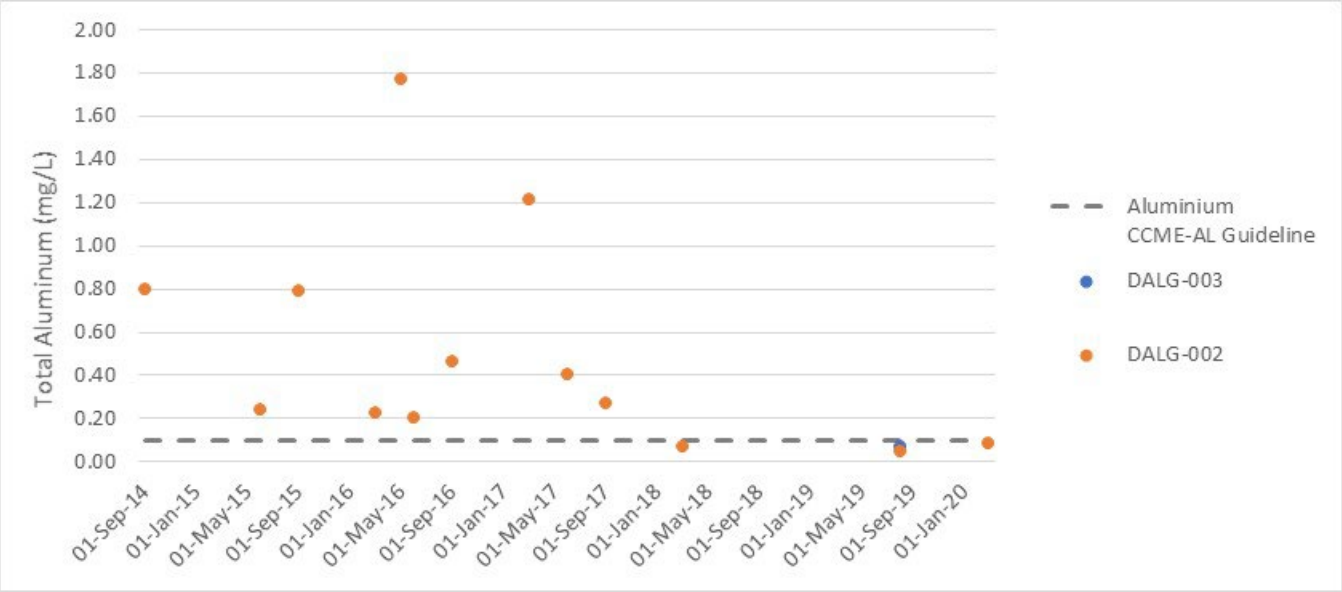

Figure 3-45. Total aluminum concentrations in Dalglish Creek sites between September 2014 and March 2020.

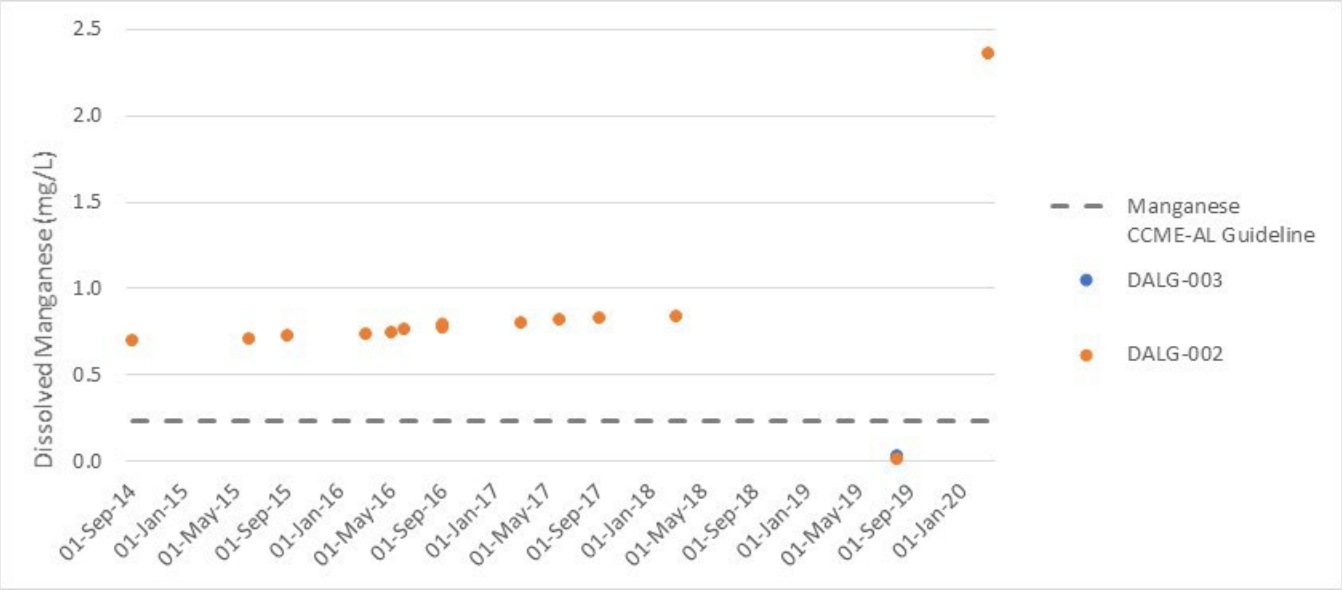

Figure 3-52. Dissolved manganese concentrations in Dalglish Creek sites between September 2014 and March 2020.

3.1.4.4 Hydrocarbons

As in the other Project sampling areas, VHs, VPHs, and VOCs were undetectable in Dalglish Creek. No seasonal/temporal pattern to PAH concentrations was identified in Dalglish Creek (Figure 3-53). The PAHs that comprised the majority of total parent PAHs in Dalglish Creek included naphthalene, phenanthrene, and retene (Figure 3-54).

3.2 HYDROLOGY

3.2.1 HYDRO-CLIMATE

ECCC meteorological data were used to evaluate daily rainfall, snowpack and temperature trends and the relationship with local and regional flow regimes in and around the RSA. The mean daily rainfall and snowpack data were calculated through the period of record available (1998 – 2005, 2007 – 2008) and plotted to identify the seasonal trends in rainfall-driven snowmelt events, annual precipitation trends and their relationship (Figure 3-55). Precipitation in the region begins to accumulate as snowpack begins as early as mid-September. Water in the region is stored as snowpack and accumulates through the winter. Spring rainfall events begin to occur as early as mid-April, increasing snowpack melt and contributing to surface water discharge. Some snowpack can be retained as late as early June, when snow depths at the Eagle Plains meteorological station will decline rapidly with sustained positive temperatures and rainfall events.

Mean daily temperature approaches 0°C in mid-April, corresponding to the first annual rainfall events, increasing frequency and magnitude beginning in May (Figure 3-56). Rainfall events occur throughout the summer months with the maximum mean daily rainfall occurring in July. Mean daily rainfall remains high in August and gradually declines through late August into September. Mean daily air temperatures decrease and approach 0°C in September and October, corresponding to the decrease in rainfall magnitude. Sustained negative temperatures over the winter result in precipitation accumulating in snowpack and refreezing the active permafrost layer. This area is classed as semi-arid, and the combination of persistent low temperatures and low to moderate snowpack are considered insufficient to insulate the ground fully, and cold penetration contributes to a thin permafrost active layer (Palmer Environmental Consulting Group 2015). The continuous permafrost thickness is reported between 61 to 244 m, with an average active layer depth of 0.74 m.

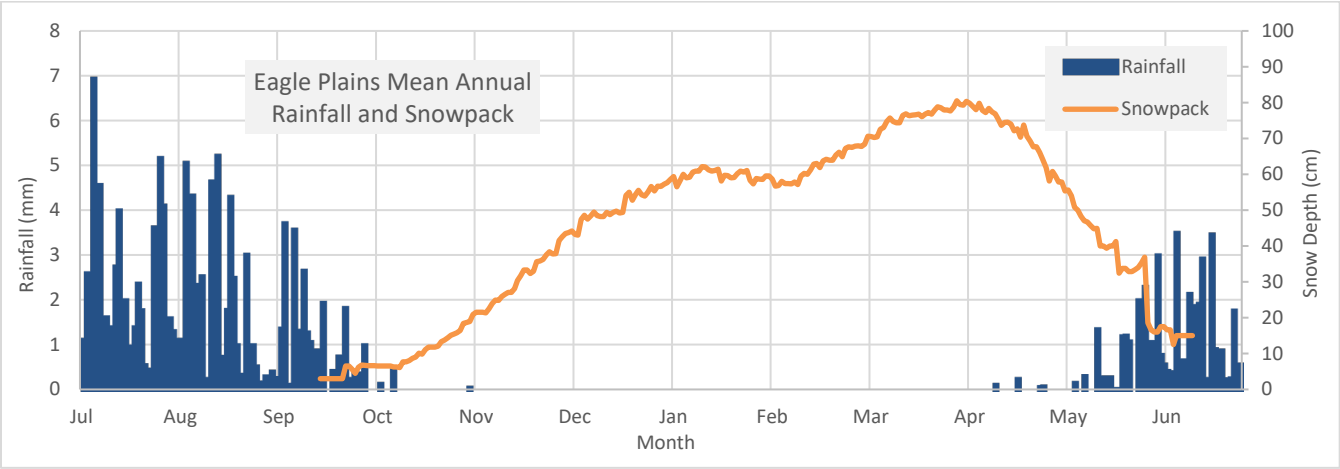

Figure 3-55. Mean daily rainfall and snowpack data averaged over the entire period on record from the Eagle Plains meteorological station (1998 – 2005, 2007 – 2008).

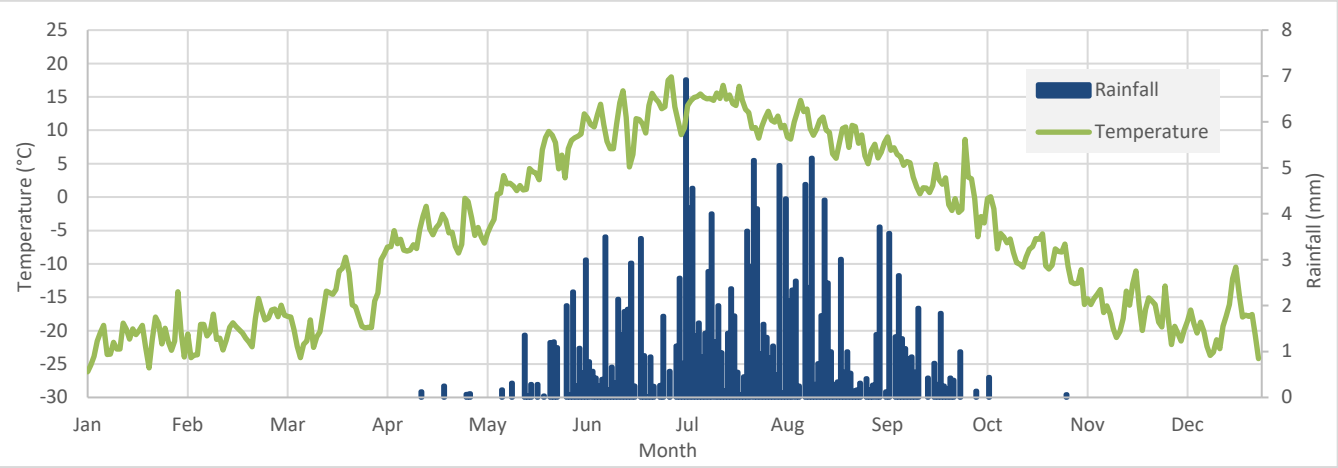

Figure 3-56. Rainfall and temperature data averaged over the entire period on record from the Eagle Plains meteorological station (1998 – 2005, 2007 – 2008).

3.2.2 REGIONAL SURFACE FLOW TRENDS

The WSC data were used to evaluate annual discharge trends in the region and inform a surface water flow regime baseline. Mean daily discharge data for each station's entire period of record was plotted (Figure 3-57) to identify the timing and magnitude of peak events such as spring freshet and compare the trends with the regional flow regimes to better inform site-specific baseline flow regimes. Regional flow trends are consistent with a northern climate where flows are primarily driven by spring snowpack melt (freshet). This is evident in the high peak flows during late April to late May, with a rapid recession following freshet events. Flows are generally stable over the summer months and sustained by baseflow contributed by inter-flow in surficial material or suprapermafrost water. Rainfall events drive peaks in the summer discharge. During late September through early October discharge decreases regionally as precipitation accumulates as snowpack and the active layer refreezes. Flows continue to decline over the winter, with low flow or zero-flow periods occurring annually from February into April.

Flows continue to decline from October into the winter period, and WSC data indicate these higher-order watercourses do not tend to exhibit zero-flow levels (Figure 3-58). The lowest flow period in the region is typically observed between late February and early April, with some occurrences observed as early as February 9 and as late as May 1.

Peak flows in the region are commonly observed between early and mid-May. Some precipitation-driven maximum discharge outliers occur after freshet as late as August 12. Table 3-1 indicates the three most extreme minimum and maximum flow values on record and the date on which the values were observed. Most maximum discharge values occurred in May, and most minimum discharge values occurred in April, and the timing of both are characteristic of snowmelt-driven flow regimes.

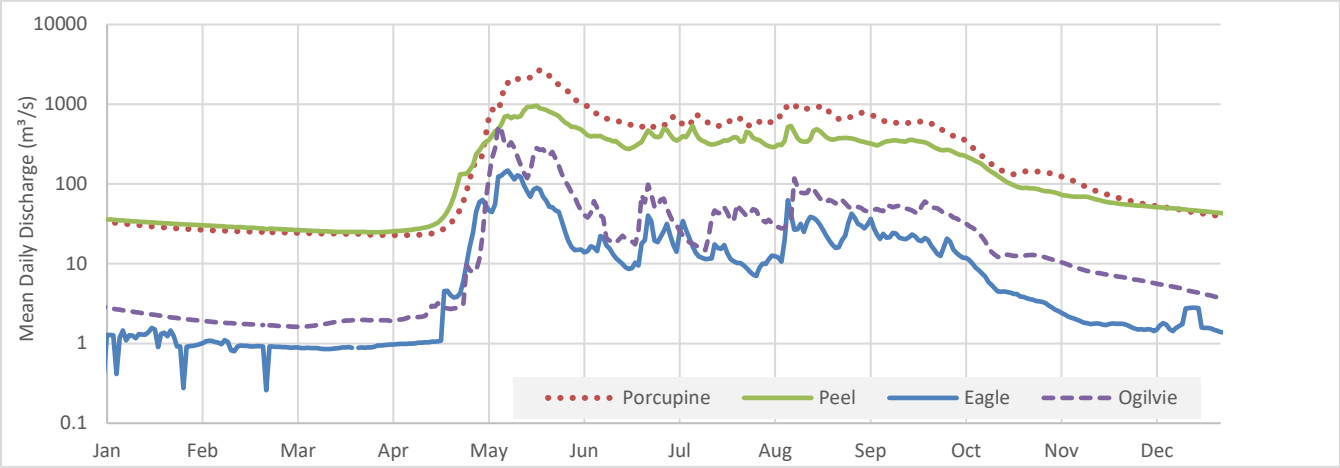

Figure 3-57. Mean daily discharge over available periods of record for the Eagle, Ogilvie, Porcupine and Peel Rivers. Note: = discharge values are displayed on a logarithmic scale.

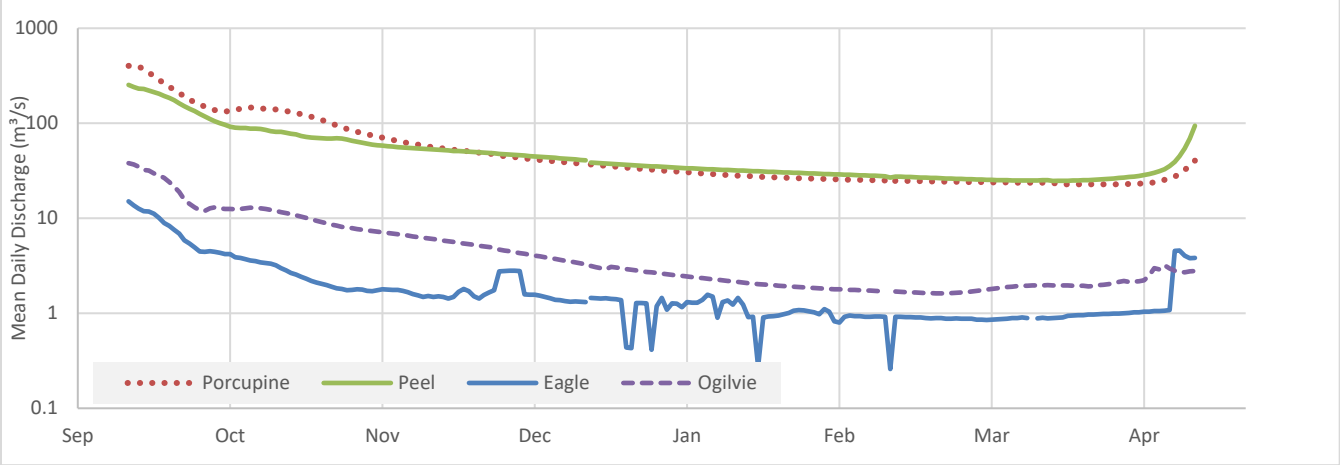

Figure 3-58. Fall and winter low flow mean daily discharges for the period on record for the Eagle, Ogilvie, Porcupine and Peel Rivers. Note: discharge values are displayed on a logarithmic scale.

Table 3-1. The minimum and maximum recorded mean daily discharge values for the entire period on record for Eagle, Peel, Ogilvie, and Porcupine rivers.

Watercourse	Minimum Recorded Discharge		Maximum Recorded Discharge	
Eagle River	0.152 m^3/s	April 27, 2017	334 m^3/s	May 19, 2015
	0.164 m^3/s	April 13, 2014	294 m^3/s	May 15, 2019

	2.41 m^3/s	April 1, 2020	510 m^3/s	May 16, 2017
Porcupine River	12.5 m^3/s	March 23, 2008	6320 m^3/s	May 25, 2011
	13.8 m^3/s	April 1, 2005	5770 m^3/s	May 16, 2015
	13.8 m^3/s	April 13, 2006	5600 m^3/s	May 18, 2019

3.2.3 TRIBUTARY SURFACE FLOW TRENDS

The WRB data for McParlon and Dalglish creeks were used to establish baseline flow trends for watercourses originating within the RSA. Mean daily discharge data for the period of record (Figure 3-59) were evaluated to identify timing and characteristics of peak flow events and compare the tributary and regional flow regimes. The peak flows are primarily snowmelt driven, tributary watercourses originating from the RSA exhibit high flow variability and flashiness between May and October. Precipitation events create short flashy discharge events followed by discharge returning to baseflow conditions (Figure 3-59). The two tributary watercourses exhibit similar flow regiments and discharge values, which is expected given their close geographical proximity. Both creeks either de-water or freeze to bed between early October and late April. No flow data are available for this period.

Discharge data for each tributary creek originating in the RSA were compared with the flow regime of each of the respective regional destination watercourse to compare the timing of peak flow events, low flow periods and the duration of these events (Figure 3-60 and Figure 3-61). The flow regimes in the destination watercourses have a lag relative to the tributary watercourses. However, the flow responses are similar. The regional watercourses respond to precipitation events more slowly. The peaks in discharge are longer duration than in the flashy tributaries, reflecting the cumulative inputs from tributaries over a larger contributing area.

McParlon Creek and Dalglish Creek exhibit zero-flow (defined as discharge < 1L/s) during the winter months. Data gaps exist between early October and late April where the channels freeze to bed, de-water, or channel ice inundates water level loggers and these channels are at zero-flow for most or all this period. Peak flows in the tributaries tend to occur in late April through early May, and in the regional watercourses in mid-May through early June. In the tributaries, flashy discharge is observed resulting from rainfall events throughout May to October. As indicated in Table 3-2, precipitation-driven peak flow outliers in the

tributaries may occur as late in the summer as August 11 in McParlon Creek and August 8 in Dalglish Creek and fluctuations in the discharge through the duration of the record also reflective of precipitation events.

The comparison between the tributary and regional watercourses shows similarities between the patterns and timing of the flow regimes. Lags between tributary and regional watercourses are variable related to the magnitude of the event driving the discharge fluctuation.

The regional and tributary watersheds are snowmelt driven, with seasonal inputs from rainfall, and little to no groundwater influxes to support the low flow winter periods after the active permafrost layer freezes seasonally. Groundwater – surface water interactions in these watersheds are limited to suprapermafrost perched groundwater within the shallow active layer of the permafrost. Water movement to surface flow is limited in these watersheds to direct runoff and interflow and lateral migration through the active layer, driven by precipitation or snowmelt, during the season of thaw in the active layer.

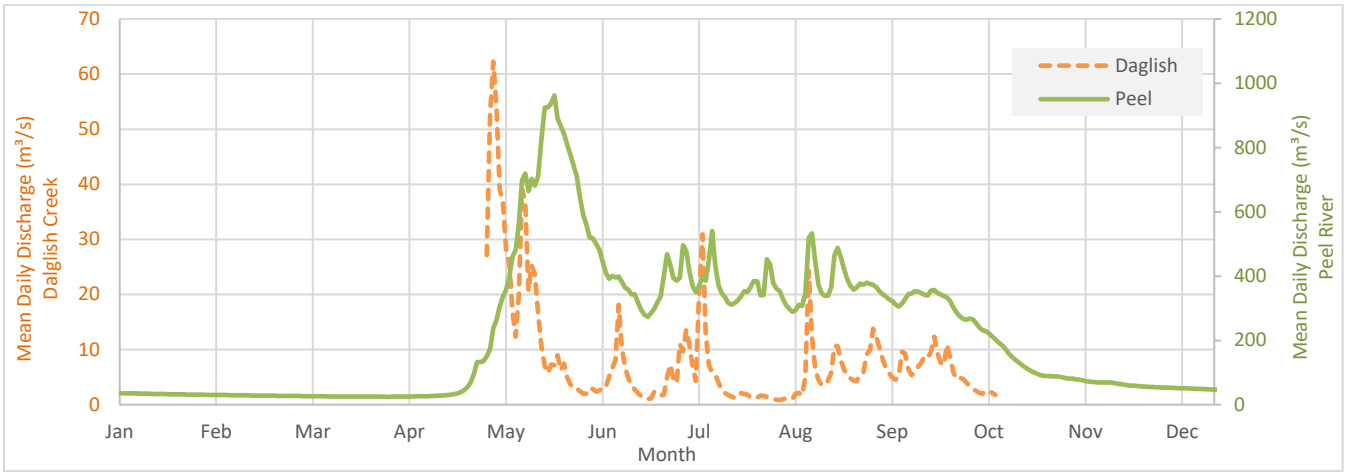

Figure 3-61. Comparative discharge plot for mean daily discharge for Dalglish Creek and Peel River for the periods record.

Table 3-2. Maximum discharge values for the entire period on record for tributary watercourses McParlon and Dalglish creeks.

Watercourse	Maximum Recorded Discharge	Date
McParlon	138.92 m³/s	May 14, 2015
	131.49 m³/s	August 11, 2016
	64.58 m³/s	May 5, 2014
Dalglish	106.75 m³/s	July 7, 2015
	82.10 m³/s	August 8, 2016
	70.85 m³/s	May 5, 2014

4 DISCUSSION AND SUMMARY

4.1 WATER QUALITY

Water quality was comparable across the RSA, with neutral to slightly acidic, brown-stained water due to tannic acids from surrounding sediments/soils. Variable turbidity and TSS concentrations were likely associated with melting permafrost and resulting slumping banks that continuously deposit material into the water columns. Water hardness ranged from soft to moderately soft in the open water season, changing to moderately hard to hard during the winter, under-ice season. Water hardness affects the toxicity of various metals in the water column; harder water can bind with more metals, rendering them less bioavailable to aquatic biota.

Dissolved oxygen concentrations were highest during freshet but decreased throughout the summer and were low throughout the RSA during the under-ice season. Most streams in the RSA are small and freeze to the substrate in the winter except for some isolated pools. These winter conditions result in minimal to no stream flow and, consequently, low dissolved oxygen concentrations that provide fish with little to no overwintering habitat.

The primary source of ions to natural surface waters is the weathering of rocks. Therefore the chemical composition of the water reflects the local geology. The dominant ions in all areas were bicarbonate, calcium, and sulphate.

Nutrient concentrations were generally low across the RSA. Concentrations of nitrogen compounds were low to below laboratory detection, and total phosphorus concentrations indicated that streams were oligotrophic to mesotrophic. Low nutrient concentrations combined with cold water temperatures and low dissolved oxygen concentrations result in low-productivity streams throughout the RSA.

Metals including aluminum, cadmium, copper, iron, and manganese were present throughout the RSA at concentrations that exceeded the CCME-FAL guidelines. Additionally, some other metals were present at concentrations above the CCME-FAL in isolated samples from each watershed area, including arsenic from Chance and Dalglish creek sites, and selenium from McParlon, Eagle and Dalglish creek sites. These metals are naturally present and enter the surface water environment through various processes, including the weathering of rocks, atmospheric deposition, permafrost melting, and the subsequent sediment introduction of the watercourses.

Volatile organic carbons were not present at or above laboratory detection limits at any of the sample locations. Common PAHs present in the RSA included naphthalene, biphenyl, phenanthrene, and retene. These PAHs are associated with natural processes, including forest fires (retene; Gabos et al. 2001) and naturally occurring oil and gas deposits in the area.

4.2 HYDROLOGY

Hydrological regimes observed in the study area are characteristic of snowmelt-dominated flow regimes of northern climates. Regional watercourses (i.e., stream orders 6 and greater) exhibit peak discharge in May when temperatures increase, rain melts the snowpack, and stored water is rapidly discharged as surface water flow. Over the summer, the flow in large watercourses is sustained by rainfall events, and to a lesser extent, shallow suprapermafrost lateral flows in the active layer. In the fall, when precipitation begins to be stored as snowpack and the active permafrost layer begins to refreeze, discharge trends downward from September and more rapidly through October when temperatures decrease below 0°C. Annual low flows occur over the winter, with the lowest discharge rates occurring during February, March, and April.

As stream order decreases, the relative response, both in time and magnitude, of discharge rates increases in response to precipitation events because of smaller contributing areas to the watercourse. As temperatures decrease below freezing between October and November, precipitation begins to become stored as snowpack, and the active layer begins to re-freeze and subsequently discharges decrease rapidly and most tributary streams either de-water or freeze to bed by March. Tributary watercourses within the RSA do not exhibit flow again until the following spring melt begins. Intermediate order watercourses like McParlon and Dalglish creeks may retain limited water in residual pools and water quality metrics, such as very low dissolved oxygen, were indicative of zero or very low flow.

The hydrology metrics within the RSA are consistent with hydrology for similar watercourses across northern Canada, and more specifically, within the Yukon River Basin (Brabets et al. 2000, Buttle et al. 2012). Studies on hydrology report similar hydrograph trends for snowmelt-dominated watersheds, both in current research and historically. The general trend describes minimal runoff and a corresponding decrease in streamflow, beginning in October and ending in late April. Regionally, runoff occurs from May to September, dependent on basin characteristics, including drainage area. In some watersheds, including the Porcupine, winter low flow periods approach zero flow, and this is attributed to continuous permafrost, which is effectively a barrier to groundwater influxes to the surface water. The thin active layer of the permafrost does not retain storage capacity for groundwater, and suprapermafrost groundwater perched on the permafrost is only seasonal lateral migration of interflow, or seasonal melt water. Zero flow conditions are not observed in the larger watercourses and mainstem channels because the discharge is a cumulation of the flows from large catchment areas. Locally there may be a thicker active layer that supports flows later into winter before the freeze is complete.

The literature reports that climatic conditions influence observed flows. These conditions drive channel freeze up and thaw, snowmelt, precipitation, runoff, and permafrost — all of which influence the timing and amount of groundwater influxes to suprapermafrost water within the active layer. The literature indicates that streams that reach or approach zero-flows seasonally are predominantly in headwater (lower order) catchments — supporting what the hydrology data show for the RSA.

Applied Guidelines: 'Federal CCME Canadian Environmental Quality Guidelines 2018), CCME: Freshwater Aquatic Life

Hardness-Dep = Hardness Dependent guideline for CCME-WATER-AL

[a] The CCME WATER-AL guidelinefor total ammonia-N is temperature and pH dependent

[b] The CCME WATER-AL guideline for aluminium is lowered to 0.005 mg/L when pH is below 6.5

[c] The CCME WATER-AL guideline for dissolved zinc is hardness and dissolved organic carbon dependent

COLOUR KEY:

Exceeds CCME Guideline

QA/QC Codes: RPD - Relative Percent Difference, <DL - below detection limit, and <2XDL - less than two times the detection limit.

Water quality results, Chance Oil and Gas

EXECUTIVE SUMMARY

The Eagle Plains Project (the Project) is an oil and gas exploration program in north-central Yukon, approximately 605 km north of Whitehorse along the Dempster Highway. Chance Oil and Gas Ltd. intends to conduct exploratory activities over 10 years to confirm the quality, quantity, and areal extent of hydrocarbons. Project activities will include seismic exploration and exploratory wells supported by an expanded winter road network. The purpose of this study was to collect information to understand better the distribution of fish and fish habitat across the Regional Study Area (RSA) in both summer and winter. This information will be used to assess the Project's potential effects on fisheries values and guide measures to mitigate effects, if warranted.

The RSA is located within the Eagle Plains Ecoregion, which consists of a relatively subdued topography of rolling hills and sloping plains between the Richardson and Ogilvie Mountains. The RSA is centred on a local height of land, with areas to the north and west draining into the Yukon River (Pacific) system via the Porcupine watershed, and areas to the southeast draining into the Mackenzie River (Arctic) system via the Peel watershed. The largest named streams in the RSA include Chance (Porcupine), McParlon (Porcupine), Dalglish (Peel), and Enterprise (Peel) creeks. The RSA encompasses 1,467 streams, most of which are smaller headwater streams; there are 1,142 first-order streams[1], 239 second-order, 68 third-order, 16 fourth-order, and 2 fifth-order streams in the RSA. Few ponds and lakes occur in the RSA, with none greater than 5 ha. Before this study, very little was known about fisheries values in the RSA; Arctic grayling had been detected in a handful of locations across the RSA.

This study aimed to determine fish occurrence patterns across the RSA. This included: (i) a quantitative estimate of the probability of fish occurrence in all streams during summer and (ii) a more qualitative description of fish distribution based on habitat in winter (due to limitations in surveying fish presence during the winter). Due to the large number of streams in the area it was not possible to survey all streams that had the potential to be affected by exploration activities. Instead, a predictive, model-based approach was used, like a recent study conducted by the Yukon Government in the adjacent Peel watershed. The approach consisted of surveying a representative subsample of streams across the RSA and interpolating the probability of fish presence at all streams in the RSA using a statistical model. The environmental variables considered in the model included: stream order, stream slope, terrain slope, elevation, catchment area, and, as measures of potential overwintering habitat, distance to third-, fourth-, and fifth-order streams, as well as the distance to in-line ponds. The relationship between fish presence and environmental conditions was analyzed using logistic regression. Models with different combinations of the environmental variables were compared using corrected Akaike Information Criterion (AIC) scores.

To obtain a representative subsample of streams to support statistical analyses, survey sites were selected using a stratified random design, stratifying by stream order. Summer field surveys included fish sampling, habitat assessment, and water quality sampling. Fish sampling involved electrofishing supplemented with minnow trapping at a subsample of sites. Fish habitat descriptions included a broad suite of stream characteristics, such

[1] Stream order refers to the relative position of a stream within a watershed and is based on the number of upstream tributaries. The greater the stream order number, the larger the stream and the lower/further downstream it occurs within a watershed.

as stream width and depth, gradient, type and extent of cover, and type of bed material, as well as qualitative assessments of spawning, overwintering and rearing potential. Water sampling included temperature, turbidity, conductivity, and dissolved oxygen. In winter, sampling initially required drilling holes through the ice to determine if water was present. If water was present, the presence of fish was assessed with an underwater camera and water temperature, conductivity, and dissolved oxygen were measured. A total of 118 sites were surveyed in the summer, from July 25 to August 1, 2019, and 49 sites were surveyed in the winter, from March 7 to 13, 2020.

Survey results showed clear fish distribution patterns in summer and habitat availability for fish during winter. In summer, the best model for fish occurrence was based solely on stream order. The probability of fish occurrence was 8% in first-order streams, 45% in second-order, 89% in third-order, 99% in fourth-order, and 100% in fifth-order streams. Fish were detected in almost none of the first-order streams, half of the second-order streams, and almost all third-order and greater streams during summer sampling. The variability of fish presence in second-order streams was partly attributable to differences in site-specific conditions (e.g., different channel widths and stream depths at different streams); however, across many second-order streams the intermediate probability of fish occurrence simply reflects marginal fish habitat conditions. Five fish species were captured during the summer sampling program. Arctic grayling (*Thymallus arcticus*) were the most widespread captured species, accounting for 85% of captured fish. Slimy sculpin (*Cottus cognatus*), longnose sucker (*Catostomus catostomus*), round whitefish (*Prosopium cylindraceum*), and burbot (*Lota lota*) were also captured in limited numbers and locations. No salmon were observed in the RSA, consistent with historical information about salmon distribution within the area. In terms of habitat, most streams (all streams in the Porcupine watershed) consisted of low gradient, slow-moving streams with turbid water and bed materials dominated by fines and organics. Most streams were rated as having low spawning potential and moderate summer rearing potential for most fish species.

Winter field assessments determined that most first-, second- and third-order streams either freeze to bed or dewater during the winter. The presence of water at one second-order stream and four third-order streams all occurred in residual pools in ponds the streams flowed through. The outlet channels of these ponds were all dewatered, indicating that water was limited to residual pools and no stream flow was present. Of the 16 fourth- and fifth-order streams surveyed, 63% of the sites contained water, but the majority also appeared to be residual pools with no flow; only four sites had evidence of flowing water. Of the fifteen sites where water was detected, only one site had dissolved oxygen levels able to support fish. No fish were detected via underwater cameras.

The results of this study indicated a dynamic pattern of fish occurrence in the RSA between summer and winter. Overwintering habitat is very limited in the RSA and most fish likely migrate out of the RSA to find suitable overwintering habitat in larger rivers. The lower reaches of Chance Creek and select sites along McParlon, Dalglish, and Enterprise creeks may offer limited overwintering habitat to a small number of fish (based on water conditions in March 2020 and the presence of non-migratory slimy sculpin at some sites). During summer, transient fish, most notably Arctic grayling, travel tens to greater than 100 km from larger, higher order rivers outside the RSA to use second order and greater streams as seasonal rearing habitat.

ACKNOWLEDGEMENTS

This work was completed within the traditional territories of the Vuntut Gwitchin First Nation (VGFN), First Nation of the Na-Cho Nyäk Dun, and the Tetlit Gwich'in Council (Secondary Use Area). Tyrel Kassi, a VGFN citizen, played an active role in all field components of the project. We thank him for the diligence and perspectives that he shared during the project. During summer fieldwork, crews include Petra Szekeres (EDI crew lead), Pat Tobler (EDI crew lead), Matt Power (EDI), Jonathan Lowey (EDI), and Tyrel Kassi (a VGFN member). Winter fieldwork was conducted by EDI employees Petra Szekeres (lead), Jonathan Lowey, and Tyrel Kassi. Horizon Helicopters provided transportation to sampling sites for both field trips.

1 INTRODUCTION

1.1 PROJECT DESCRIPTION

The Eagle Plains Project (the Project) encompasses a 2,386 km² area in north-central Yukon, approximately 600 km north of Whitehorse and 40 km south and west of Eagle Plains Hotel, along the Dempster Highway (Map 1-1). The Project occurs within the Eagle Plains petroleum basin, north of the Ogilvie River and west of the Richardson Mountains. The basin contains proven natural gas and oil reserves (Peel Watershed Planning Commission 2019), including 4.6 billion m³ of gas and 3.2 million m³ of oil (Hannigan 2014).

The Regional Study Area (RSA; Map 1-1) has had intermittent periods of oil and gas exploration since the 1950s. That activity has resulted in the development of winter roads, seismic lines, and exploratory wells across parts of the current RSA. Approximately 40 exploration wells have been drilled at Eagle Plains. Eight wells are currently being maintained in suspended status and the remaining wells have been decommissioned. Seismic exploration has included approximately 10,000 km of two-dimensional (2D) lines (mostly before 1985), and about 325 km² of three-dimensional (3D) seismic was conducted in 2013/2014 (Northern Cross (Yukon) Ltd. 2014).

The current exploration program will build on past exploration to better define the extent, amount and quality of oil and gas deposits in the area. Under the current program, Chance Oil and Gas Ltd. Proposes conducting additional seismic exploration over large extents of the RSA and drill up to 30 exploratory wells over 10 years. Depending on the results of the drilling program, extended flow testing may be conducted over several months at a subset of the wells to determine the quantity and quality of the oil and gas deposit. The existing winter road network will be expanded to support the seismic and drilling programs. Most work is expected to be conducted in the winter (e.g., seismic line clearing and drilling); however, seismic recordings and extended flow testing may also occur during summer.

1.2 PURPOSE AND OBJECTIVES

Baseline environmental information and data are required for proposed oil and gas projects submitted to the Yukon Environmental and Socio-economic Assessment Board (YESAB) Executive Committee for screening under the *Yukon Environment and Socio-Economic Assessment Act* (YESAA), as well as applications submitted for an Industrial Licence and Type A Water Licence from the Yukon Water Board, among other permits and licences (YESAB 2016).

Aspects of the Project activities (e.g., winter operations using winter roads that avoid soil disturbance) and design (e.g., location of roads to avoid streams and riparian areas) will minimize the potential effects of the Project on fish and fish habitat; however, a small number of streams will need to be crossed. The purpose of this study was to collect baseline information on fish and fish habitat within the RSA. This information can be used to assess the Project's potential effects on fish and fish habitat in the permit proposal to the YESAB and support management measures to mitigate potential effects.

The overall objective of the 2019 and 2020 fisheries and aquatics study was to collect information on fish occurrence across the range of streams within the RSA and use predictive modelling to quantify the probability of fish presence in all streams within the RSA.

The specific objectives of this study were to:

- develop and implement a fish occurrence inventory across the RSA during summer, including:
  - compiling historic fish occurrence data;
  - assembling relevant stream variables to support survey stratification and statistical modelling;
  - developing stream stratification criteria and conducting a stratified random sample to obtain a representative field sample;
  - conducting fish and fish habitat surveys using standardized field survey methods;
  - quantifying relationships between fish presence and environmental variables using statistical models and using the results to predict the probability of fish presence across the remaining streams in the RSA;
- conduct winter water level and quality surveys to determine potential overwintering habitat within the RSA; and,
- provide recommendations for using the results of this study for the YESAB assessment and management measures to mitigate the project's potential effects on fish and fish habitat.

Fish surveys were conducted in July and August when fish distribution is likely most widespread. It was predicted that fish presence was greatly reduced in lower-order streams in winter due to reduced water flow and water quality (i.e., dissolved oxygen). This is due to the lack of permafrost melting as a water source in winter and the general lack of groundwater sources in permafrost-controlled systems (Connon et al. 2014). To address this issue, winter surveys were also conducted to assess water levels and quality across various stream types within the RSA.

1.3 STUDY AREA

The Project encompasses 2,386 km² (238,566 ha), centred in the Eagle Plains Ecoregion in north Yukon. The area consists of subdued topography of rolling hills and sloping plains. The Dempster Highway crosses the southern portion of the RSA (Map 1-1) along a local height of land. From there, the RSA drains into the Porcupine River watershed to the north (via Chance Creek) and west (via McParlon Creek and the Whitestone River) and into the Peel River watershed to the southeast (via Dalglish Creek).

The RSA overlaps four First Nation traditional territories. Most of the RSA is located within the traditional territory of the Vuntut Gwitchin First Nation (VGFN). The southeastern portion is in an area of overlapping traditional territories of VGFN, the Tetlit Gwich'in Council (TGC), the First Nation of Na-cho Nyäk Dun (NND), and Tr'ondëk Hwëchin First Nation (THFN). Although the RSA is located outside any First Nation Settlement Lands, it adjoins VGFN Settlement Lands on parts of its east and southwest borders.

Anthropogenic development in the RSA and the surrounding Eagle Plains is low. The Dempster Highway is the main vehicle access corridor, running from Dawson City, Yukon in the southwest, to Inuvik, Northwest Territories, to the northeast, and transiting the RSA along the way. Several winter access roads also branch off the Dempster Highway. Past oil and gas exploration includes a network of seismic lines, in various stages of regeneration and approximately 40 well sites, all but 8 of which have been decommissioned. The Eagle Plains settlement is located along the Dempster Highway, about 30 km east of the Project boundary and consists of the Eagle Plains Hotel and the Government of Yukon's Highway Maintenance Branch.

The Project is located within the North Yukon Planning Region and Peel Watershed Planning Region and is, therefore, subject to the North Yukon Land Use Plan (NYLUP) and Peel Watershed Land Use Plan (PWLUP) (Vuntut Gwitchin Government and Yukon Government 2009, Peel Watershed Planning Commission 2019). The Project falls within the Integrated Management Area (IMA) Zone IV of both plans, with lower ecological and cultural values and the most permissible development of the four IMA zones. Both Plans describe General Management Directions for fish and fish habitat and identify potential concerns associated with water removal from sensitive and vital overwintering fish habitats, stream crossings, and seismic lines resulting in increased traffic and use of otherwise inaccessible regions and fish stocks.

1.3.1 ECOLOGICAL OVERVIEW

The Eagle Plains Ecoregion is in the Taiga Cordillera Ecozone, characterized by subarctic coniferous forest (90%), and mixed forest and Arctic/alpine tundra (5% each; Yukon Ecoregions Working Group 2004). Black spruce woodlands dominate this Ecoregion, with black spruce-tussock tundra at lower elevations, and shrub-tundra above 800 m (Smith et al. 2004). The Ecoregion is characterized by long winters, generally extending from October to May, with a mean annual temperature of −7.5°C (average −28°C in January and 13°C in July). The Eagle Plains Ecoregion has extensive permafrost, approximately 89 m deep, with the active layer in the top 1 m (i.e., thaws in summer and refreezes in the winter). Permafrost landscapes are prone to dynamic changes in the late spring and summer months due to the thawing of the active layer, resulting in changes to hydrology and overall water quality. Permafrost thaw has been occurring at unprecedented rates

in northern latitudes, characterized by elevated discharge rates, elevated silt deposits into waterways, and changes to adjacent riparian zones (e.g., slumping banks, higher sediment loads; Connon et al. 2014).

The major drainages within and adjacent to the RSA include the Porcupine (Yukon Basin) and Peel (Mackenzie Basin) river watersheds, with the subdrainages of the Eagle and Whitestone rivers entering the Porcupine drainage and the Ogilvie River entering the Peel drainage. The largest drainages within the RSA include Chance (Porcupine), McParlon (Porcupine), Dalglish (Peel), and Enterprise (Peel) creeks. The RSA encompasses 1,467 streams, most of which are smaller headwater streams; there are 1,142 first-order streams, 239 second-order, 68 third-order, 16 fourth-order, and 2 fifth-order streams in the RSA (using the Strahler method; Barker et al. 2011). Few ponds and lakes occur in the RSA, with none greater than 5 ha.

Several fish species are found in the major drainages adjacent to the RSA (Table 1-1); however, limited information was available on fisheries values within the RSA, with some available knowledge on fish presence and distribution. The only works conducted in the proximity of the RSA include work conducted by the Yukon Government for the Peel watershed that modelled the likelihood of fish presence based on different environmental variables (Barker et al. 2011), as well as preliminary baseline fish sampling in support of past oil and gas exploration in the area (Anderson Resources Ltd. 2001).

Permafrost and climate strongly affect hydrology and fish presence within the Eagle Plains Ecoregion. Low precipitation occurs in the area, with permafrost largely controlling stream flow. Groundwater flow appears to be very limited across the RSA, as the Eagle Plains Ecoregion is characterized by extensive ground ice (Smith et al. 2004). Peak stream flows are associated with snow and permafrost melt in June, with minimum flows occurring in March. Small streams, and even some intermediate-sized streams, often experience zero flows during the winter months (Smith et al. 2004). Fish presence is expected to be seasonal in response to the variable hydrology throughout the year. Due to the absence of water in lower-order streams during most months of the year, and even intermediate streams experiencing no winter flows, fish are excluded from many streams for much of the year. As a result, little suitable year-round habitat is available for resident fish, with many species instead employing transient, seasonal rearing use of local streams. Arctic grayling is a highly transient fish species and known to travel long distances (e.g., West et al. 1992, EDI 2015).

Conversely, slimy sculpin have high site fidelity and do not travel distances greater than a few hundred metres within their lifetime (Gray et al. 2004, 2018) — as such, they are often used as an indicator species for overwintering potential. Suitable overwintering habitat is often the most limiting factor for seasonal fish presence in northern latitudes and is a requirement for non-transient species. Other habitat requirements include adequate food sources and stream productivity; cover (e.g., vegetation, undercut banks) for rearing, resting, and predator avoidance; and suitable water quality metrics, notably dissolved oxygen levels (CCME 1999).

In the late 1990s, members of the VGFN discussed catching grayling in the spring and whitefish in the summer. They noted that important fishing sites in their territory were where small creeks entered the Peel River and the Ogilvie River. They observed fewer fish than many years before and fewer fish in lakes, although more in rivers (Sherry and Vuntut Gwitchin First Nation 1999, p. 249, 247).

2 METHODS

2.1 STUDY DESIGN

Limited information regarding fish presence and fisheries values within the RSA is available. Due to the large number of streams within the RSA, it was not feasible to survey all streams. Also, the exact location of Project development, including stream crossings, have not been predetermined. To address these issues, a study design was developed to predict the probability of fish presence across all streams, based on field surveys at a representative subsample of streams. This approach follows a similar study in the adjacent Peel watershed (Barker et al. 2011).

The approach uses the observed relationships between fish presence and environmental variables, such as stream order, gradient, catchment area, and adjacent vegetation, to interpolate the statistical probability of fish presence in non-surveyed streams. The authors of the Peel study indicated the importance and relevance of completing landscape-scale statistical modelling to understand the relationships between fish and their environment. They further highlighted the utility of using predictive modelling in costly or logistically difficult areas to complete comprehensive sampling, as with the Eagle Plains RSA. As such, the current study used the same approach as Barker et al. (2011), conducting a representative field-based study and using those results to support a comprehensive landscape-scale predictive model with GIS-derived environmental data to determine the probabilities of fish presence at all 1,467 streams in the RSA.

The study design included the following steps:

- compile historic fish occurrence data;
- assemble relevant stream variables to support survey stratification and statistical modelling;
- develop stream stratification criteria and conduct a stratified random sample to obtain a representative field sample;
- conduct fish and fish habitat surveys using standardized field survey methods; and,
- quantify relationships between fish presence and stream variables using statistical models and use the results to predict the probability of fish presence across the remaining streams in the RSA.

To obtain a representative subsample of streams to support statistical analyses, summer survey sites were selected using a stratified random design, stratifying by stream order. Stream order refers to the relative position of a stream within a watershed and is based on the number of upstream tributaries. The greater the stream order number, the larger the stream and the lower/farther downstream it occurs within a watershed. Stream order correlates to several different stream characteristics, including stream width and depth, gradient, and channel morphology, which makes it a good metric for stratifying field samples.

2.2 HISTORIC FISH INVENTORY INFORMATION

Before study design and field surveys, existing fisheries information was compiled to guide study design and site selection (e.g., to avoid surveying sites where fish presence was known). The Fisheries Information Summary System (FISS) was examined for fisheries information within the RSA and available grey literature that contained information on streams within or adjacent to the RSA (Anderson Resources Ltd. 2001, Barker et al. 2011). Stream files from Fisheries and Oceans Canada (DFO) were also searched for fisheries information within the RSA.

2.3 GIS-BASED STREAM DATA DERIVATION

The GIS-based environmental data were required to estimate the probability of fish presence at all streams across the RSA (i.e., because it was not feasible to collect field data for all 1,467 streams in the RSA). Nine stream variables were chosen for the analysis: stream order; distance to third, fourth, and fifth-order streams; stream slope; terrain slope; elevation; catchment area; and distance to large inline pools[2]. All these variables are known to affect fish occurrence and fish habitat (e.g., Barker et al. 2011). Stream order is a valuable qualitative proxy for water volume and flow rate metrics. Higher-order streams (i.e., third-order and greater) were initially predicted to have stream conditions sufficient for overwintering habitat, and thus distances to these streams may relate to fish presence. Landscape components such as slope (stream and terrain) and elevation relate to flow, flooding potential, temperature, and productivity, respectively. The total catchment area upstream from a location measures total water quantity, which may also affect the probability of fish presence. Inline pools may also be important during high summer temperatures and low-flow dry seasons or as overwintering habitat for fish. The nine predictors were developed in ArcGIS as unique raster layers at a 100 m × 100 m resolution.

2.4 FIELD SURVEYS

Fish presence, habitat, and water conditions were assessed in the field in July, August 2019, and March 2020. The summer sampling consisted of two crews: one crew of two EDI Environmental Dynamics Inc. (EDI) employees and another of two EDI employees and a VGFN assistant. A helicopter shared by both crews accessed all sites; sites for the day were coordinated to make the most efficient use of sampling and helicopter time. Sampling in March 2020 was limited to fewer variables due to the winter conditions, including the lack of water at many sites. There was one crew of two EDI employees and a VGFN assistant for March fieldwork.

[2] Large pools or ponds (>0.25 ha) occurring along a stream reach.

2.4.1 SUMMER

Surveys for fish presence and habitat conditions in the RSA occurred between July 25 and August 1, 2019, with two field crews. Field assessments included habitat quality assessments and fish sampling via electrofishing (and occasional minnow trapping) when sufficient water was present. In total, 118 streams in the RSA were assessed for fish presence and had British Columbia (BC) site cards filled out. Stream orders with higher occurrence had higher sampling effort (i.e., more lower-order streams sampled; Table 2-1). Stratified random sampling was used to sample a subset of streams from each order while providing relatively even spatial coverage across the RSA. Site assessment occurred on 52 first-order streams, 42 second-order, 18 third-order, four fourth-order, and two fifth-order sites (Table 2-1; Map 2-1). Sampling occurred in all the watersheds within the RSA — the Bell (upper Porcupine), Whitestone (Porcupine), and Ogilvie (upper Peel). Some larger order streams were visited at two spatially separated sites within the RSA to achieve the appropriate spatial coverage (e.g., Chance Creek). Each site with water had in situ water quality parameters recorded; a YSI ProPlus and YSI ProSOLO were used to collect data on temperature (°C), dissolved oxygen (% and mg/L), specific conductivity (µS), and pH (pH was only recorded on the ProPlus). Where applicable, digital photos and GPS coordinates were taken at the downstream and upstream extents sampled.

A broad suite of stream characteristics were documented in the field, following the BC Ministry of Environment's Fish and Fish Habitat Inventory standards and using the BC site cards (BC Ministry of Environment 2008). The primary metrics of interest included: channel and wetted widths, residual pool depth, gradient, type and total cover, and bed material. Qualitative estimates of habitat quality for spawning, overwintering, and rearing potential was also recorded. The BC Fish and Fish Habitat Inventory definitions were used to classify drainages as either: a stream; no defined channel; or no visible channel drainage. The definition relies on both fluvial material (sediment or substrate) and a stream channel (BC Ministry of Environment 2008). Field results from site cards and electrofishing supported the field-based predictive model.

All streams that contained water at the time of survey were surveyed for fish using standard electrofishing methods. The electrofishers were a Smith-Root LR-24 and a Smith-Root 12B POW. A minimum sampling effort of approximately 100 m and 500 sec was attempted at each site; however, this was not achieved at a small number of first- and second-order streams (n = 11) due to partially dry stream channels. Sampling covered an average of 92 m (± 43 SD; range = 25 – 200 m) and 455 sec (± 89 SD; range = 211 – 693 sec) per site (Attachment A). The electrofisher settings were also variable due to large discrepancies in specific conductivity between sites. Electrofishing was completed by moving upstream. Once a fish was stunned, it was transferred to a bucket with fresh water to be measured and to recover. During fish handling, fish experienced limited air exposure, no contact with abrasive or dry surfaces, and minimal handling; nets were knotless rubberized mesh, and all fish were measured using a soft tape measure with the gills submerged underwater. Captured fish were enumerated, identified to species, and measured to fork length (FL; mm); burbot and slimy sculpin were measured to total length (TL; mm). The species and count were recorded if a fish was not captured and only observed. Fish were released back into the stream once electrofishing had concluded.

Minnow trapping was conducted at six sites, primarily in larger streams or ponds to complement or verify electrofishing data. Minnow traps were placed in areas of good cover and suitable depth and stream velocity. Each site had three small gee-type minnow traps (0.6 cm mesh size) baited with roe in a perforated bag and deployed along stream margins in slow water habitats. In the case of the pond that was sampled, sampling occurred along the pond shore. Water depth, site characteristics, and photos were recorded for each trap and traps were left to soak overnight (Attachment A).

Table 2-1. Summary of sampled stream orders during summer sampling in July and August 2019.

Stream Order	Streams in RSA	Streams Sampled in Summer	Percent Sampled (%)
1	1,142	52	1.9
2	239	42	17.6
3	68	18	26.5
4	16	4	25.0
5	2	2	100.0

2.4.2 WINTER

The RSA was visited again from March 7 to 13, 2020, to assess the presence of water and overwintering fish habitat at a subsample of streams across the RSA. In total, 49 unique sites were visited—1 first-order stream, 14 second-order, 18 third-order, 13 fourth-order, and three fifth-order (Map 2-1). Sites were accessed via helicopter. Only one first-order stream was surveyed because summer surveys found very low fish presence in first-order streams, and because past work adjacent to the RSA in the Peel watershed indicated most first- and second-order systems are dewatered or froze to bed in winter (Barker et al. 2011). Some larger order streams were visited at more than one location of the stream (e.g., Chance Creek) as they extended through the entire RSA, and because those streams were suspected to be the primary overwintering habitats within the RSA.

It is important to highlight the difficulties associated with winter assessments and the nature of random sampling (i.e., uncertainties as to what part of the stream is most likely to contain water). To address these issues, efforts were made to target some sites that had either pools (characterized by widening or a bend in stream) or a visible inline pond, as these sites were more likely to have residual pools at lower winter flows. If sites corresponded to an inline pond or a pool, a site was sampled in the stream channel (i.e., where it appeared to be average channel width), as well as in the inline pond and/or pool, and lastly at the inlet or outlet to determine if there was flowing water (Photo 2-1; Table 2-2). As such, some sites included two or three distinct sampling locations. This situation occurred most frequently at some of the third- and fourth-order sites visited (Table 2-2). While every effort was made to locate survey sites at locations most likely to contain water, it is possible that some survey locations missed the 'best' microsites in the vicinity (i.e., locations with the deepest pool or the part of the channel with the most flow).

Upon arrival at a site, the stream bed was located under the snow and the snow was removed from the surface of the stream. The ice was initially checked with an ice spud (probe) for thickness. Occasionally an ice spud was sufficient to penetrate the ice; in the event of thicker ice, a power auger was used. The hole was assessed

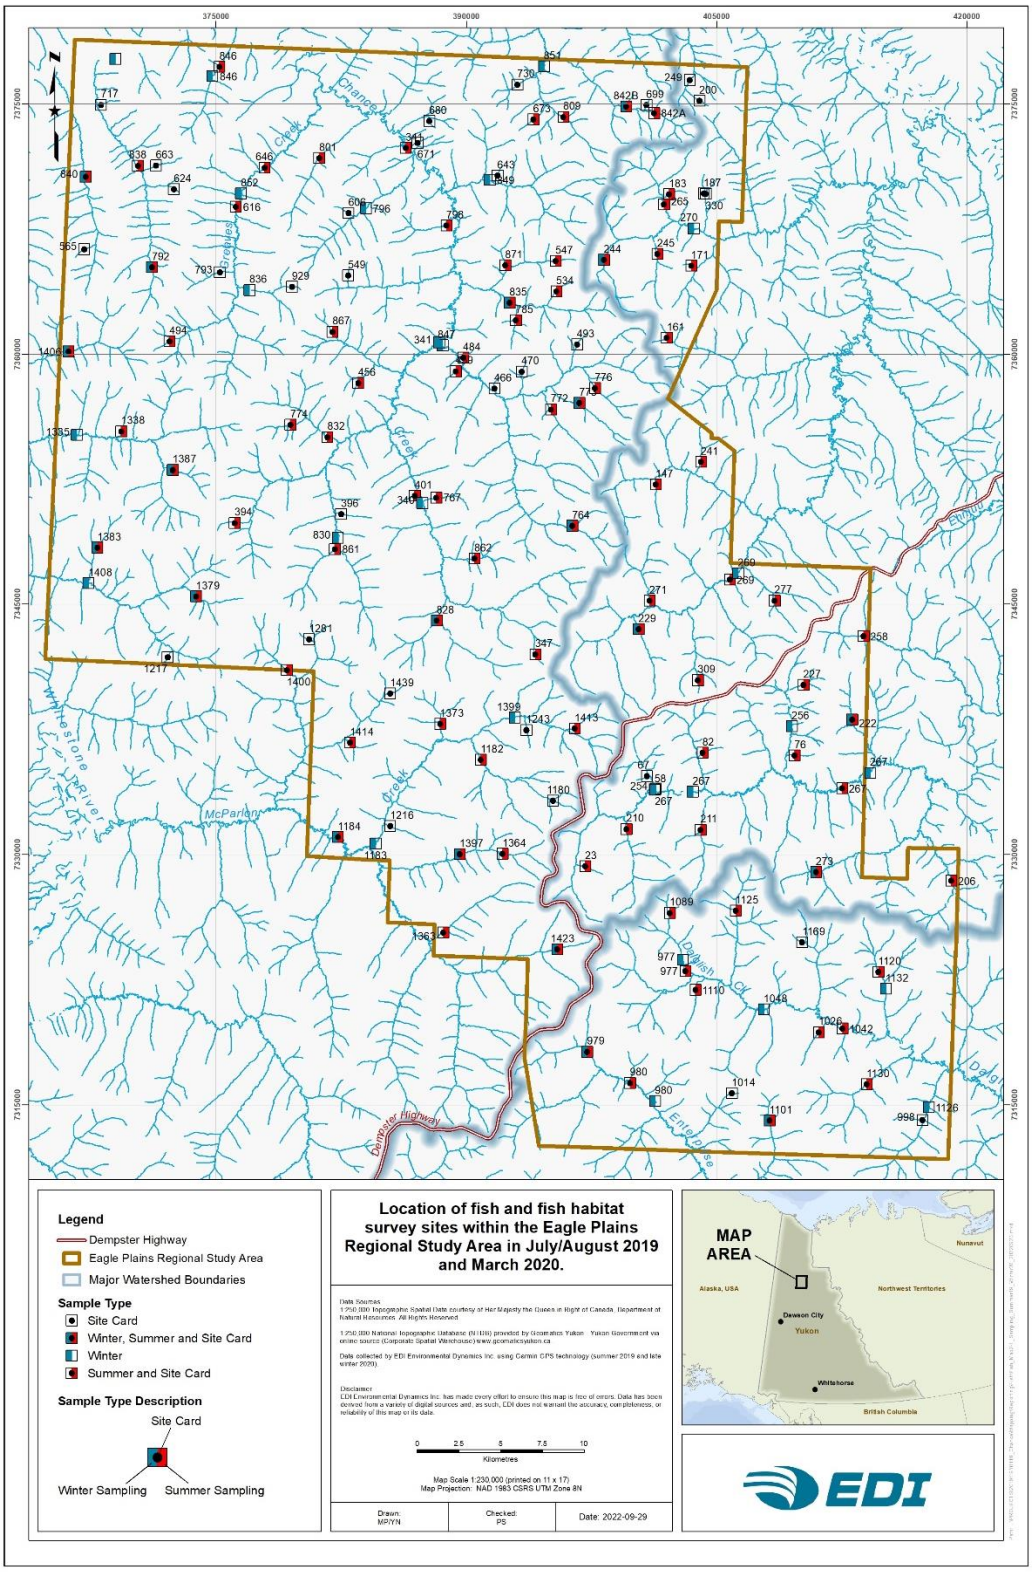
for the presence of water. If no water was found in the first drilled hole, then another spot along the stream was surveyed (though on some occasions, only a single hole was drilled due to concerns of cold exposure). If the bank width of a stream was small enough (<2 m), a trench was chipped across. At channels greater than 2 m wide, one to five holes were drilled across the width of the channel to evaluate for the presence of water. If water was identified at the site, and the water was greater than 10 cm deep, an Aqua-Vu underwater fish viewing camera was submersed and the video feed was viewed for 10 to 20 minutes to check for fish activity. Each site with sufficient water had in situ water quality parameters recorded using a YSI ProSOLO to collect temperature (°C), dissolved oxygen (% and mg/L), and specific conductivity (µS/cm). At all holes drilled or chipped, the overlaying snow depth, ice depth, hollow depth, water depth, and depth from substrate to the top of the ice were recorded (m); hollow depth was measured when a hollow space was present between the ice and water or frozen substrate. Photos and GPS coordinates were recorded for each site visited, as well as notes of the findings from each site.

Table 2-2. Distribution of sampled streams regarding stream order and type of environment sampled in March 2020.

Stream Order	Sampled Stream Channel	Sampled Inline Pond or Pool	Sampled Inline Pond or Pool Inlet/Outlet	Total Sampling Locations[1]
1	1	0	0	1
2	13	1	1	15
3	15	4	4	23
4	10	5	4	19
5	3	0	0	3

[1] Some sites were sampled in more than one distinct location (e.g., the same site was sampled in a stream section, a pool, and the pool outlet).

Photo 2-1. Example sampling locations within the average channel width, the outlet (or inlet), and inline pond (or pool) during sampling in March 2020.



Map 2-1. Location of fish and fish habitat survey sites within the Eagle Plains Regional Study Area in July/August 2019 and March 2020.

2.5 FISH PRESENCE — PREDICTIVE MODELLING

Estimates of fish presence during summer were derived using logistic regression analysis. Logistic regression quantifies the contribution of environmental covariates to fish presence and yields predictions in the form of probabilities. Several candidate models, consisting of different combinations of the nine environmental variables (see Section 2.3), were developed and information-theoretic procedures were used to select the most parsimonious model (Burnham and Anderson 2002). Environmental covariates were chosen based on their relevance to fish ecology and their potential for variation in the RSA. For the analysis, stream order was treated as an ordinal, continuous variable because (1) the limited and unbalanced sample sizes across stream orders and (2) the expectation that the probability of fish presence would increase in consecutively higher-order streams (Table 2-3). All other predictors were treated as continuous, numeric variables: elevation, catchment area, stream and terrain slope, distance to inline ponds, and distance to third-, fourth-, and fifth-order streams. Predictor values were extracted from the 100 m raster layers for each of the 118 sampled locations and corresponded with the presence or absence of fish. Statistical analyses were conducted using R Statistical Software, version 3.6.1 (R Development Core Team 2020).

Before model construction, multicollinearity among variables was evaluated to confirm unbiased estimates of coefficients (and their associated error) for each environmental covariate. A correlation matrix (for variables with high Pearson's correlation coefficients, $r > 0.7$) and variance inflation factor scores (scores >4) were used — neither identified problematic variables. Due to large and differing ranges of values among continuous numeric predictors, these variables were centered and standardized to have a mean of zero and a standard deviation of one.

Analyses began by specifying a 'global model' with all environmental covariates. Diagnostic plots of the global model's residuals to fitted values did not identify any concerns of heterogeneity or outliers. Coefficient estimates associated with each covariate were also evaluated based on logical predictions and removed if contrary to fish biology. For instance, in the global model, "distance to fith-order streams" had a positive coefficient (i.e., increased probability of occurrence associated with distances farther from fifth-order streams). Such an estimate is illogical from an ecological perspective and likely the result of spurious correlation; the expectation is that the probability of occurrence should decrease with distances farther from fifth-order streams because of low water volumes and flow rates. Therefore, this distance covariate was dropped from additional consideration.

Beginning with the global model, model comparisons were conducted via sequential log-likelihood ratio tests in which covariates were removed one at a time depending on their contribution to residual deviance (i.e., analysis of deviance table using a $p < 0.05$ threshold). A series of candidate models were considered during model selection, ranging from the global model to those with single predictors. As per information theoretic procedures, corrected Akaike Information Criterion (AICc) scores, used when the sample size is small (e.g., $n = 118$), were calculated for each model (R package "AICcmodavg", Mazerolle 2019). An AICc score is the amount of information a candidate model loses when compared to the "true", unknown (and unattainable) model, which perfectly describes a natural phenomenon (Burnham and Anderson 2002). In this case, the model with the lowest AICc score (and statistics) yields the best approximation for explaining fish

presence, given the data. Significant main effects, as well as AICc weights (w_{AICc}) and corresponding evidence ratios (e.g., $\frac{w_{model\,8}}{w_{model\,7}}$) were considered for model selection.

The final step was model validation. Predictions from the final model were evaluated with observed data using a Receiver Operating Characteristics (ROC) curve (or area under the curve, AUC) in R software (package "pROC", Robin et al. 2011). The ROC curves (or AUC scores) identify the proportion of true positives to false positives based on predictions from the model, using an iteratively variable threshold to convert probabilities to binary responses (1, 0). An AUC value of 1 signifies that the model perfectly distinguishes between presence and absence (1, 0), while 0.5 means it cannot differentiate between them.

An alternative model was developed using field data collected in the RSA to evaluate further the robustness and predictive power of the GIS-based analysis. This additional analysis was also conducted to determine whether field-based covariates could address aspects of fish presence that geospatial data could not (i.e., to improve model accuracy and confidence). Stream order was retained for the analysis, and the following field-based covariates were also included: channel width, wetted width, residual pool depth, overwintering habitat quality, dissolved oxygen, and gradient. During preliminary multicollinearity tests, two variables were removed from further analyses — channel width and wetted width — because of their high correlation with stream order (r = 0.78 and 0.80, respectively) and high variance inflation factor (VIF) scores. The model construction, selection, and evaluation procedures followed were identical to those used for the GIS-based model.

Table 2-3. Contingency table comparing fish presence and absence among stream orders from sampled locations in the Regional Study Area during July and August 2019.

Stream Order	% Fish Present	Total Sites Visited
1	3.8	52
2	54.8	42
3	77.8	18
4	100	4
5	100	2
TOTAL		**118**

3 RESULTS

3.1 HISTORICAL INFORMATION

Very little fisheries information was found during the literature search for historical and baseline information within the RSA. No information was contained in FISS within the RSA. The only fish inventory conducted in the RSA is limited baseline fish sampling supporting past oil and gas exploration in the area (Anderson Resources Ltd. 2001; Attachment B). In the adjacent Peel watershed, the Yukon Government conducted broad inventory work that modelled the likelihood of fish presence based on different environmental variables (Barker et al. 2011).

Anderson (2001) indicated that historical fish surveys in the broader Eagle Plains area primarily focused on larger drainages rather than smaller order streams, with data being somewhat dated in the proximity of the RSA (e.g., mainstem Eagle, Ogilvie, Peel, and Porcupine rivers; Bryan et al. 1973, Steigenberger et al. 1975, Eby and Associates 1977, Lindsey et al. 1981). Anderson (2001) concluded that diversity and habitat use are lower within the headwaters of these mainstem rivers (i.e., within the smaller streams of the RSA) and that overwintering habitat would be limited to areas of groundwater or deeper pools.

Anderson (2001) surveyed the physical stream characteristics and conducted electrofishing, beach seining, minnow trapping, gillnetting, and angling on eight streams and two ponds within and adjacent to the currently proposed RSA during June, August, and September 2001 (Attachment B). Species captured and observed by Anderson (2001) included: Arctic grayling, slimy sculpin, longnose sucker, burbot, round whitefish, and lake whitefish. They electrofished for an average of 350 sec (± 192.4 SD; range = 33 – 795 sec; Attachment B) per site. Regarding habitat, fish cover was primarily in the form of turbidity, large woody debris, and undercut banks. Although turbidity could provide cover, several negatives are associated with excess turbidity (e.g., poor foraging opportunities and increased ventilation/metabolic costs; Henley et al. 2000, Lowe et al. 2015, Alaska Department of Environmental Conservation 2016). Overhanging and instream vegetation was also present in some streams and the occasional pool. Many stream banks were characterized by erosion and slumping banks from melting permafrost, contributing to the turbidity at some sites.

The Yukon Government Peel watershed study by Barker et al. (2011) used GIS-based covariates to develop hypothesis-driven models to predict the presence and abundance of Dolly Varden, Arctic grayling, and slimy sculpin; they also used a model which considered all fish species. Habitat covariates included: elevation, mean slope, upstream extent, distance to ≥5th-order streams, rock proportion and upland vegetation cover. The hypothesis-driven models they developed included different combinations of covariates: flooding (rock proportion + mean slope + upstream extent + distance to ≥5th order streams); freezing (elevation + upstream extent + distance to ≥5th order streams); drying (upstream extent + distance to ≥5th order streams); stream volume (upstream extent); migration (elevation + distance to ≥5th order streams); and productivity (vegetation proportion + elevation + upstream extent). The field findings and predictive model indicated fish were absent from nearly all first-order streams and present in nearly all fourth-order streams; they assumed fish were present at fifth-order streams. The model combining all species found very low probability of fish

presence in first-order and upper reaches of second-order streams and had high predicted fish presence in most third- and fourth-order streams. Their predictive hypothesis-driven models indicated that the stream volume model was the best predictor for Dolly Varden and slimy sculpin presence. In contrast, the productivity model best predicted Arctic grayling presence and all fish combined. The stream productivity model also had the most predictive power for fish abundance of Dolly Varden, Arctic grayling, and slimy sculpin (Barker et al. 2011).

3.2 FIELD SURVEYS

3.2.1 SUMMER

3.2.1.1 Fish Sampling

A total of 118 sites were visited across all orders, 81 of which contained enough water to sample for fish (Map 3-1; Attachment C). Twenty-seven first-order and four second-order drainages were considered non-classified (NCD; i.e., not a stream) based on the definition provided in the BC Site Card Field Guide (BC Ministry of Environment 2008). To be an NCD, a drainage lacks evidence of a defined bank or fluvial deposits (i.e., stream bed material; BC Ministry of Environment 2008). Another six first-order streams could not be sampled for fish as they were dry or did not contain enough water for sampling (Map 3-1; BC Ministry of Environment 2008). Field crews supporting the wildlife and vegetation components of the baseline studies noted that water levels were considerably higher in June than in late July and early August when streams were assessed for fish presence (a June peak is common in this region; Yukon Ecoregions Working Group 2004).

Overall, the proportion of sites with fish present increased considerably with increasing stream order (Table 3-1). Few fish were captured in first-order streams, with only 3.8% of sites visited containing fish (Table 3-1). The only fish captured in first-order streams were adult Arctic grayling in one site in the Dalglish Creek watershed (Site 1026) and another in the MacParlon Creek watershed (Site 1423; Table 3-1; Map 3-1; Attachment C). These two Arctic grayling were among the largest captured throughout the RSA (Table 3-2). Both streams had a wetted width of less than 1 m and were considered to have moderate rearing habitat, though both had poor connectivity and the fish were in isolated residual pools at the time of sampling (i.e., the fish had moved into the streams during higher flows and had become stranded).

Second-order streams had the most variable fish presence, with 52.4% of visited sites containing fish (Table 3-1). Four fish species were captured in second-order streams: Arctic grayling, slimy sculpin, longnose sucker, and burbot (Table 3-2). Arctic grayling were captured most frequently in second-order streams. Notably, young-of-the-year (YOY; <50 mm) Arctic grayling were captured at one site in the Chance Creek watershed (Site 861; Map 3-1; Attachment C) and another site in the Eagle River watershed (Site 229; Photo 3-1; Table 3-2; Map 3-1; Attachment C). Slimy sculpin were captured at three second-order streams (Site 210, 211, 273; Map 3-1; Attachment C), all in the Eagle River watershed. Longnose sucker and burbot were captured at two second-order streams (Sites 1387, 1383) in the Whitestone River watershed, and

longnose sucker were captured at one other site in the MacParlon Creek watershed (Site 1373; Map 3-1; Attachment C).

Third-order streams had a fish presence at 77.8% of sites, with five fish species captured (Table 3-2). Adult Arctic grayling were captured at all but three sites (Photo 3-2), and YOY Arctic grayling were present at six sites total: three sites in the Chance watershed (Site 828, 832, 835), one in the Dalglish watershed (977), one in the MacParlon watershed (Site 1182), and one site in the Whitestone watershed (Site 1406; Table 3-2; Map 3-1; Attachment C). Slimy sculpin were captured at one site in the Enterprise Creek watershed (Site 980) and one site in the MacParlon watershed (Site 1397; Table 3-2; Map 3-1; Attachment C). Round whitefish were only captured at two sites in the whole RSA, both in the Dalglish Creek watershed (Site 977, 1130; Photo 3-3; Table 3-2; Map 3-1; Attachment C). Lastly, a single longnose sucker was captured (Photo 3-4) and a burbot was observed at the same site in the Chance Creek watershed (Site 840).

Fourth- and fifth-order streams had fish present in 100% of the sites visited, albeit few sites were visited as fish presence was anticipated in these higher-order streams (Barker et al. 2011). Arctic grayling and slimy sculpin were the only species captured in fourth- and fifth-order streams (Table 3-2; Attachment C). Slimy sculpin were captured at two fourth-order streams (Site 267 and 269) and in one fifth-order stream (MacParlon Creek; Site 1184).

Minnow traps were set at six locations within the RSA (Attachment C). Only one site successfully captured fish, with two Arctic grayling caught in the same trap in a third-order stream (fork length = 45 mm each; catch-per-unit-effort = 0.5 fish per 24 hr). Minnow trapping was initially used at a subset of sites to verify the success of electrofishing. As minnow trapping was not gathering any new information, electrofishing became the preferred method for capturing fish.

Table 3-1. Summary of fish sampling sites and corresponding fish presence from July and August 2019.

Stream Order	Sites Visited	Sites Sampled for Fish	Sites with Fish Present	Percent of Sites Visited with Fish Present (%)
1	52	19	2	3.8
2	42	38	22	52.4

3.2.1.2 Water Quality

First- and smaller second-order streams were frequently characterized by little or no flow, inconsistent connectivity, and isolated residual pools. Many wetted first-order streams did not have consistently flowing water at the time of sampling, and many sites were sampled from isolated residual pools; this was occasionally the case in some smaller second-order streams as well. As such, the fish captured in these streams were at least temporarily stranded and likely travelled upstream into these first and second-order streams during high spring water levels. These low or no flow streams were characterized by low dissolved oxygen (Table 3-3; Attachment D). Water temperatures were lowest in first-order streams due to the greater inputs from the melting of the active layer of the permafrost; in some streams, ice was discovered below the substrate. As stream order increased, water temperature also increased on average (Table 3-3). General guidelines for dissolved oxygen in fish-bearing waters indicate that most fish require dissolved oxygen levels above 6 mg/L, with potentially lethal consequences to prolonged exposure below 2 mg/L (Doudoroff and Shumway 1970, Davis 1975, Leppi et al. 2016). The lowest dissolved oxygen that contained fish was 2.2 mg/L in a first-order stream, where fish were caught in a disconnected residual pool (Table 3-3; Attachment D).

Table 3-3. Water quality parameters at sites that contained fish during July and August 2019 fish sampling.

Stream Order	Sites with Fish Present	Dissolved Oxygen (%)		Dissolved Oxygen (mg/L)		Temperature (°C)	
		Average DO of Sites with Fish Present (± SE)	Range	Average DO of Sites with Fish Present (mg/L ± SE)	Range	Average Temperature of Sites with Fish Present (± SE)	Range
1	2	31.4 ± 17.2	18.2 – 44.5	3.7 ± 2.7	2.2 – 5.3	8.7 ± 1.8	8.4 – 8.7
2	22	65.8 ± 2.9	42.9 – 89.8	7.2 ± 0.3	4.3 – 10.2	11.2 ± 0.5	7.3 – 16.2
3	14	72.7 ± 4.6	6.2 – 15.4	7.8 ± 0.5	7.6 – 14.5	11.6 ± 0.5	7.6 – 14.5
4	3	82.0 ± 6.4	70.6 – 92.8	8.7 ± 0.2	8.4 – 8.9	12.6 ± 2.6	8.1 – 17.1
5	2	99.0 ± 15.7	70.6 – 92.8	10.1 ± 1.5	8.4 – 9.0	14.4 ± 0.4	14.0 – 14.7

3.2.1.3 Habitat

Most first- to third-order streams in the RSA were characterized by fine bed material and overhanging vegetation (Photo 3-5, Photo 3-6, Photo 3-7). Areas of permafrost melting and slumping of stream banks added to the siltation of the stream bottoms and turbidity. The exception was lower order streams in the Peel watershed (e.g., Dalglish and Enterprise creeks and tributaries) that had bed material predominantly comprised of gravels (Photo 3-8). Larger third-, fourth- and fifth-order streams throughout the RSA were still characterized by a large amount of fines and moderate turbidity, although some had sections of gravel present (Photo 3-8, Photo 3-9, Photo 3-10).

Habitat quality in the RSA generally increased with increasing stream order. Generally, first- and second-order streams provided discontinuous habitat at the time of survey due to low water flow. In first- and second-order streams, habitat complexity was low, with most cover restricted to undercut banks, overhanging vegetation,

and occasional woody debris (Photo 3-5, Photo 3-6). A few pools occurred, many of which were not substantial in size or residual depth (Table 3-4; Attachment D). However, in all third-order and greater streams, the depths of pools and runs generally offered adequate cover to support fish in many stream sections. Channel widths also generally increased with increasing stream order. Stream gradient generally decreased with increasing stream order; the highest stream gradient was 7.0% at a first-order stream (Table 3-5). However, the gradient is unlikely to play a major role in fish presence in the RSA because fish passage is normally not hindered below 20% gradient. At many sites there was an indiscernible amount of gradient (Table 3-5; Attachment E)—this was particularly true in poorly defined and braided streams.

Table 3-4. Stream measurement metrics summary based on stream order from sampling in July and August 2019.

Stream Order	Sites[1]	Channel Width		Wetted Width		Residual Pool Depth	
		Average (m; ± SE)	Range (m)	Average (m; ± SE)	Range (m)	Average (m; ± SE)	Range (m)
1	2	31.4 ± 17.2	18.2 – 44.5	3.7 ± 2.7	2.2 – 5.3	8.7 ± 1.8	8.4 – 8.7
2	22	65.8 ± 2.9	42.9 – 89.8	7.2 ± 0.3	4.3 – 10.2	11.2 ± 0.5	7.3 – 16.2
3	14	72.7 ± 4.6	6.2 – 15.4	7.8 ± 0.5	7.6 – 14.5	11.6 ± 0.5	7.6 – 14.5
4	3	82.0 ± 6.4	70.6 – 92.8	8.7 ± 0.2	8.4 – 8.9	12.6 ± 2.6	8.1 – 17.1
5	2	99.0 ± 15.7	70.6 – 92.8	10.1 ± 1.5	8.4 – 9.0	14.4 ± 0.4	14.0 – 14.7

[1] Sites that were not considered a stream (i.e., no banks or bed material) were not included in these calculations.

Table 3-5. Stream gradient summary based on stream order from sampling in July and August 2019.

Stream Order	Gradient (%)	
	Average (± SE)	Range
1	2.05 ± 0.31	0.00 – 7.00
2	1.16 ± 0.17	0.00 – 3.50
3	1.06 ± 0.28	0.00 – 3.50
4	0.44 ± 0.21	0.00 – 1.00
5	0.63 ± 0.13	0.50 – 0.75

3.2.2 WINTER

Forty-nine sites were evaluated for fish presence potential in March 2020 within the RSA (Map 3-2; Table 3-6; Attachment F). Efforts were made to sample a typical stream section with average channel width. Sampling was also conducted at inline ponds or pools along the stream, where they occurred, and at their corresponding inlets/outlets (Table 3-7). If water was detected in one of the holes drilled at a site (e.g., pond/pool/stream) but not in others, the site was still designated as containing water. Fifteen of the 49 sites visited in March contained water (Map 3-2; Table 3-6).

In March 2020, no water was present in the single first-order stream visited, and the only second-order stream with water present was in a small inline pond, although the water was in the form of wet mud and not suitable fish habitat at the time of sampling (Photo 3-11; Table 3-6, Table 3-7). The ice depth was 0.63 m, with 0.32 m between the bottom of the ice at the top of the water—the water measured 0.05 m in depth (Photo 3-12). At all other second-order sites no water was detected during winter sampling (Photo 3-12). In third-order streams, all four inline ponds/pools sampled contained water (Photo 3-13), but with the outlets frozen to bed or as layered ice, indicating water level lowering and draining (Photo 3-14; Table 3-6, Table 3-7). As such, the water in the inline ponds and pool was likely to be standing water, acting as a residual pool as the rest of the stream water level dropped and froze during the fall and winter. The water quality of these sites was unsuitable for long-term fish rearing, with very low dissolved oxygen levels (range = 0.1 – 0.5 mg/L; Table 3-8; Attachment F, Attachment G) and generally dark-coloured water with a strong anoxic smell. Adequate under-ice dissolved oxygen is important for fish overwintering, with potentially lethal effects to prolonged exposure to below 2 mg/L, with preferred levels at or above 6 mg/L (Doudoroff and Shumway 1970, Davis 1975, Leppi et al. 2016). The water was deep enough to use the fish camera at two sites; during 10 to 20 minutes of observation, no indication of fish presence was found at either site.

Eight of 14 fourth-order streams contained water in March 2020. Five of the sites (646, 270, 340, 1408, 267) contained water in a pool or inline pond, and of these, two also contained water in the adjacent stream channel (both sites on stream 267), suggesting flowing water may have been present (Table 3-6, Table 3-7). The other three sites had water present in the stream channel (also used for water quality sites in the EDI Surface Water Quality and Hydrology Baseline Report: NCY-PT19, DALG-003, EAGL-t-004; EDI 2021). Four of the sites had enough water to use the fish camera for 15 to 20 minutes—no fish were detected at any of the sites. Most of the sites containing water did not have suitable water quality parameters for fish presence, with average dissolved oxygen levels ranging from 0.2 to 1.7 mg/L at five of the six sites that had water quality collected (Table 3-11). Only one of the fourth-order streams (Site 267) had low to moderate dissolved oxygen levels in the pool and stream channel sampled (3.97 mg/L and 8.50 mg/L, respectively; Table 3-8; Attachment G); these dissolved oxygen levels are likely sufficient for fish to overwinter (Leppi et al. 2016).

Fifth-order stream sampling included two sites on Chance Creek and one on McParlon Creek. Chance Creek was sampled for fish at the water quality site CHNC-003 and at a site at the farthest downstream extent before leaving the RSA. Five holes were drilled across the channel at site CHNC-003, with four of the five holes frozen to the bed (Photo 3-15). The fifth hole contained very little water (0.17 m) and was a ferrous orange in colour. The downstream site on Chance Creek also had five holes drilled cross-sectionally, with all holes

frozen to bed and no detectable water. Water quality site CHNC-001 (located outside of the RSA) did contain water very near to the confluence with the Whitestone River. The site on McParlon Creek contained water but had poor overwintering habitat potential, with a low dissolved oxygen level (1.70 mg/L) and anoxic-smelling water (Table 3-8). Due to the nature of sampling beneath the ice, it is possible that the best overwintering habitat (e.g., areas of flow) could have been missed. However, this issue was minimized by sampling multiple locations at each site and drilling multiple holes across the channels.

Generally, most sites with water had a strong anoxic smell and low dissolved oxygen levels (Table 3-8). No fish were detected using the underwater fish viewer on the nine occasions water depth was sufficient to use it. The temperature did not vary considerably among sites (Table 3-8; Attachment F), with no sites appearing to have groundwater influence (i.e., warmer water inputs) at the sampled locations (Table 3-8; Attachment F, Attachment G).

Table 3-6. Summary of sites visited and those that contained water from the overwintering assessments in March 2020.

Stream Order	Sampled Sites	Sites Containing Water	Percent of Sites Visited that Contained Water (%)	Average Water Depth[1] (± SE; m)	Water Depth Range[1] (m)
1	1	0	0	–	–
2	14	1	7	0.05 ± 0.00	0.05 – 0.05
3	18	4	22	0.64 ± 0.24	0.1 – 1.1
4	13	8	62	0.37 ± 0.11	0.01 – 1.1
5	3	2	67	0.33 ± 0.16	0.17 – 0.48

3.3 FISH PRESENCE — PREDICTIVE MODELLING

Eight models were developed that represented plausible combinations of the nine environmental variables to explain fish presence in the RSA (Table 3-9). The top model for predicting fish presence contained a single variable, stream order (Table 3-9). There was also support for models that included either distance to third--order stream or distance to third-order stream + terrain slope (i.e., Δ AICc <2 relative to the top model). Together, the top three models account for 83% of model weights. Although the 2nd and 3rd ranked models have modest wAICc values, adding those extra variables does little to improve prediction accuracy over the univariate model with stream order (Table 3-10). Based on this, the univariate model of stream order is recommended for management use due to its simplicity and model parsimony. The odds of fish presence increased with stream order (Table 3-10; Map 3-3). Absolute probabilities of occurrence associated with each stream order were as follows: 7.6% in first-order, 45.3% in second-order, 89.3% in third-order, 98.8% in fourth-order, and 99.9% in fifth-order streams. A test of the model's performance using a ROC curve indicated that the model was statistically valid for prediction with an AUC score of 0.87.

For the secondary analysis using field-based data, the top two models had nearly equivalent AICc scores and weights (Table 3-11). The model that included only stream order and pool depth was selected as the best model because it was the most parsimonious[3] and because a post hoc Fisher's exact (contingency table) test revealed that if stream order were used as a categorical variable, it would be highly associated with overwintering habitat ($p = 0.0005$). That model was then evaluated using a ROC curve, resulting in an AUC score of 0.89.

The GIS-based and field-based models performed relatively equivalently, though the latter had slightly higher accuracy in differentiating between the presences and absences of fish. In both models, stream order was the best predictor and explained a substantial proportion of the variation in fish presence. In the field-based model, stream order and pool depth had a relatively similar magnitude of effect on fish occurrence, but the room for error in those estimates were narrower for stream order. In terms of model prediction, including pool depth made a nominal difference in estimates of fish presence over the univariate model with stream order (Table 3-12).

[3] a simple model with exceptional explanatory predictive power; explains data with minimal number of parameters.

Table 3-9. Candidate logistic regression models predicting fish presence, ranked by AICc raw scores, differences (Δ AICc), and weights (w_{AICc}), in the Eagle Plains Regional Study Area.

Rank	Model Structure	K[1]	AICc	Δ AICc	wAICc[2]
1	stream order	2	102.81	0	0.35
2	stream order + distance to third-order stream	3	103.31	0.50	0.27
3	stream order + distance to third-order stream + terrain slope	4	103.86	1.05	0.21
4	stream order + distance to third-order stream + terrain slope + distance to inline pools	5	105.29	2.48	0.10

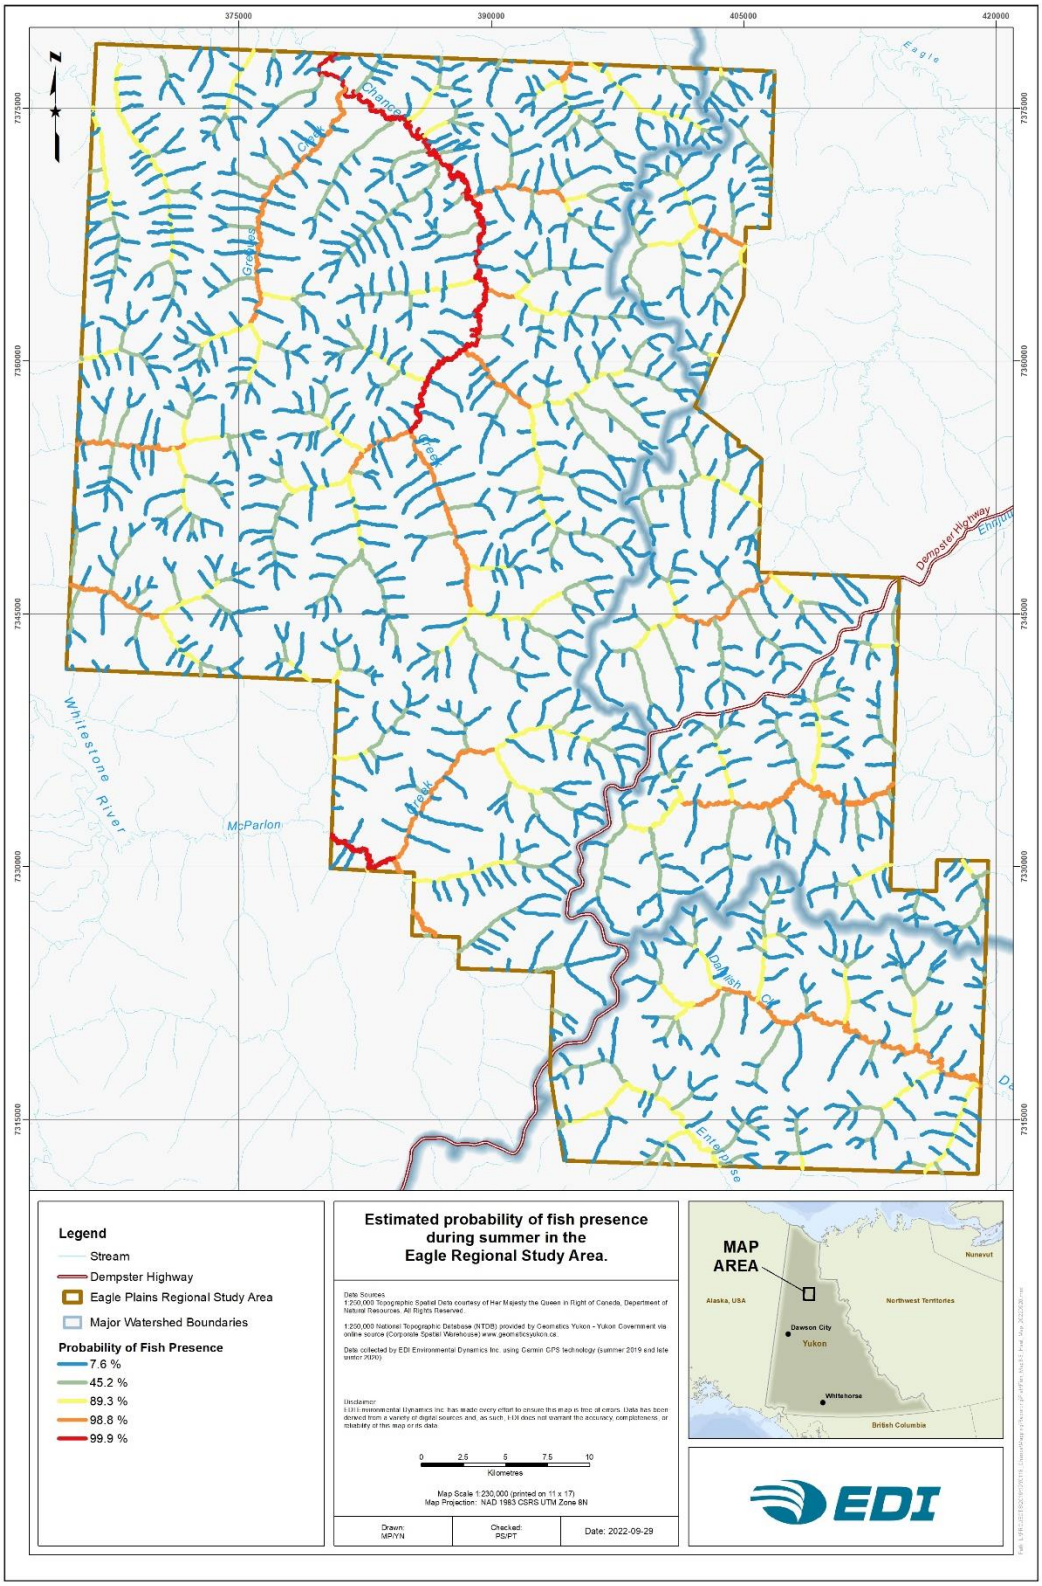

Map 3-3. Estimated probability of fish presence during summer in the Eagle Plains Regional Study Area.

4 DISCUSSION

These baseline investigations on fish and fish habitat in the RSA showed clear patterns of fish distribution in summer and of habitat availability for fish during winter. During the summer, the strong relationship between fish presence and stream order provides a clear and simple pattern of fish distribution that can be used for management to assess and mitigate potential Project effects to fish values in the RSA. Almost no first-order streams contained fish and all third-order or greater streams did contain fish during summer sampling. The variability of fish presence in second-order streams was partly attributable to differences in site-specific conditions (e.g., different channel widths and stream depths at different streams); however, across many second-order streams the intermediate probability of fish occurrence simply reflects marginal fish habitat conditions with low fish densities. Although evidence exists that additional GIS-based covariates (distance to third-order stream and terrain slope), and a field-based covariate (pool depth) may slightly improve model performance, the improvements those variables add to prediction accuracy are nominal. As such, they were not included in the final model, in favour of a simple univariate model's simplicity and ease of use (i.e., stream order only).

Electrofishing was successful at capturing several species within the RSA. Five species were captured: Arctic grayling, slimy sculpin, longnose sucker, round whitefish, and burbot. All but Arctic grayling were captured in low densities throughout the RSA. Six longnose sucker were captured at four sites in the Chance Creek, Whitestone River, and MacParlon Creek watersheds (Porcupine drainage) in second- and third-order streams. Longnose sucker are a generalist species and are the most widespread sucker in the north, commonly found in headwater streams (McPhail 2007). Four burbot were captured at three sites in second- and third-order streams in the Whitestone River and Chance Creek watersheds (Porcupine drainage). Burbot are widely distributed throughout the Northern Hemisphere and are not uncommon in riverine habitats (McPhail 2007). A study in the National Petroleum Reserve in Alaska completed a tagging study and found that burbot commonly travel up to 100 km in a season and were found in small headwater tributaries (Morris 2003). Lastly, two round whitefish were found in a third-order stream in the Dalglish Creek watershed (Peel drainage). While round whitefish are more commonly associated with larger riverine systems, they are still found in smaller streams, barring steep gradients (McPhail 2007).

The results of this study are similar to the findings in the adjacent Peel watershed study (Barker et al. 2011). The Peel study also observed a very low probability of fish in first-order streams and a high probability in third- and fourth-order (authors assumed presence in fifth-order streams; Barker et al. 2011). The Peel study findings also indicated the greatest variability in fish presence and abundance occurred in second-order streams. The Peel study identified ≥50% probability for Arctic grayling to be present in third-order streams (and only in larger, lower reaches), with probabilities 'declining rapidly to nil' in upstream sections (Barker et al. 2011).

A comparison of the AUC scores between the two studies (AUC = 0.87 Eagle Plains model vs. 0.75 Peel model) suggests that the Eagle Plains model provides somewhat better predictive performance than the Peel model in quantifying fish occurrence. This may be due to how environmental variables were assessed between the two studies. The Peel study was designed to test specific ecological hypotheses about fish distribution. In

contrast, this study was designed to develop the best model to predict fish occurrence, and the two studies varied their model sets accordingly. Another potential limitation in the Peel study is that they did not use stream order as a variable in the model. Instead, they used 'upstream extent', described as the cumulative length of all stream segments upstream from the sampled location (Barker et al. 2011). In the Peel study the predictor's coefficients were weak in magnitude (e.g., $\beta = 0.0001$ on a logit scale; Barker et al. 2011). By comparison, the coefficient of stream order in the current study was fairly strong (i.e., $\beta = 2.14$ on a logit scale). This demonstrates how a simple variable like stream order captures most of the variation in fish presence. For the GIS-based model, stream order outperformed eight other predictors: distance to third-, fourth-, and fifth-order streams; stream slope; terrain slope; elevation; catchment area; and distance to inline pools.

Higher stream orders are typically associated with higher quality and more diverse fish habitat, and thus greater abundances and species diversity (Gorman and Karr 1978, Harvey and Stewart 1991). Although stream order is a simple metric, it is correlated with several other stream characteristics that, individually and in combination, tend to support more fish. As stream order increases, the metrics involved with stream width, depth, water volume, habitat complexity, and potential for overwintering habitat all increase (Harrel et al. 1967, Gorman and Karr 1978, Reynolds 1997). The results from the current study support this concept, whereby fish presence increased as stream order increased. During the summer field studies, more fish were observed or captured in higher-order streams, with very few (n = 4) fish being captured or observed in the 52 first-order streams sampled. In third-, fourth- and fifth-order streams, the proportions of streams containing fish were approaching or reaching 100%. Habitat assessments also indicated that habitat quality (e.g., pool depths) and complexity increased with increasing stream order, with higher-order streams having higher quality habitat for rearing, spawning, and potential overwintering (Attachment C).

The field studies conducted in the RSA provide a temporal picture of habitat availability and utilization. Between the summer (n = 118) and winter (n = 49) sampling, a total of 167 sites were sampled within the RSA (some sites from the summer were revisited during winter sampling). As such, all the sampling conducted provided updated information on temporal fish distribution within the RSA. Ultimately the findings of the current study illustrated the disproportionate amount of habitat available to fish during the summer compared to winter. While most of the habitat assessed in the summer was considered to have poor or no spawning habitat (with some higher-order streams considered moderate to good), the observed and captured fish indicated that rearing habitat was widespread throughout the RSA. While not many sites were considered to have optimal Arctic grayling spawning habitats, YOY were captured in second- to fifth-order streams, suggesting that spawning does occur in some streams sampled. Young-of-the-year Arctic grayling were captured in two second-order streams; both streams had channel widths of greater than 3 m and had fines for bed material (Attachment D). Young-of-the-year Arctic grayling were present in eight third-order streams, three fourth-order streams, and in both fifth-order streams sampled.

Notwithstanding the gradient of habitat quality across stream orders, the overall diversity and habitat quality in the RSA was relatively low at a regional level. Streams are low gradient, with slow-moving, turbid water. The stream beds and banks are predominantly fines and organics, which reduce water quality, forage diversity and quantity, and spawning potential compared to streams with clearer water and rocky steam beds/banks

(Gorman and Karr 1978). On average, streams in the RSA were rated as moderate quality rearing habitat and low or nil quality spawning habitat for the dominant species, Arctic grayling. Despite the suboptimal conditions, Arctic grayling were the most frequently captured species during summer fieldwork (85%) and were the most widespread regarding being higher upstream in headwater streams.

The ability of Arctic grayling to travel long distances to occupy seasonally available streams is well known. During the open water months, Arctic grayling travel upstream into the feeding areas of headwater streams for more optimal foraging opportunities and less competition (Tack 1980, Hughes 1999, McFarland 2015). This was clearly apparent in the current study, whereby Arctic grayling were found high in the headwaters of different watersheds during the summer. Streams within the RSA are highly influenced by local hydrology (i.e., permafrost, snowmelt, and precipitation events), as illustrated during summer fieldwork (Smith et al. 2004). When terrestrial field crews were in the RSA in June, water levels were considerably higher than during fish sampling in July and August; the peak flow throughout Eagle Plains typically occurs in June (Smith et al. 2004). As a result, more accessible habitat for Arctic grayling was available higher in the watersheds in June, and they occupied habitats that are otherwise inaccessible during much of the year, using headwater streams for feeding opportunities. Foraging success during the short open water season is critical for fish to acquire sufficient energy reserves before winter, when habitats are less productive overall (Morris 2003, Heim et al. 2016). Arctic grayling forage on aquatic and terrestrial invertebrates, and depending on availability, on smaller fish; these feeding behaviours change seasonally (e.g., aquatic invertebrates during the winter months; Armstrong et al. 1986, McFarland 2015). Some Arctic grayling were found isolated in residual pools with no downstream connectivity and were at risk of being stranded in areas that would become anoxic or freeze, unless a heavy rainfall event elevated the water flow and allowed them to travel downstream. Arctic grayling movements in Arctic ecosystems are strongly tied to seasonal changes in discharge and temperature (Heim et al. 2016).

Another finding from this study that is consistent with the literature is of larger Arctic grayling occupying habitats higher in headwater streams (Hughes 1992, Hughes and Reynolds 1994, Heim et al. 2016). Foraging opportunities tend to be higher in smaller, headwater streams (less water volume to cover for drift-feeding) and large grayling often occupy these areas and exclude smaller grayling from them (Vascotto 1970, Hughes 1992, 1999, Hughes and Reynolds 1994, Heim et al. 2016). This size-sorting was evident in the results herein—on average, the largest Arctic grayling were found in first-order streams (238.8 ± 13.3 mm SE), with average fork length decreasing as stream order increased (e.g., third-order average fork length = 117.8 ± 12.6 mm SE; fifth-order average fork length = 46.0 ± 6.1 mm SE).

In the late summer and fall, Arctic grayling seasonally migrate considerable distances (up to 320 km; Tripp and McCart 1974), leaving smaller headwater lakes and streams to overwinter in larger waterbodies, as the small headwater streams they inhabited in the summer often dewater or freeze to bottom during the winter months (Armstrong et al. 1986, West et al. 1992, Stewart et al. 2007, Heim 2014). This pattern appears consistent with our winter field results. Several of the same streams were visited in the summer and winter, and in nearly all cases, the streams were found to be dewatered or frozen to bed. Information on the Eagle Plains Ecoregion supports that small to intermediate streams in the region have no flow during the winter months (Smith et al. 2004).

Although water was detected in 15 of 49 sites during the winter field visit, the water depth and dissolved oxygen levels were insufficient to support overwintering fish at most sites. Adequate under-ice dissolved oxygen is a requirement for overwintering fish, as it affects fish respiration and metabolism, reproduction, growth, and survival (Leppi et al. 2016). General freshwater fish guidelines for dissolved oxygen indicate that most fish require dissolved oxygen levels above 6.0 mg/L, with potentially lethal consequences to prolonged exposure below 2.0 mg/L (Doudoroff and Shumway 1970, Davis 1975, Leppi et al. 2016). In third- and fourth-order streams sampled in the winter, dissolved oxygen levels ranged from 0.1 – 1.2 mg/L in all but one fourth-order stream. This site had dissolved oxygen levels of 4.0 mg/L in a pool, and 8.5 mg/L in the adjacent stream channel (where water was less stagnant). The only fifth-order stream with enough water to take water quality parameters was on McParlon Creek, and had dissolved oxygen levels of 1.7 mg/L. As such, based on the accepted published values of overwintering dissolved oxygen values, only one site sampled contained moderate dissolved oxygen levels for fish to overwinter.

A baseline water and sediment quality report (Golder Associates Ltd. 2018) assessed several of the same sites that were considered for the fish and water quality work completed in this report and the EDI Surface Water Quality and Hydrology Baseline Report (EDI 2021). Overall, the findings from the Golder study, completed between 2014 and 2017, are consistent with this study's water quality parameters and their suitability for fish rearing. Their findings determined that while there was sufficient dissolved oxygen during freshet and the open-water season, the ice-covered seasons had dissolved oxygen levels below the federal guidelines for aquatic life (5.5 – 9.5 mg/L; CCME 1999, Golder Associates Ltd. 2018). The water quality site CHNC-001 (located downstream, outside of the RSA) has been recorded by the Yukon Government from summer 2014 to fall 2017. During the three years of winter sampling (mid-March), the dissolved oxygen levels varied from 0.93 – 5.8 mg/L. As detailed in the EDI Surface Water Quality and Hydrology Baseline Report, CHNC-001 contained water during March 2019 with dissolved oxygen levels of 3.05 mg/L (EDI 2021). Though this site appears to contain water during the winter (potentially due to its proximity to the Whitestone River), the under-ice dissolved oxygen is considered poor to moderate for fish rearing (Doudoroff and Shumway 1970, Davis 1975, Leppi et al. 2016). Several other sites sampled by the Yukon Government were frozen or were characterized by shallow, muddy water (Golder Associates Ltd. 2018).

Slimy sculpin are considered an important indicator species for overwintering habitat, as they have strong site fidelity and only move a few hundred metres during their lifetime (Gray et al. 2004, 2018). Therefore, it is commonly accepted that if a slimy sculpin is captured in the summer, overwintering habitat will occur within several hundred metres of that location. Within this study, all slimy sculpin were captured in a concentrated area in the southern end of the RSA. Individuals were caught in five sites in Eagle River tributaries (Porcupine drainage; second- and fourth-order), two sites in the MacParlon River watershed (Porcupine drainage; third- and fifth-order), and one site in a tributary to Enterprise Creek (Peel drainage; third-order; Attachment C). Slimy sculpin were captured at eight sites during the summer sampling. These sites were revisited, and five winter sites contained water near summer slimy sculpin sites. As discussed above, one of these sites was the only site with sufficient under-ice dissolved oxygen to support overwintering fish (8.5 mg/L, site 267; Attachment G). Two other winter sites downstream of this site contained water, but at the point of sampling, they both had insufficient dissolved oxygen for overwintering fish. With the evidence

of summer sampling capturing slimy sculpin in second-order streams upstream of these sites, it is likely pockets of overwintering habitat exist elsewhere and within the range a slimy sculpin would travel.

Despite appropriate sampling methods, no salmon were captured or observed in the RSA. This finding is consistent with past work in the Porcupine River watershed that indicated salmon rearing appears to be limited to natal streams (streams in which they spawn; Anderton 2004). Known salmon spawning areas in the Porcupine drainage downstream of the RSA include the Whitestone (Chinook), Bell (Chinook and chum), and Rock rivers (Chinook and chum; Anderton 2004, EDI 2016), all of which are tens of km downstream from the RSA. From a habitat perspective, the predominance of slow-moving, turbid water, with silty/organic stream beds offers no spawning potential and low-quality juvenile rearing for salmon. Based on the far distances to suitable spawning habitat outside the RSA and the poor quality of rearing habitat within the RSA, salmon are unlikely to use the streams within the RSA.

5 CONCLUSIONS

This study successfully met its objectives of improving the understanding of fish distribution across the RSA in summer and winter. The results of this study indicate a dynamic pattern of fish occurrence in the RSA between summer and winter. Overwintering habitat is very limited in the RSA, and most fish likely migrate out of the RSA to find suitable overwintering habitat in larger rivers. During summer, transient fish, most notably Arctic grayling, travel tens to greater than 100 km from larger, higher order rivers to use second-order and greater streams in the RSA as seasonal rearing habitat.

Overall, the habitat diversity in the RSA was low and dominated by slow-moving, turbid water, with fines and organics bed materials. Despite this habitat not typically being considered quality rearing habitat for Arctic grayling, this fish was the most widespread species in the RSA, accounting for 85% of fish captured in the summer. Burbot, round whitefish, longnose sucker and slimy sculpin made up the other 15% of fish captured during the summer field program. No salmon were captured or observed within the RSA; these findings are consistent with the known extent of salmon use in the Porcupine River watershed. During the summer, fish presence was predominantly explained by stream order—fish were detected in almost none of the first-order streams, approximately half of the second-order streams, and almost all third-order and greater streams. The strong relationship between fish presence and stream order provides a clear and simple pattern of fish distribution that can be used for management to assess and mitigate potential Project effects to fish values in the RSA.

While fish (especially Arctic grayling) were found widely across the RSA during the summer months, nearly all sites assessed in the winter were frozen to bed, dewatered, or had insufficient under-ice dissolved oxygen levels for fish to overwinter. The lower reaches of Chance Creek and select sites along McParlon, Dalglish, and Enterprise creeks may offer limited overwintering habitat to a small number of fish (based on water conditions in March 2020 and the presence of non-migratory slimy sculpin at some summer sites). However, the extent of suitable overwintering habitat appears limited to small pockets capable of supporting only small numbers of fish. Most fish (i.e., all species other than slimy sculpin) likely migrate to higher-order streams outside the RSA with better overwintering conditions and larger stream extents.

[4] See (BC Ministry of Environment 2008) for more detailed descriptions.

[5] N=no, Y=yes, NS=not sampled

[6] Total cover = Any structure within the wetted width or within 1 m above the water surface that provides rearing habitat; L=low (≤ 5%), M=moderate (6-20%), H=high (≥21%)

[7] F=fines, O=organics, C=cobble, G=gravel
(-) denotes metrics not taken or not applicable, most often due to insufficient water.

EXECUTIVE SUMMARY

The Chance Oil and Gas Project (the Project) is in northeast Yukon, 32 km southwest of the Eagle Plains settlement and 260 km northeast of Dawson City. The site is accessed via the Dempster Highway. The Regional Study Area (RSA) encompasses 2,386 km². It contains no major rivers but has notable tributaries, including Greaves Creek, Chance Creek, McParlon Creek, Enterprise Creek, and Dalglish Creek. The Dempster Highway runs southwest to northeast through the southern half of the RSA. The Project overlaps the traditional territories of three First Nations, including the Vuntut Gwitchin First Nation, First Nation of Na-Cho Nyäk Dun, and the Tetlit Gwich'in Council Primary and Secondary Use Area.

Chance Oil and Gas Limited proposes conducting exploration activities for oil and gas. This will include a combination of seismic exploration (mostly three-dimensional [3D]) and drilling up to 30 exploratory wells. Both seismic and drilling activities will be conducted during the winter. However, some potential exists for year-round maintenance at certain wells for flow-testing. Access will be via existing and new winter roads.

Baseline vegetation information and data are required for most proposed oil and natural gas projects for screening under the *Yukon Environment and Socio-Economic Assessment Act* and other permits and licence applications. This Ecological and Landscape Classification (ELC) baseline report aims to provide information and data on the current condition of ecological communities (i.e., ecosites) within the RSA.

The Project falls within the Taiga Cordillera Ecozone and is located entirely within the Eagle Plains Ecoregion. The Eagle Plains Ecoregion is a 20,400 km² area in north Yukon between the Richardson and Ogilvie Mountains. Most of the region is low altitude rolling topography. The Eagle Plains Ecoregion is primarily unglaciated terrain within the continuous permafrost zone, where permafrost can be found up to 200 m thick. Several permafrost-produced landforms and processes can be found across the region. Within the continuous permafrost zone, the depth to and specific location of the permafrost depend mainly on the thickness of the surface organic horizon and the moisture content of the active layer. Evidence of forest fires is observed throughout the RSA. Fires increase the depth of the active permafrost layer, causing slope failures and changes in ecosystem moisture regimes.

Tree growth is limited by cool and short summers and permafrost in many areas, causing stunted forests. This results in disclimax vegetation communities with tall and low shrub structural stages. Upland black and white spruce forests typically have well-developed shrub communities, including Labrador tea, scrub/shrub birch, willow, alder, rose, blueberry, lowbush cranberry and spiraea with a groundcover of lichen and moss. Areas with low slope gradients and fine-textured soils often have ground cover dominated by cottongrass tussocks and are associated with shrub species such as scrub/shrub birch, black spruce, and Labrador tea.

In interviews, members of the Vuntut Gwitchin First Nation (VGFN) have discussed the ecology and phenology of their traditional berry harvesting areas. Most berry harvesting focused on blueberries, raspberries, salmonberries and cranberries, and important berry harvesting areas were in wetter areas.

The ELC mapping approach consisted of interpreting digital imagery to delineate and attribute polygons based on vegetation patterns and environmental conditions, such as slope, aspect, and slope position. Site-level

ecosystem units have not been previously described for the RSA; therefore, new ecosystem units (i.e., ecosites, ecological communities) were developed. The mapping and classification methodology conforms to the Yukon Government classification and mapping guidelines.

A total of 6,617 ELC polygons were delineated and attributed within the RSA, representing 31 different ecosystem communities. The ELC polygons had an average polygon size of 36 ha. Large polygons generally covered large homogenous slopes and were often in fire-disturbed areas. Smaller polygons were used to delineate small water bodies, wetland features or high-value wildlife habitats (e.g., areas with high lichen abundance for caribou and productive riparian conifer forests that offered mature stand structure characteristics not found in other parts of the RSA). Field surveys documented 126 different plant species, including six tree species, 29 shrub species, 48 forb species, seven ferns and fern allies, 12 graminoid species, 11 lichen species, ten moss species, and two liverwort species.

Most of the RSA has a soil moisture regime ranging from moist to wet, typically associated with seasonal melting of the active layer of the permafrost. Sixty-four percent of the RSA is composed of moist ecosystem units and another 13% is composed of wet ecosystem units. Seventeen percent of the RSA has ecosystem units within a mesic soil moisture regime. Only 2% of the RSA is composed of dry ecosystem units typically found on warm steep aspects.

Thirty-one ecosystem units were mapped within the RSA. The RSA is composed of 2,528 ha of wetland habitat. The most common ecosystem unit mapped in the RSA is Moist Spruce – Labrador Tea (44%), followed by Moist Spruce – Alder – Labrador Tea (12%) and Mesic Black Spruce – Alaska Paper Birch (9%). The least common ecosystem units mapped are Dry Sparsely Vegetated <0.05%), Mesic Birch – Willow (<0.05%) and Moist Birch – Willow <0.05%). Both Birch – Willow ecosystem units are influenced by old anthropogenic disturbances. Other less common ecosystem units that occur on undisturbed units are Dry Aspen - Lichen (<0.05%), Mesic White Spruce – Alaska Paper Birch – Alder <0.05%), and Wet Shrub Scrub Birch – Graminoid (<0.05%). Bogs were the most common wetland ecosystem unit mapped across the RSA. Fen and marshes were observed and mapped. No swamps were identified during the field program and no swamps were mapped within the RSA.

Most of the RSA is mapped in a 'Shrub' structural stage (74%), which includes 29% in Tall Shrub (>2 m) and 45% in Low Shrub (<2 m). Tall Shrub consists mainly of disclimax stunted black and white spruce ecosystem unit types and regenerating burns (old burns >25 years). Low Shrub areas consist primarily of younger regenerating burns (recent burns <25 years) and disclimax shrub sites, dominated by willow or scrub/shrub birch. About 1% of the RSA is in an old forest structural stage, and 21% is in a mature forest structural stage.

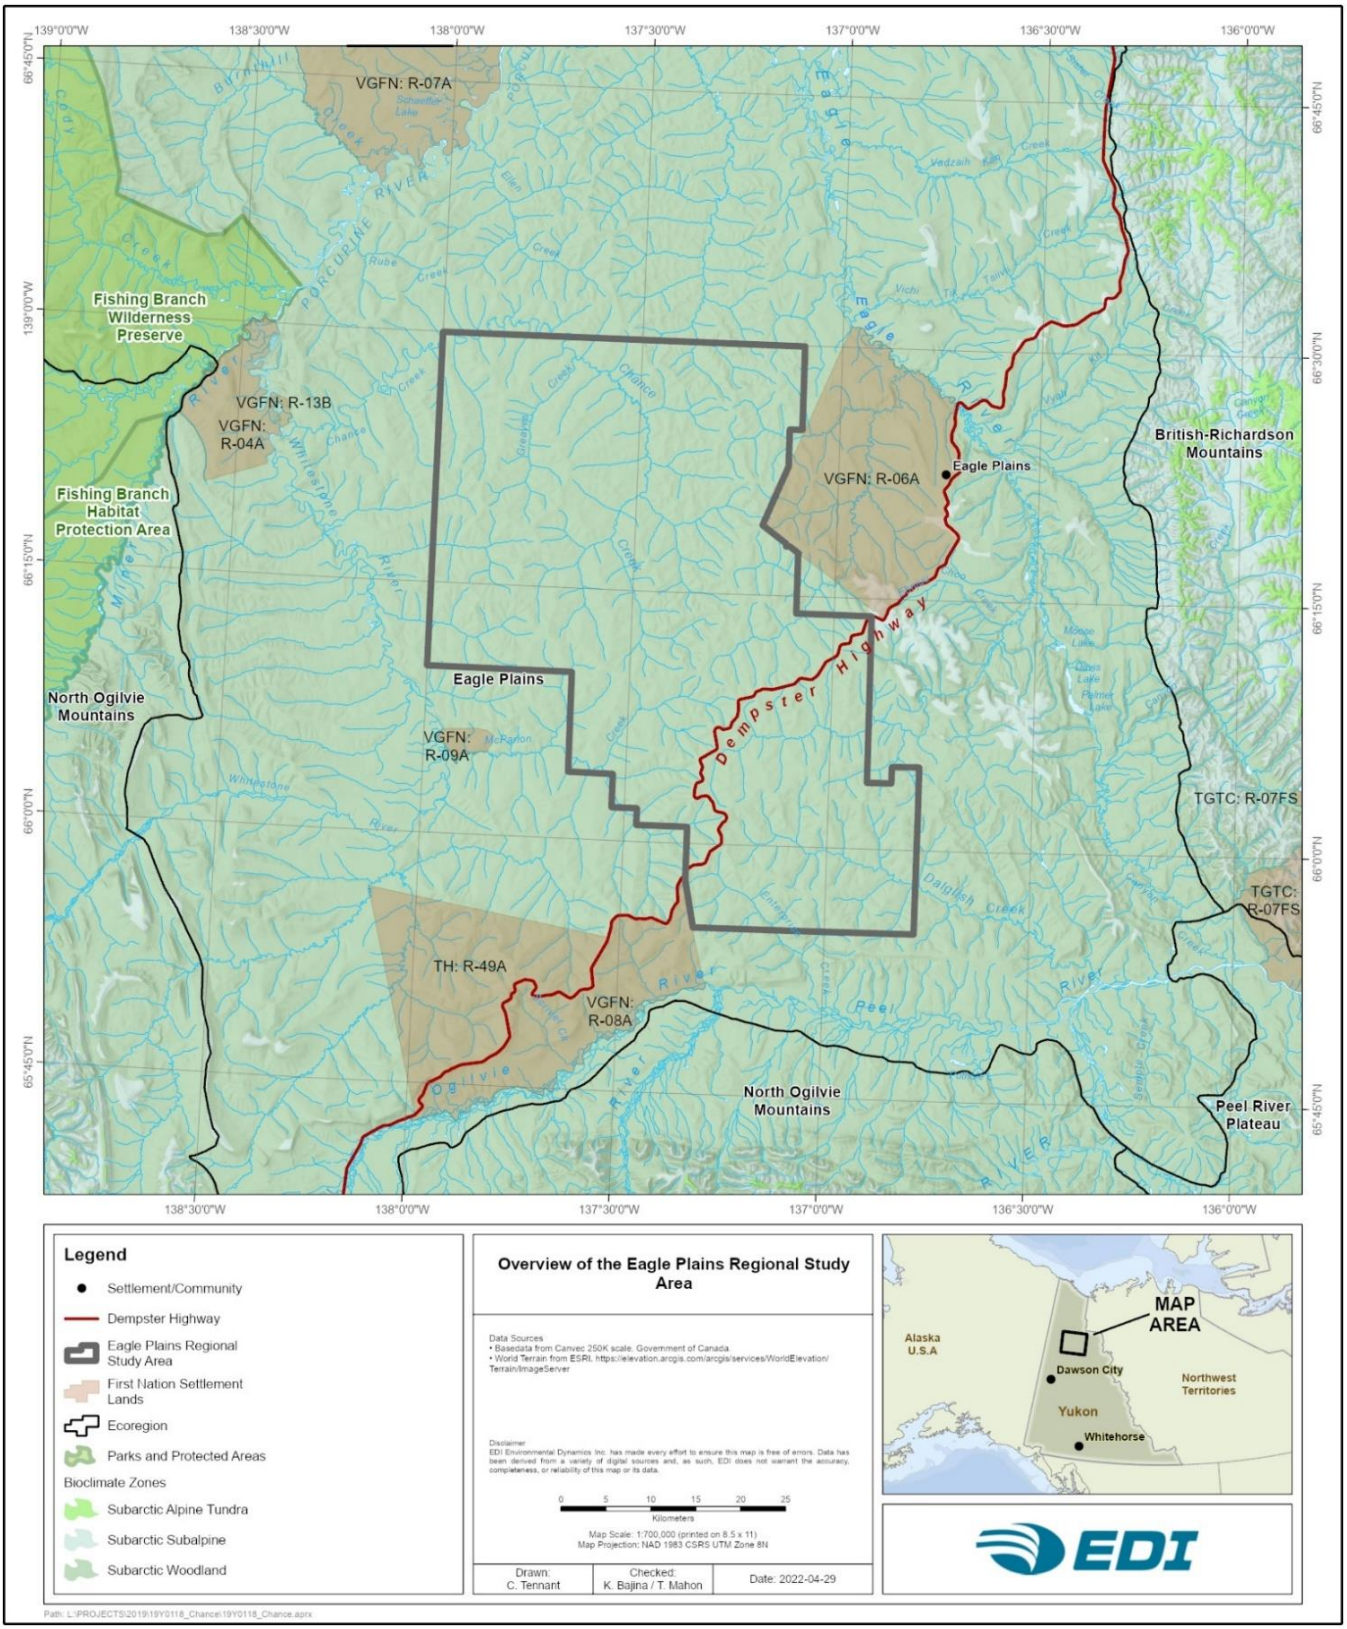
1 OVERVIEW

Chance Oil and Gas Limited (Chance) proposes conducting exploration activities for oil and gas within a 2,400 km^2 area in Eagle Plains. The Eagle Plains Exploration Project (the Project) is located along the Dempster Highway in northern Yukon, approximately 32 km southwest of the settlement of Eagle Plains and 260 km northeast of Dawson City (Map 1-1). The work will include a combination of seismic exploration (mostly three-dimensional [3D]) and drilling up to 30 exploratory wells. Both seismic and drilling activities will be conducted during the winter, though some potential exists for year-round maintenance at certain wells for flow-testing. Access will be via existing and new winter roads. The Project would build on 2D and 3D seismic exploration completed by Northern Cross Limited and others in the Eagle Plains area. The extent and density of seismic activity are not determined at this point but will be adapted based on the program's findings. Both seismic and drilling activities will be conducted during the winter and accessed via existing and new winter roads.

The Project is located within the North Yukon Planning Region and Peel Watershed Planning Region. Several First Nation Settlement Lands occur near or adjacent to the Project, but none overlap the Project itself. The Fishing Branch Wilderness Preserve is approximately 15 km west of the northwest boundary of the Regional Study Area (RSA); no other designated parks or preserves occur near the Project (Map 1-1).

The Project overlaps the traditional territories of three First Nations, including the First Nation of Na-cho Nyäk Dun (NND), Tetlit Gwich'in Council (TGC) Primary and Secondary Use Area and the Vuntut Gwitchin First Nation (VGFN) (Map 1-1).

In interviews, members of the Vuntut Gwitchin First Nation (VGFN) have discussed the ecology and phenology of their traditional berry harvesting areas. They observed that blueberries, raspberries and salmonberries began to ripen in July, and salmonberries grew in acidic, peaty soils (Sherry and Vuntut Gwitchin First Nation 1999, p. 108). Cranberries grew on lakeshores, mountainsides and hilltops and would ripen from the end of August until early September. Important berry harvesting areas were in wetter areas where berries grew bigger around lakes and Whitestone Village (Sherry and Vuntut Gwitchin First Nation 1999, p. 109, 110). However, during the interviews in the late 1990s, VGFN elders expressed concerns with increasing sun strength drying out moss and possibly affecting berry production. They noted that it had become harder to find berries, which they felt may have been attributed to acid rain, groundwater pollution and the rainfall at the beginning of spring (Sherry and Vuntut Gwitchin First Nation 1999, p. 115, 116).



Map 1-1. Overview of the Eagle Plains Regional Study Area.

1.1 PROJECT OVERVIEW

Baseline vegetation information and data are required for most proposed oil and natural gas projects submitted to the Yukon Environment and Socio-economic Assessment Board (YESAB) Executive Committee for screening under the *Yukon Environment and Socio-Economic Assessment Act* (YESAA), and applications to be submitted for a Geoscience Exploration Licence and a Water Licence, among other permits and licences. To receive authorization for the Eagle Plain Exploration Project to proceed, the Project must be evaluated under YESAA. Specific vegetation objectives, as identified in the YESAB's Proponent's Guide to Information Requirements for Executive Committee Project Proposal Submissions (YESAB 2005), are to:

- provide information on land cover types, forest cover and site quality;
- document plant communities to the species level, on the sites that may be disturbed as a result of development;
- describe vegetation and vegetation assemblages, including any identified rare, sensitive, or endangered species and ecological reserves; and,
- identify any wetlands in the RSA.

The overall objective of this Ecological and Landscape Classification (ELC) baseline report is to provide information and data on the current condition of ecological communities (i.e., ecosites) within the RSA. The collection of ELC baseline data will describe the current conditions of ecological communities found within the RSA to assist with assessing potential Project effects on vegetation and assessing wildlife habitat in the area. Baseline information and data on other vegetation components such as rare plants, traditional and medicinal plants and invasive plant species were not assessed as part of this study. The ELC mapping can guide the assessment of those components based on the environmental conditions and vegetation species associated with the various ecosystem units documented as part of the ELC program. Wetlands were identified and classified as part of the ELC mapping.

1.2 REGIONAL ECOLOGICAL OVERVIEW

The Project falls within the Taiga Cordillera Ecozone and is located entirely within the Eagle Plains Ecoregion. The Taiga Cordillera Ecozone is associated with most of the northern half of the Yukon. The Taiga Cordillera Ecozone is characterized by mountain topography (though the Eagle Plains region is not mountainous), both glaciated and unglaciated terrain, and continuous permafrost underlying most soils. The climate in the Taiga Cordillera varies from its northern to southern extent. Annual precipitation ranges from less than 300 mm in the north to over 700 mm in the southeast. Generally, summers are cool to warm with extended periods of daylight, while winters are long, cold, and dark. Weather is influenced heavily by the Arctic and Alaskan Coasts (Ecological Stratification Working Group 1995).

The RSA is in the Eagle Plains Ecoregion, a 20,400 km^2 area between the Richardson and Ogilvie Mountains. Most of the region is low altitude rolling topography, between 300 m and 600 m above sea level (asl), with few scattered peaks above and around 1,000 masl. Most of the Ecoregion drains north into the Yukon River via the Whitestone, Porcupine and Eagle rivers. The southeast corner of the region drains east to the

Mackenzie River via the Peel, Wind and Ogilvie Rivers. The drainages in the northeast of the RSA are tributaries of the Porcupine River. These include the headwaters of the Eagle River and the upper reaches of the Whitestone River, which are the Chance and McParlon Creek sub-drainages. The drainages of the southwest of the RSA contain several creeks, including Dalglish and Enterprise Creeks, which flow directly into the Peel River (Access Consulting Group and EBA Engineering Consultants Ltd. 2001a). Few lakes occur in the Ecoregion and mainly consist of lowland oxbow and thermokarst lakes (Yukon Ecoregions Working Group 2004a). Within the RSA, several wetland complexes are associated with the larger creeks.

The Eagle Plains Ecoregion experiences a moderate amount of precipitation, with annual amounts around 400 mm. Most precipitation falls as rain throughout the summer months, averaging 50 to 80 mm per month, June through August. Precipitation is less from September to April and falls as snow. The temperature in this Ecoregion is affected by season and latitude, causing extended winter conditions that usually last from October through to early May. A strong variation occurs in seasonal temperatures on the Eagle Plains Plateau. Average winter temperatures are around −30°C and −25°C, with extremes as low as −60°C. Average summer temperatures are around 13°C, with extremes as high as 30°C. Minimal wind data are available for this region. Winter winds are generally light, and summer winds are moderate to light, generally from the west or east (Yukon Ecoregions Working Group 2004a).

The Eagle Plains Ecoregion is within the continuous permafrost zone, where permafrost can be found up to 200 m thick. Several permafrost-produced landforms and processes can be found across the region, including ice-wedge polygons, cryoturbation, solifluction, soil creep and active layer detachment slides on shale. Within the continuous permafrost zone, the depth to and specific location of the permafrost depends mainly on the thickness of the surface organic horizon, which acts as an insulator during the warmer summer months, and on the moisture content of the active layer (Yukon Ecoregions Working Group 2004b).

The Eagle Plains Ecoregion is primarily underlain by sedimentary rock, primarily sandstone and shale. Colluvial deposits cover most of the Ecoregion, with the remaining areas being covered by glaciolacustrine, glaciofluvial and alluvial deposits. Most of the surficial features result from processes associated with permafrost and frozen ground, including thermokarst subsidence and soil creep, cryoturbation, solifluction and active layer detachment slides on shale. Most of the Eagle Plains Ecoregion is unglaciated terrain (Yukon Ecoregions Working Group 2004a).

The Eagle Plains Ecoregion has predominately Crysolic soils with patches of Brunisolic soils. Cryosols are soils underlain by near-surface permafrost, while Brunisols are mildly weathered forest soils (Yukon Ecoregions Working Group 2004b). Soils on the well-drained slopes and active alluvial locations, where permafrost is absent, are classified as Dystric Brunisols. Due to long weathering periods, these soils may contain large amounts of iron oxides and may have pH as low as 4. Tuberic Cryosols are associated with hummocks and produce patterned ground formations. They are often found under open stands of black spruce, tamarack and birch. The active permafrost layer in these ecosystems generally ranges between 20 cm and 90 cm below the surface. The active layer depth is dependent on the location of the hummocks and will be deeper directly under hummock and shallower under the inter-hummock areas (Yukon Ecoregions Working Group 2004a).

Drainages of the Ecoregion are often represented by dendritic to trellis patterns, formed due to the fine-grained soils over sedimentary bedrock and unglaciated terrain. Larger streams are typically meandering. The presence of a permafrost layer restricts vertical drainage, and imperfect drainage is common. Low slope gradients and fine-textured soils restrict lateral groundwater flow, often limiting water availability during the low flow period (November to April). Some areas with moderate or steep slopes and colluvium mineral soil will be well to moderately well-drained (Access Consulting Group and EBA Engineering Consultants Ltd. 2001a).

Peak streamflow in the Ecoregion occurs in May and June because of the annual snow melt. Secondary peaks occur due to summer rain events. The region's annual mean runoff ranges from 173 to 233 mm, with an ecosystem mean of 201 mm. Cold winter temperatures and permafrost dramatically reduce winter flows, and some small streams will experience zero winter flows. Minimum flow generally occurs in March or earlier depending on seasonal temperatures and precipitation (Yukon Ecoregions Working Group 2004a).

Evidence of forest fires can be observed throughout the RSA. Alaskan paper-birch is commonly the first tree species to colonize burn areas. Occasionally, on well-drained sites, aspen (*Populus tremuloides*) and balsam poplar (*Populus balsamifera*) may be the first tree species to re-colonize. The extent of burns can be recognized by the current black spruce – Alaskan paper birch woodlands (Yukon Ecoregions Working Group 2004a). Fires increase the depth of the active permafrost layer, causing slope failures and changes in ecosystem moisture regimes.

The Eagle Plains Ecoregion is within the Subarctic Bioclimate Region, characterized by stunted, open canopy spruce-dominated habitats (Environment Yukon 2016). It occurs between the Arctic tree limit and the closed canopy boreal forests characteristic of southern Yukon, and acts as a transition zone between the two (Yukon Ecoregions Working Group 2004b). Two subzones occur within the Subarctic Bioclimate Region: Subarctic Woodland Zone, and Subarctic Alpine Zone (Environment Yukon 2016). General information about each Bioclimate zone is presented in Table 1-1. The ELC mapping did not distinguish between the two Bioclimate zones because only a very small portion of the RSA was in the Subarctic Alpine Zone. Permafrost often limits tree growth in many areas of the Ecoregion, causing stunted forests. This results in disclimax vegetation communities with tall and low shrub structural stages. The most common climax forest community is black spruce (*Picea mariana*) woodlands associated with hummocks. Upland black and white spruce (*Picea glauca*) forests typically have well-developed shrub communities, including Labrador tea (*Rhododendron groenlandicum*), scrub/shrub birch (*Betula glandulosa*), willow (*Salix* species), alder (*Alnus* species), rose (*Rosa* species), blueberry (*Vaccinium* species), and *Spiraea* and with a groundcover of lichen and moss. Well-drained sites commonly have white spruce stands with lichen ground cover. Areas with low slope gradients and fine-textured soils often have ground cover dominated by cottongrass tussocks and are associated with shrub species such as scrub/shrub birch, black spruce, Labrador tea, and occasionally tamarack (*Larix laricina*) (Yukon Ecoregions Working Group 2004a).

Graminoid and shrubby fens, bogs and graminoid marshes are scattered throughout the region. Several sedge species are dominant in both the graminoid fens and marshes, including narrow-leaf cottongrass (*Eriophorum angustifolium*), aquatic sedge (*Carex aquatilis*), northern beaked sedge (*Carex utriculata*) and mud sedge (*Carex limosa*). Shrub species in fens include leatherleaf (*Chamaedaphne calyculata*) and bog rosemary (*Andromeda*

polifolia). The ground cover of the shrubby bogs is dominated by sphagnum, sometimes with extensive lichen cover. Shrub species typically include low bush cranberry (*Vaccinium vitis-idaea*), bog cranberry (*Vaccinium oxycoccos*), bog rosemary, baked apple/cloudberry (*Rubus chamaemorus*), Labrador tea, scrub/shrub birch, willow, black spruce and occasionally tamarack.

Riparian forests are found as narrow strips along most major watercourses in the study area. These are well-drained white and black spruce stands and may have prickly rose (*Rosa acicularis*), willow, shrub and Alaska paper birch (*Betula neoalaskana*) in their understory. Deciduous stands can be found on warm, moderately well to well-drained slopes. These stands are typically Alaska paper birch, but some sites may also have balsam poplar, willow or trembling aspen. Deciduous stands are often found in areas of recent anthropogenic disturbance, such as old roads, drill sites and gravel pits.

Table 1-1. Bioclimate zones in the Eagle Plains RSA.

Bioclimate Zone	Description	RSA (ha)
Subarctic Woodland Zone (SUW)	Mixed wood or coniferous forests with an open canopy. Occur on plateaus, plains, valley bottoms and lower slopes of mountains. Vegetation dynamics and distribution is influenced by slope position and aspect, and the distribution and depth of permafrost (Environment Yukon 2016)	238,620
Subarctic Subalpine Zone (SUS)	Tall or low shrubs, with sparse to sporadic tree cover. Occurs at high elevations in northern mountain systems or in areas influenced by Arctic weather systems (Environment Yukon 2016).	19

1.2.1 EXISTING ECOLOGICAL DATA

In addition to the broad ecoregion description provided in Yukon Ecoregions Working Group (2004a), two types of local, regional ecological data exist for the area. A preliminary ecosystem classification was developed for Eagle Plains Ecoregion (Rosie 2000) and predictive Ecosystem Mapping models were developed for the North Yukon (Meikle et al. 2005) and Peel Planning Areas (Meikle and Waterreus 2008). Rosie (2000) describes possible vegetation types in the Peel River Plateau, Richardson Mountains and Eagles Plains Ecoregions. This report has no spatial or non-spatial files associated with it. Field work was carried out by the Yukon Territorial Government Protected Areas Secretariat in July and August 2000 to gather site, vegetation, and soil information. Approximately 153 plots were established across all three Ecoregions. Rosie tabulated and analyzed the collected data to develop vegetation types associated with the three Ecoregions. She developed six vegetation type categories with associated vegetation communities (Attachment A):

1. Alpine Communities: Ground Shrub Types; Alpine Blockfields and Rocky Slopes.
2. Shrub Types: Shrub Birch Stands; Willow Stands, Mixed Shrub Birch/Willow Stands; Alder Stands
3. Treed Types: Black Spruce Stands; White Spruce Stands; Birch Stands; Balsam Poplar Stands
4. Graminoid Types and Wetlands: *Eriophorum* Tussock Community; Wetlands

5. Slumps (Detachment Slides)

6. Miscellaneous Other Types: Small Gravel Beach at Davis Lake; Gravel Bar on Caribou River; Transect from River Inward to Older part of Floodplain; Small brook on mountain slope; Repeating Pattern of Vegetation on Steep Mountain Slope.

The Rosie (2000) report states that the most encountered vegetation communities found in these Ecoregions were described, but several uncommon types could likely have been missed during the field program.

Two Predictive Ecosystem Mapping (PEM) products were also available for the RSA. They are the North Yukon PEM and the Peel Watershed PEM. These two spatial PEM products cover the Chance RSA. The North Yukon PEM was completed in 2005, and the Peel Watershed PEM was completed in 2008. Both products use the Earth Observation for Sustainable Development of Forests (EOSD) as their model's land cover classification input.

The North Yukon PEM (Meikle et al. 2005) covers the following six Ecoregions: Richardson Mountains, Eagle Plains, Old Crow Flats, Old Crow Basin, Davidson Mountains, and North Ogilvie Mountains. The Mountain landscapes are organized by elevation (Bioclimate Zones), and Plateau landscapes are organized by relative moisture gradient (Ecosite). Mapping was completed with input data at scales ranging from 1:100,000 to 1:250,000, and a raster mapping approach was chosen for this PEM product (Meikle et al. 2005).

Meikle et al. (2005) did use an ecosite approach and it resulted in 3 Bioclimate Zones (Taiga Wooded; Taiga Shrub; Alpine) and 28 biophysical classes, organized by high elevation, low-middle elevation, riparian and wetland landscape positions (Attachment A). They list the Landscape Types associated with the Bioclimate Zones with representative photographs but do not provide vegetation descriptions.

The Peel Watershed PEM (Meikle and Waterreus 2008) covers the Peel Watershed, which contains in whole or in part the following six Ecoregions: Eagle Plains, British-Richardson Mountains, Ft. McPherson Plain, Peel River Plateau, North Ogilvie Mountains and Mackenzie Mountains. The goal of this product was to produce mapped classes with distinctions reliably supported by input data that were also meaningful for anticipated uses by the Peel Watershed Planning Commission.

The Peel Watershed ecosystem classification is derived from the EOSD interpretation with other inputs such as bioterrain to describe thirty-one Ecosystem Classes. The ecosystem classes developed by the authors were correlated by adjacent projects that used similar approaches, such as the North Yukon PEM (Meikle et al. 2005) and the Vegetation Types described by Rosie (2000). The 31 biophysical classes are organized by high elevation, medium to low elevation, riparian, wetland and open water groups (Attachment A). The associated Peel Watershed PEM report includes a one-page factsheet for each of the 31 ecosystem classes. The factsheets provide an ecosite descriptive paragraph with representative photo, a list of model inputs and correlation to other classifications.

Some of the North Yukon and Peel Watershed PEM product limitations are:

1. The documentation associated with the North Yukon PEM is a PowerPoint presentation. Many technical details associated with the product are undocumented and require guessing of how the PEM was constructed and the environmental conditions associated with the BEU outputs.

2. Accuracy due to errors inherent in the input data (EOSD, bioterrain and moisture class)

3. Missing data (cloud cover, shadows)

4. Ecosystem classification detail level. The number of BEU classes used to describe the area is perhaps too few, given the ecological diversity of this large area, potentially failing to classify important ecosystems (e.g., habitats for wildlife or rare plants).

5. The ecosystem classification is based on vegetation plot data but the completed PEM product was never field verified, so the accuracy of the product is unknown

6. The way wetlands are defined potentially underestimates wetland classes.

Overall, there is a lack of wetland differentiation within the PEMs and Rosie's work. Often various types and classes of wetlands provide habitat for rare plants and traditional and medicinal plants. The PEMs do not provide any structural stage data, which can be important for wildlife suitability mapping. For example, a young forest provides a different type of habitat than a mature forest. Similarly, an area composed of low shrubs could be mapped as unsuitable habitat. In contrast, an area composed of tall shrubs could be considered suitable habitat.

The adequacy of the two PEMs was assessed, and the PEMs were determined to be inadequate for the needs of this project. The inadequacies were determined based on field observations. Some of the key issues which need to be addressed in a final map product to help support wildlife needs include:

- Mapping needs to be refined to identify lichen sites. Although areas mapped as Dry in the PEMs currently include most lichen sites, they also include much larger extents that do not contain lichen.
- Mapping needs to be refined to include structural stage (or lumped structural stage categories), at least for Sb-leading types.
- Mapping needs to differentiate between deciduous shrubs (mostly from recent burns) and shrub-stage Sb.

Beyond wildlife-specific needs, the following observations are systematic PEM 'problems' that limit its accuracy and utility:

- Riparian areas: these units are generally too wide — often twice as wide as what was observed. Also, they often are not riparian areas, rather wet sites in valley bottoms and lower and toe slope positions, where moisture is received from upslope areas versus streams. These units also tend to truncate short on first and second-order streams, which have similar, if narrower, wet shrubby

areas as the 3XXs. These truncated areas are typically mapped as Moist units when they are Wet units.

- Most Dry areas are not dry. They are stunted Sb-permafrost bog.
- Location of Wet vs Moist areas. The relative locations of Wet and Moist locations do not correspond with slope positions. Most Wet areas are on Mid-Upper-Crest positions in association with Dry areas, above Moist areas in Lower-Toe-Valley Bottom sites. It would make more intuitive sense if the wet and moist classifications were reversed (i.e., wet areas below moist).
- There is a bias to overestimate Herb areas. Many areas mapped as Herb were Shrub, including several burns.
- There are no Moist areas mapped for the Peel PEM

Notwithstanding the limitations of the PEMs and the preliminary ecosite classification developed by Rosie, the information from these sources was used to help develop the ecosystem units for this ELC study.

1.3 ECOSYSTEM LANDSCAPE CLASSIFICATION

Ecological and Landscape Classification mapping is an integrated approach to mapping and classifying land units according to their ecological similarity (Environment Yukon 2016). The ELC mapping provides information on various landscape components' biological and physical characteristics to facilitate a range of interpretations and assist in sustainable management (Rowe and Sheard 1981, Environment Yukon 2016). For example, defining ecosystem units (i.e., ecosites, ecological communities) with similar vegetation, site and soil characteristics provides information on the current condition of vegetation, can facilitate the development of vegetation mitigation measures during infrastructure development, and aid in assessing habitat suitability for wildlife across a landscape.

Two ecological frameworks are used for ELC work in the Yukon: The Yukon Bioclimate Ecosystem Classification (YBEC) Framework and the National Ecological Framework (NEF) of Canada (Environment Yukon 2016). The YBEC system is modelled, in general, after the Biogeoclimatic Ecosystem Classification (BEC) System of British Columbia (Pojar et al. 1987, Meidinger and Pojar 1991). The BC classification system consists of a site-level, or local, classification but considers climate to be the overarching primary influence on ecosystem development and distribution. Within areas of a similar climate, ecosystems (ecological communities, ecosites) are expected to vary due to differences in topography and soil. The YBEC system provides detailed local-level ecological mapping and interpretations, set within a regional context (Environment Yukon 2016). Conversely, NEF describes the biophysical properties of large land units based on ecological similarity (Ecological Stratification Working Group 1995). An example of this framework is the Ecoregions of the Yukon Territory (Smith et al. 2004), which provides generalized regional biophysical information about the landscapes of the Yukon but does not support detailed site-level mapping.

Combined, the YBEC and NEF frameworks group ecosystems at different levels in a complementary way (regional to local levels). This ELC study aimed to work within these frameworks, using a hierarchical ecosystem classification of ecoregions, bioclimate zones and local ecosites (ecological communities, ecosystem

units). Ecoregions are large areas (scale of 1:3,000,000 to 1:1,000,000) within the NEF system characterized by a distinctive regional climate expressed by vegetation (Smith et al. 2004, Environment Yukon 2016). Bioclimate zones are broad areas within the YBEC system with the same regional climatic patterns, such as subalpine, alpine and boreal high areas. These zones are used to establish the ecological context for local ecosites (i.e., ecological communities, ecosystem units), which are the classification system's site-level 'building blocks.' They represent vegetation potential and are relatively stable and enduring features defined by landscape position and characteristic site conditions, including soil moisture and nutrient regimes (Environment Yukon 2016).

Within the RSA, the diversity of plant species occurrences is due to the range in elevation and topography, extensive permafrost and river and creek floodplains. Aspect, slope gradient and presence of near-surface permafrost heavily influence plant community composition across the landscape.

1.4 SPATIAL BOUNDARIES

The Eagle Plains RSA is 2,386 km² (238,640 ha). It is characterized by rolling taiga topography and does not contain major rivers (Map 1-1, Photo 1-1). Notable tributaries include Greaves Creek, Chance Creek, McParlon Creek, Enterprise Creek, and Dalglish Creek. The Dempster Highway runs southwest to northeast through the southern half of the RSA.

The RSA is dissected by numerous 2D seismic lines and winter roads from previous exploration activities dating back to the 1960s. Most 2D exploration occurred between 1961 and 1984, with new 2D exploration in 2001 (Access Consulting Group and EBA Engineering Consultants Ltd. 2001b, GEOTIR 2014). Approximately 2,200 km of new 3D LIS exploration was conducted in a 325 km² area between November 2013 and April 2014 (GEOTIR 2014). This new 3D exploration is located near the centre of the RSA, spanning north and south of the Dempster Highway.

One of the key requirements for the YESAB proposal effects assessment will be having a study area-wide ecosystem map.

Photo 1-1. Example of the RSA's rolling topography and changes in vegetation composition.

2 METHODS

An examination of the adequacy of existing ecosystem maps was completed to verify if these maps would meet effect assessment needs and could be used to support habitat mapping for wildlife Valued Components. Currently, vegetation mapping defines vegetation communities in the RSA and their value as habitats for focal wildlife species, rare plants, and traditional and medicinal plants.

Typically, ecosystem mapping can be developed using one of three methods:

1. Manual process — where an ecologist visually completes an interpretation of aerial photographs or satellite images to identify and delineate ecosystems and their attributes (e.g., Yukon Ecological and Landscape Classification framework);

2. GIS modelling, or predictive approaches — where an ecologist uses their knowledge of ecosystem patterns and relationships to predict the locations of ecosystems on the landscape using a model-based approach (e.g., PEM); and,

3. Hybrid approach — where an ecologist uses manual approach methods to supplement or increase the accuracy of certain features within a map modelled with GIS.

Two options for vegetation mapping were presented to Chance: the use of existing PEM products or the creation of a new ELC product. Initially, it was decided to use the existing PEM products to create an ecological spatial database for the RSA.

Most of the RSA is within the North Yukon PEM with a small portion of the southern section of the RSA within the Peel Watershed PEM. The Peel Watershed PEM and North Yukon PEM ecosystem classification and mapping methodologies are very similar, and the ecosystem classification methodology for both was developed and conducted by the Yukon Land Use Planning Council working with the Habitat and Regional Management Section, Environment Yukon. Both ecological classifications were derived by designing and implementing a model that uses applicable spatial digital data layers. The model inputs were:

- broad landcover data (EOSD raster layer);
- Yukon Bioclimate Zones;
- slope and aspect from a Digital Elevation Model (DEM); and,
- soil moisture model.

The resolution of the PEMs output was 25 m; however, the native resolution of the EOSD layer is 200 m, which delimits the functional accuracy of the final PEM. As a result, the spatial accuracy of the final product is approximately 100 m (half the width of a 200 m pixel).

The initial step for this mapping exercise was to amalgamate the spatial North Yukon PEM (Meikle et al. 2005) and the Peel Watershed PEM (Meikle and Waterreus 2008) into a single cohesive database that covered the entire RSA. The spatial file was converted from a raster (grids) format to a vector (polygons) format for the field assessment maps.

EDI recommended that a two-staged field assessment be implemented. The first field assessment would be to verify the quality and accuracy of the PEM layer. If the PEM was inadequate, a second field survey would be tailored to support a new ELC product. Otherwise, the second survey would supplement the first round of surveys to meet overall sample size requirements. Additional details on the field sampling program are provided in the next section.

2.1 FIELD SAMPLING AND DATA ENTRY

Plots and PEM polygon checks were distributed throughout the entire RSA, with sampling occurring across the various ecosystem types and structural stages, including a representative sample of ecosystems across the various slope positions and moisture/nutrient combinations on the edatopic grid. Sampling was focused on sites and ecosystems of special interest, including:

- a representative sample of the full range of potential ecosites;
- wetlands and riparian areas;
- non-forested site series, including bluffs and lichen, bryophyte, herbaceous, and shrub communities;
- ecosystems of interest that have the potential to occur in the RSA;
- focal wildlife species key habitats; and,
- other special or anomalous features of interest.

Field crews recorded field data using Yukon Standard Site Visit Forms (SIVIs) for all ground inspection plots. Visual checks were recorded separately in field notebooks. Data collection followed the standard ecological data collection techniques and methods defined in the *Field Manual for Describing Yukon Ecosystems* (Environment Yukon 2017) and the *BC Field Manual for Describing Terrestrial Ecosystems* (BC MFLNRORD and BC MOE 2010). Section 5 of the latter reference provides detailed information specific to the Site Visit Form and mandatory data fields for ground plots.

Ground inspections provide data for characterizing ecosystem attributes, including vegetation composition, slope position, soil characteristics, and structural stage. Visual checks are quick field recordings of site, soil and vegetation conditions that help inform ecosite identification or other useful attributes (e.g., structural stage, soil moisture). Visual checks are intended to be quick assessments and can include observations from a helicopter (air call), viewpoint, or as a note while walking through a habitat. The GPS coordinates were recorded and digital photographs were taken at all plot locations.

Upon completion of field sampling, the plot cards and associated notes were reviewed for completeness and accuracy during an internal data quality assurance (QA) process. All associated digital photographs and GPS coordinates were examined to ensure they corresponded to, and were named for, the appropriate field plots. Ground inspections with vegetation percent cover information were entered into the Yukon Biophysical Inventory System (YBIS). Visual checks without vegetation percent cover information were entered into an excel spreadsheet database.

2.2 ELC SYSTEM AND DATABASE DEVELOPMENT

To best meet the needs of the Project, a manual ELC mapping approach was completed, where mappers examine and interpret digital ortho-imagery to manually delineate and attribute polygons with ecological information. This method typically provides more detail and accuracy than predictive modelling approaches. The mapping and classification methodology conforms to the Yukon Ecological and Landscape Classification and Mapping Guidelines, Version 1.0 (Environment Yukon 2016), and the Standard for Terrestrial Ecosystem Mapping in British Columbia (Resources Inventory Committee 1998) were used as guidelines.

Ecosystem Landscape Classification mapping projects in the Yukon are encouraged to follow the YBEC Framework. The YBEC system is developing detailed site-level ecosystem units (i.e., ecosites, ecological communities) for bioclimate subzones located throughout the territory. Currently, site-level ecosystem units do not exist for the RSA; therefore, the YBEC system methodology was used to develop Project-specific ecosystem units (i.e., ecosites, ecological communities). Wherever possible, non-forested and sparsely/non-vegetated ecosystem units (e.g., alpine ecosites, talus, pond, mine) used standard codes and definitions from the BC BEC System. Standards and guidelines used during ELC development for the Project included:

- Yukon Ecological and Landscape Classification and Mapping Guidelines, Version 1.0. (Environment Yukon 2016);
- Standard for Terrestrial Ecosystem Mapping in British Columbia (Resources Inventory Committee 1998);
- Field Manual for Describing Terrestrial Ecosystems. Second Edition (BC MFLNRORD and BC MOE 2010);
- Biogeoclimatic Ecosystem Classification of Non-forested Ecosystems in British Columbia, Technical Report 068 (Mackenzie 2012); and,
- Ecoregions of the Yukon Territory: Biophysical properties of Yukon landscapes (Smith et al. 2004).

ELC data collection and plant species nomenclature referenced the following resources:

- Field Manual for Describing Yukon Ecosystems, draft document (Environment Yukon 2017);
- Field Manual for Describing Terrestrial Ecosystems, Second Edition (BC MFLNRORD and BC MOE 2010);
- Flora of the Yukon Territory, Second Edition (Cody 1996);
- Yukon Conservation Data Centre plant list 2019,
- Online Flora of North America, www.eFloras.org; and,
- Yukon Biophysical Inventory System. Data management system and government utilized vegetation codes database—Environment Yukon's Information Management Branch (IMT).

2.2.1 SPATIAL DATA PREPARATION

Various digital data were acquired, for use in ArcMap (ArcGIS 10.7.0), in preparation for ELC mapping. Medium and high-resolution satellite imagery for the Project was sourced from the Yukon Government (2019) and Chance. Other data sources acquired or prepared to support ELC mapping included:

- Digital Elevation Model (DEM; Yukon Government 2002);
- 1:50,000 Yukon Stream and Water Bodies Mapping (Government of Canada 2012);
- 1:250,000 Draft Yukon Bioclimate Zone Boundaries (Yukon Government 2014);
- 1:100,000-1:1250,000 Surficial Geology Mapping (Yukon Government 2014);
- 50 m Contours (Government of Canada 2012);
- Yukon Fire History (Yukon Government 2020);
- Peer Solutions Fire History (Peer Solutions 2021);
- The Earth Observation for Sustainable Development of Forests (EOSD) Land Cover map (25 m pixel; Wulder et al. 2014);
- User-defined spatial slope (flat, gentle, moderate and steep) and aspect (warm, cool) layers (refer to Attachment A for slope and aspect class values); and,
- ELC mapping database (YBIS).

Data sources, such as the EOSD, surficial materials mapping, and Yukon stream and water bodies mapping, generated at a smaller scale were used as reference material to assist ELC mapping; however, the data were used with appropriate caution given the differences in scale.

2.2.2 ELC SYSTEM DEVELOPMENT

The PEM units and polygons were used during the planning and field work stages. However, the field assessments revealed several limitations of the PEM products, including lack of structural stage, very generalized broad-ecosystem units and large polygons that did not capture specific wildlife habitats or habitat features.

To complete the ELC mapping of the RSA, new broad-ecosystem classification units were developed that had similar floristic composition and clearly interpretable ecological context in terms of site-scale climate, landscape position, substrate, hydrology conditions, and moisture and nutrient regimes. The goal was to develop Project-specific ecosites representing the range of ecological communities within the RSA while being reliably and repeatedly identifiable from a mapping perspective. The final ELC system used for the Project merged the methodology outlined by the YBEC system with aspects of the BEC system used in BC and referenced some of the existing units (Attachment A).

A plot tabling method was used to develop Project-specific ecosites, similar to the methods used by Environment Yukon to develop ELC systems for the subzones of the Boreal Low Bioclimate Zone (D. Meidinger pers. comm). Field plots were initially sorted based on environmental variables (e.g., elevation,

slope position, aspect, soil characteristics, moisture and nutrient regime) as these factors drive the ecological communities that exist across the landscape.

Following initial sorting, ecosites were developed through detailed plot-by-plot comparisons of plant species presence and percent cover, using indicator species wherever possible. By their presence or absence, indicator species can demonstrate an environment's distinctive aspect or quality (e.g., golden fuzzy fen moss and glow moss indicate wet, nutrient medium to rich sites). Field plots were also plotted spatially on ortho-imagery to aid in incorporating interpretability into the classification. The final ecosites contain all available environmental variables and floristic composition information collected and included some potential units that no field data were collected for but were described in the existing ecological data (Meikle et al. 2005, Meikle and Waterreus 2008, and Rosie 2000). A table comparing the Chance ELC units to the PEM units can be viewed in Attachment A.

The vegetation association organization and ecosite and coding system follows the Yukon ELC Mapping Guidelines (Environment Yukon 2016). High elevation non-forested and sparsely/non-vegetated ecosystem are assigned the two-letter group/realm and class classification system (BC MFLNRORD and BC MOE 2010, Mackenzie 2012), while anthropogenic units are coded using two upper case letters, following the BC provincial standards (Resources Inventory Committee 1998). Wetland sites are classified according to the Canadian Wetland Classification System for class, form, subform, type and subtype (Warner and Rubec 1997). The remaining ecosites are coded with a two-digit number that indicates, by its number series, a certain range of soil moisture conditions:

- The 10s are the dry sites.
- The 00s are the mesic sites.
- The 20s are the riparian sites.
- The 30s are the moist sites.
- The 40s are the wet sites.
- Wetlands were designated with a letter referring to the wetland class (e.g., F=fen, M=marsh, S=swamp).

Ecosite names reflect plant species that are important indicators of the vegetation found within the ecosite (e.g., 33 – Moist Spruce – Labrador Tea). A description of the ecosites developed for the Eagle Plains RSA ELC mapping product can be reviewed in Table 2-1.

Table 2-1. General ecosite descriptions used for ELC mapping in the Eagle Plains RSA.

Code	Unit Name	Description and typical situation	Mapped (Y/N)
10	Sparsely Vegetated	Vegetation cover less than 10%. Not specific to any soil moisture regime (SMR) or soil nutrient regime (SNR).	Y
11	Dry Herb	Dry area dominated with herbaceous vegetation, very low shrub cover (less than 5%) and a SMR ranging from xeric to submesic. No mottles, seepage or permafrost presence in the rooting zone.	N
12	Dry Lichen	Very xeric to submesic areas dominated by *Cladonia* species (caribou forage species) with very low shrub cover (less than 5%) typically on moderate to steep south facing slopes. No mottles, seepage or permafrost presence in the rooting zone.	N
13	Dry Mix Shrub	Xeric to submesic shrubby areas with very low *Cladonia* species (caribou forage species) cover (less than 10%). This is a disclimax community. No mottles, seepage or permafrost presence in the rooting zone.	N
14	Dry Spruce-Lichen (Conifer)	Areas with spruce tree species cover greater than 5% and *Cladonia* species (caribou forage species) cover greater than 10%. Areas with xeric to submesic SMR and poor to medium SNR. No mottles, seepage or permafrost presence in the rooting zone. Difficult to differentiate from Code 06 in some imagery.	Y
15	Dry Aspen-Lichen (Deciduous)	Areas with aspen tree cover greater than 5% and *Cladonia* species (caribou forage species) cover greater than 10%. These areas also have a SMR ranging from xeric to submesic and a poor SNR. No mottles, seepage or permafrost presence in the rooting zone.	Y
16	Dry Spruce-Birch-Lichen (Mixedwood)	Areas with either white spruce, black spruce and/or birch (Alaskan paper birch) or aspen tree cover, with spruce and birch (scrub birch) shrubs and *Cladonia* species (caribou forage species) cover greater than 10%. Areas that have been burned have dense alder cover in the early successional stage. These areas have a SMR ranging from xeric to submesic and SNR ranging from very poor to poor. No mottles, seepage or permafrost presence in the rooting zone. Difficult to differentiate from Code 04 in some imagery.	Y
17	Dry Aspen (Deciduous)	Xeric to submesic moderate to steep areas dominated with aspen tree cover and very low *Cladonia* species (caribou forage species) cover (less than 5%). These areas typically have poor SNR. No mottles, seepage or permafrost presence in the rooting zone.	Y
01	Mesic Herb	Area dominated with herbaceous vegetation, very low shrub cover (less than 5%) and a mesic to subhygric SMR. No distinct mottles or seepage present, some sites may have permafrost but the frozen layer contains no signs of ice crystals or ice layers.	N
02	Mesic Birch - Willow	These areas have been historically anthropogenically disturbed and regeneration has been affected. These areas are typically dominated by either Alaska paper birch or willow tree species or a mix of both deciduous species. Soil moisture regime is typically subhygric and SNR ranges from poor to medium. No distinct mottles or seepage present, some sites may have permafrost but the frozen layer contains no signs of ice crystals or ice layers. If vegetation is very sparse and difficult to see in imagery, may be called Anthropogenic (Code AN).	Y
03	Mesic White Spruce – Alaska Paper Birch - Alder	These areas are typically dominated by Alaskan paper birch and white spruce mixedwood with an alder understory. The SMR ranges from mesic to subhygric and the SNR ranges from poor to medium. No distinct mottles or seepage present, some sites may have permafrost but the frozen layer contains no signs of ice crystals or ice layers.	Y

Code	Unit Name	Description and typical situation	Mapped (Y/N)
04	Mesic Black Spruce – Alaska Paper Birch (mixedwood)	These areas are typically dominated by a black spruce and Alaska paper birch and with an understory of greater than 30% shrub cover. May have dense alder understory, or a very open understory. The SMR ranges from mesic to subhygric and the SNR ranges from poor to medium. No distinct mottles or seepage present, some sites may have permafrost but the frozen layer contains no signs of ice crystals or ice layers.	Y
05	Mesic Alaska Paper Birch (Deciduous)	Area is dominated by Alaska paper birch trees with an understory composed of more than 30% shrub cover. The SMR ranges from mesic to subhygric and the SNR ranges from poor to medium. No distinct mottles or seepage present, some sites may have permafrost but the frozen layer contains no signs of ice crystals or ice layers.	Y
06	Mesic Black Spruce – Labrador Tea (Conifer)	Areas dominated by black spruce trees with Labrador tea dominating the shrub layer. The SMR ranges from mesic to subhygric and the SNR ranges from poor to medium. No distinct mottles or seepage present, some sites may have permafrost but the frozen layer contains no signs of ice crystals or ice layers. Likely underrepresented in some areas due to its similarity to Code 33 in some imagery.	Y
20	Shrubby Riparian Birch – Willow	Shrubby riparian areas dominated by scrub birch, tea-leaved willow or diamond leaved willow and bog cranberry. Typically, these areas have a SMR ranging from subhygric to subhydric and SNR ranging from medium to rich. Faint to distinct mottles can be observed in the soil profile. In some cases, seepage maybe present and most sites have permafrost but found at variable depths. This is a disclimax community.	Y
21	Riparian White Spruce – Prickly Rose	Treed riparian area dominated by white spruce with a mixture of shrub species but usually rose presence in the understory. These sites are usually a thin strip of trees along streams and rivers. Typically, mesic sites but some sites can be described as subhygric. Sites usually have medium to rich SNR. Typically, no distinct mottles or seepage are present in these sites but occasionally permafrost can be observed at various depths.	Y
22	Riparian Spruce – Birch - Willow	Treed riparian area dominated by white and black spruce, some Alaska paper birch may be present and a mixture of shrub species such as scrub birch and willow can be observed in the understory. These sites are typically moister sites (subhygric to hygric) with wider strip of trees along streams and rivers. Faint to distinct mottles can be observed, slight seepage can be present, permafrost is maybe present but at variable depths. Signs of flooding also may be observed.	Y
23	Drainage Shrubby Riparian	Shrubby areas along undefined or very narrow drainage channels where shrub cover may include alder, scrub birch, Alaska paper birch, and willow. Some scattered stunted spruce (<5%) may be visible. Typically, these sites have a SMR that ranges from subhygric to subhydric and SNR ranging from poor to rich. Faint to distinct mottles can be observed, seepage may be present and most sites have permafrost but at variable depths.	Y
30	Moist Herb	These moist areas are dominated with herbaceous vegetation with less than 5% shrub cover and have a SMR ranging from subhygric to hygric. Faint to distinct mottles can be observed, no seepage or slight seepage maybe present, permafrost is present but at variable depths. Some ice crystals can be observed in the permafrost layer.	N

Code	Unit Name	Description and typical situation	Mapped (Y/N)
31	Moist Shrub \ Scrub Birch – Labrador Tea – Willow	Areas dominated by an understory composed of scrub birch and northern Labrador tea and with less than 10% spruce cover. The shrub layer also may contain tea-leaved willow. Successional pathway is unknown and this site is considered a shrub disclimax site. Maybe part of seasonal drainage pathways. Similar to other sites, the SMR ranges from subhygric to hygric and the SNR ranges from poor to medium. Faint to distinct mottles can be observed, slight seepage may be present. Permafrost is present and some ice crystals can be observed in the permafrost layer.	Y
32	Moist Shrub \ Spruce – Scrub Birch – Labrador Tea	Areas dominated by greater than 10% spruce cover, less than 5% willow cover, and greater than 15% lowbush cranberry cover. The successional pathway is unknown and this site is also considered a shrub disclimax site. The SMR ranges from subhygric to hygric and the SNR ranges from poor to medium. Faint to distinct mottles can be observed, slight seepage may be present. Permafrost is present and at various depths. Some ice crystals can be observed in the permafrost layer.	N
33	Moist Spruce – Labrador Tea	Areas dominated by greater than 10% spruce tree cover. Presence of *Cladonia* species (caribou forage species). Can be found on both cool and warm aspects. Large variation in tree canopy closure from very open to closed. The SMR ranges from subhygric to hygric and the SNR ranges from poor to medium. Faint to distinct mottles can be observed, slight seepage may be present. Permafrost is present and at variable depths. Some ice crystals can be observed in the permafrost layer.	Y
34	Moist Spruce – Alder – Labrador Tea	Area dominated by greater than 15% spruce tree cover with presence of alder understory. Presence of *Cladonia* species (caribou forage species). Generally found on cooler aspects. The SMR ranges from subhygric to hygric and the SNR ranges from poor to medium. Faint to distinct mottles can be observed, slight seepage may be observed, and permafrost is present but at variable depths due to frost boils. Some ice crystals can be observed in the permafrost layer. Can be difficult to differentiate from Code 33 in some imagery.	Y
35	Moist Spruce – Scrub birch – Labrador Tea	Area dominated by less than 15% spruce tree cover. Presence of *Cladonia* species (caribou forage species). May have dense scrub birch understory. Generally found on warmer aspects. The SMR ranges from subhygric to hygric and the SNR ranges from poor to medium. Faint to distinct mottles can be observed, slight seepage may be observed, and permafrost is present but at variable depths due to frost boils. Some ice crystals can be observed in the permafrost layer. Can be difficult to differentiate from Code 33 in some imagery.	Y
36	Moist Birch – Willow	Area dominated by willow and birch trees often associated with old anthropogenic disturbances and successional pathway unknown. The SMR ranges from subhygric to hygric and the SNR is typically medium. Faint to distinct mottles can be observed, slight seepage may be observed, and permafrost is present but at variable depths due to frost boils. Some ice crystals can be observed in the permafrost layer.	Y
40	Wet Herb	Area dominated with herbaceous vegetation with less than 5% shrub cover. The SMR ranges from hygric to subhydric and the SNR is variable. Distinct to prominent mottles can be observed, seepage is present, and permafrost layer is near the surface. A layer of ice is typically present within or above the frozen soil or frozen organic layer.	N

Code	Unit Name	Description and typical situation	Mapped (Y/N)
41	Wet Shrub – Tamarack	Area with greater than 5% tamarack cover, low presence of *Cladonia* species (caribou forage species) and a high presence of Sphagnum or glow moss. Scrub birch and Labrador tea are present in the shrub layer. Often present in thin strips between bog and riparian areas. The SMR ranges from hygric to subhydric and the SNR ranges from poor to medium. Distinct to prominent mottles can be observed, seepage is present, and permafrost layer is near the surface. A layer of ice is typically present within or above the frozen soil or frozen organic layer. May be underrepresented in mapping because this ecosite often does not make up an entire decile.	Y
42	Wet Shrub – Black Spruce – Tussock Cottongrass	Area dominated by greater than 5% black spruce and 10% tussock cottongrass. There is the presence of Labrador tea, scrub birch, *Sphagnum* and *Cladonia* species (caribou forage species). This is a disclimax shrub community. The SMR ranges from hygric to subhydric and the SNR ranges from poor to medium. Distinct to prominent mottles can be observed, seepage is present, and permafrost layer is near the surface. A layer of ice is typically present within or above the frozen soil or frozen organic layer.	Y
43	Wet Shrub – Black Spruce - Sphagnum	Area dominated by greater than 5% black spruce, less than 30% tussock cottongrass and greater than 25% *Sphagnum*. This is a disclimax shrub community. The SMR ranges from hygric to subhydric and the SNR ranges from poor to medium. Distinct to prominent mottles can be observed, seepage is present, and permafrost layer is near the surface. A layer of ice is typically present within or above the frozen soil or frozen organic layer.	Y
44	Wet Shrub – Scrub Birch – Tussock Cottongrass	Area dominated by less than 5% black spruce, greater than 10% scrub/shrub birch and greater than 30% tussock cottongrass. This is a disclimax shrub community. The SMR ranges from hygric to subhydric and the SNR ranges from poor to medium. Distinct to prominent mottles can be observed, seepage is present, and permafrost layer is near the surface. A layer of ice is typically present within or above the frozen soil or frozen organic layer.	Y
45	Wet Shrub – Scrub Birch - Graminoid	Area is composed of less than 5% black spruce; dominant shrub is scrub/shrub birch and dominant graminoid is either spruce muskeg sedge or bluejoint reedgrass. This is a disclimax shrub community. The SMR ranges from hygric to subhydric and the SNR ranges from poor to medium. Distinct to prominent mottles can be observed, seepage is present, and permafrost layer is near the surface. A layer of ice is typically present within or above the frozen soil or frozen organic layer. Difficult to differentiate from Code 44.	Y
46	Wet Black Spruce – Labrador Tea – Cladonia	Area has greater than 15% black spruce, greater than 20% *Cladonia* species (caribou forage species) and less than 5% tussock cottongrass. Often associated with Code 44 sites, as transition between wet shrub 44 and treed moist 33. The SMR ranges from hygric to subhydric and the SNR ranges from poor to medium. Distinct to prominent mottles can be observed, seepage is present, and permafrost layer is near the surface. A layer of ice is typically present within or above the frozen soil or frozen organic layer. Difficult to differentiate from Codes 33 and 47. If canopy closure is open, *Cladonia* component is visible; however, if closed canopy, then difficult to differentiate between Codes 46 and 47 because *Cladonia* and cottongrass components are difficult to see. Difficult to differentiate from Code 33 because both ecosites are found in similar areas, but moisture content can vary from area to area. Likely Code 46 is underrepresented and called Code 33 in some areas.	Y

Code	Unit Name	Description and typical situation	Mapped (Y/N)
47	Wet Black Spruce – Tussock Cottongrass - Sphagnum	Area has greater than 15% Labrador tea, and less than 10% *Cladonia* species (caribou forage species). The SMR ranges from hygric to subhydric and the SNR is typically medium. Distinct to prominent mottles can be observed, seepage is present, and permafrost layer is near the surface. A layer of ice is typically present within or above the frozen soil or frozen organic layer. Difficult to differentiate from Codes 33 and 46. If canopy closure is open, cottongrass components is visible; however, if closed canopy, then difficult to differentiate between Codes 46 and 47 because *Cladonia* and cottongrass components are difficult to see. Difficult to differentiate from Code 33 because both ecosites are found in similar areas, but moisture content can vary from area to area. Likely Code 47 is underrepresented and called 33 in some areas.	Y
48	Wet Black Spruce – Carex	Area where herbaceous layer is dominated by either spruce muskeg sedge or bluejoint reedgrass and shrub layer is a mixture of Labrador tea, scrub birch and willow species greater than 30% cover. The SMR ranges from hygric to subhydric and the SNR ranges from poor to medium. Distinct to prominent mottles can be observed, seepage is present, and permafrost layer is near the surface. A layer of ice is typically present within or above the frozen soil or frozen organic layer. Difficult to differentiate from Code 47 in some imagery. May be underrepresented in mapping because this ecosite often does not make up an entire decile.	Y
B1	Bog – Black spruce – Lichen	Treed or shrubby peatland ecosystem unit with poor nutrient regime within the rooting zone. Stunted black spruce with less than 50% sphagnum and greater than 10% *Cladonia* species. The SMR typically ranges from subhydric to hydric. These sites generally have a thick fibric organic layer and there is the presence of permafrost. Seepage is present.	Y
B2	Bog – Black Spruce – Sphagnum	Treed or shrubby peatland ecosystem unit with poor to medium nutrient regime within the rooting zone. Stunted black spruce with greater than 50% sphagnum. The SMR typically ranges from subhydric to hydric. These sites generally have a thick fibric organic layer and there is the presence of permafrost. Seepage is present.	Y
F	Fen	Treed, shrubby or graminoid peatland ecosystem unit where groundwater inflow maintains relatively high mineral content within the rooting zone. Graminoid fen has greater than 20% Sphagnum or moss cover. The ecosystem has a hydric moisture regime and a nutrient regime that can range from poor to rich. These sites generally have a thick fibric organic layer and there is the presence of permafrost. Seepage is often present.	Y
M	Marsh	Shallowly flooded mineral wetland ecosystem dominated by emergent vegetation. Area dominated by graminoids and has less than 10% Sphagnum or moss cover. Seepage, permafrost and gleying are often observed.	Y
S	Swamp	Treed or shrubby mineral wetland ecosystem unit dominated trees and shrubs on sites with a flowing or fluctuating, semi-permanent, near-surface water table.	N
W	Shallow-water	Shallow water ecological communities dominated by rooted, water submerged floating aquatic plants.	N
AN	Anthropogenic	An area of anthropogenic disturbance, not included in other definitions (e.g., areas cleared for camps).	Y
ES	Exposed Soil	Any area of exposed soil, not included in other definitions. Includes areas of recent disturbance (e.g., terrain slides) and human-made disturbances where vegetation cover is less than 5%.	Y

Code	Unit Name	Description and typical situation	Mapped (Y/N)
Fa	Flood Active Channel	Ecological communities scoured by river floodwaters for prolonged periods. Usually dominated by annuals, or herbs that can re-sprout from underground structures. May be underrepresented in mapping because this ecosite often does not make up an entire decile.	Y
LA	Lake	A body of water greater than 2 m deep or large enough to be classified as a lake (greater than 8 ha).	Y
PD	Pond	A small body of water greater than 2 m deep, but not large enough to be classified as a lake (less than 8 ha). May be underrepresented in mapping because this ecosite often does not make up an entire decile.	Y
RI	River	A watercourse formed when water flows between continuous, definable banks. The flow may be intermittent or perennial.	Y
RZ	Road	An area cleared and compacted for the purpose of transporting goods and services by vehicle. May be underrepresented in mapping because this ecosite often does not make up an entire decile.	Y

2.2.3 ELC MAPPING DATABASE

After acquiring spatial data and reviewing available supporting information, ELC mapping was completed in two dimensions directly to a digital system using ArcMap in ArcGIS 10.7.0. Polygon delineation and attribution were completed for the entire RSA. The ELC mapping was completed at a scale of 1:10,000, with a target average polygon size of 30 ha.

As the Yukon Ecological and Landscape Classification and Mapping Guidelines recommended, mappers used the delineation methods outlined in the Standard for Terrestrial Ecosystem Mapping in British Columbia (Resources Inventory Committee 1998) as a guideline. The ELC polygons were delineated by biologists based upon discernible differences among the following criteria:

- vegetation (species composition, canopy characteristics, stand age and height);
- topography (landscape position, aspect, slope, drainage patterns);
- terrain (landform/parent material);
- soils (depth and drainage); and,
- gradients and patterns (relationship patterns between ecosystem units, polygon shape and orientation).

Several large wildfires have affected the RSA between 1959 and 2018 (Map 2-1). Areas that were affected by fire, and are still regenerating, were labelled with a fire disturbance code. For older burn areas, the adjacent non-burned area was compared to the burn area to see if there was a noticeable difference in vegetation. Areas that did not have a noticeable difference were not characterized as fire disturbed as they are considered regenerated. The appropriate structural stage was assigned to reflect the stage of regeneration.

All ELC polygons were assessed individually (in two dimensions using supporting spatial data files in ArcMap) and ecological attributes were estimated and entered in the ELC database (Table 2-2). The attributes were assessed and entered, taking care that:

1) no more than three ecosystem units (i.e., ecosites) were entered per polygon;

2) defined ecosite and modifier codes were used; and,

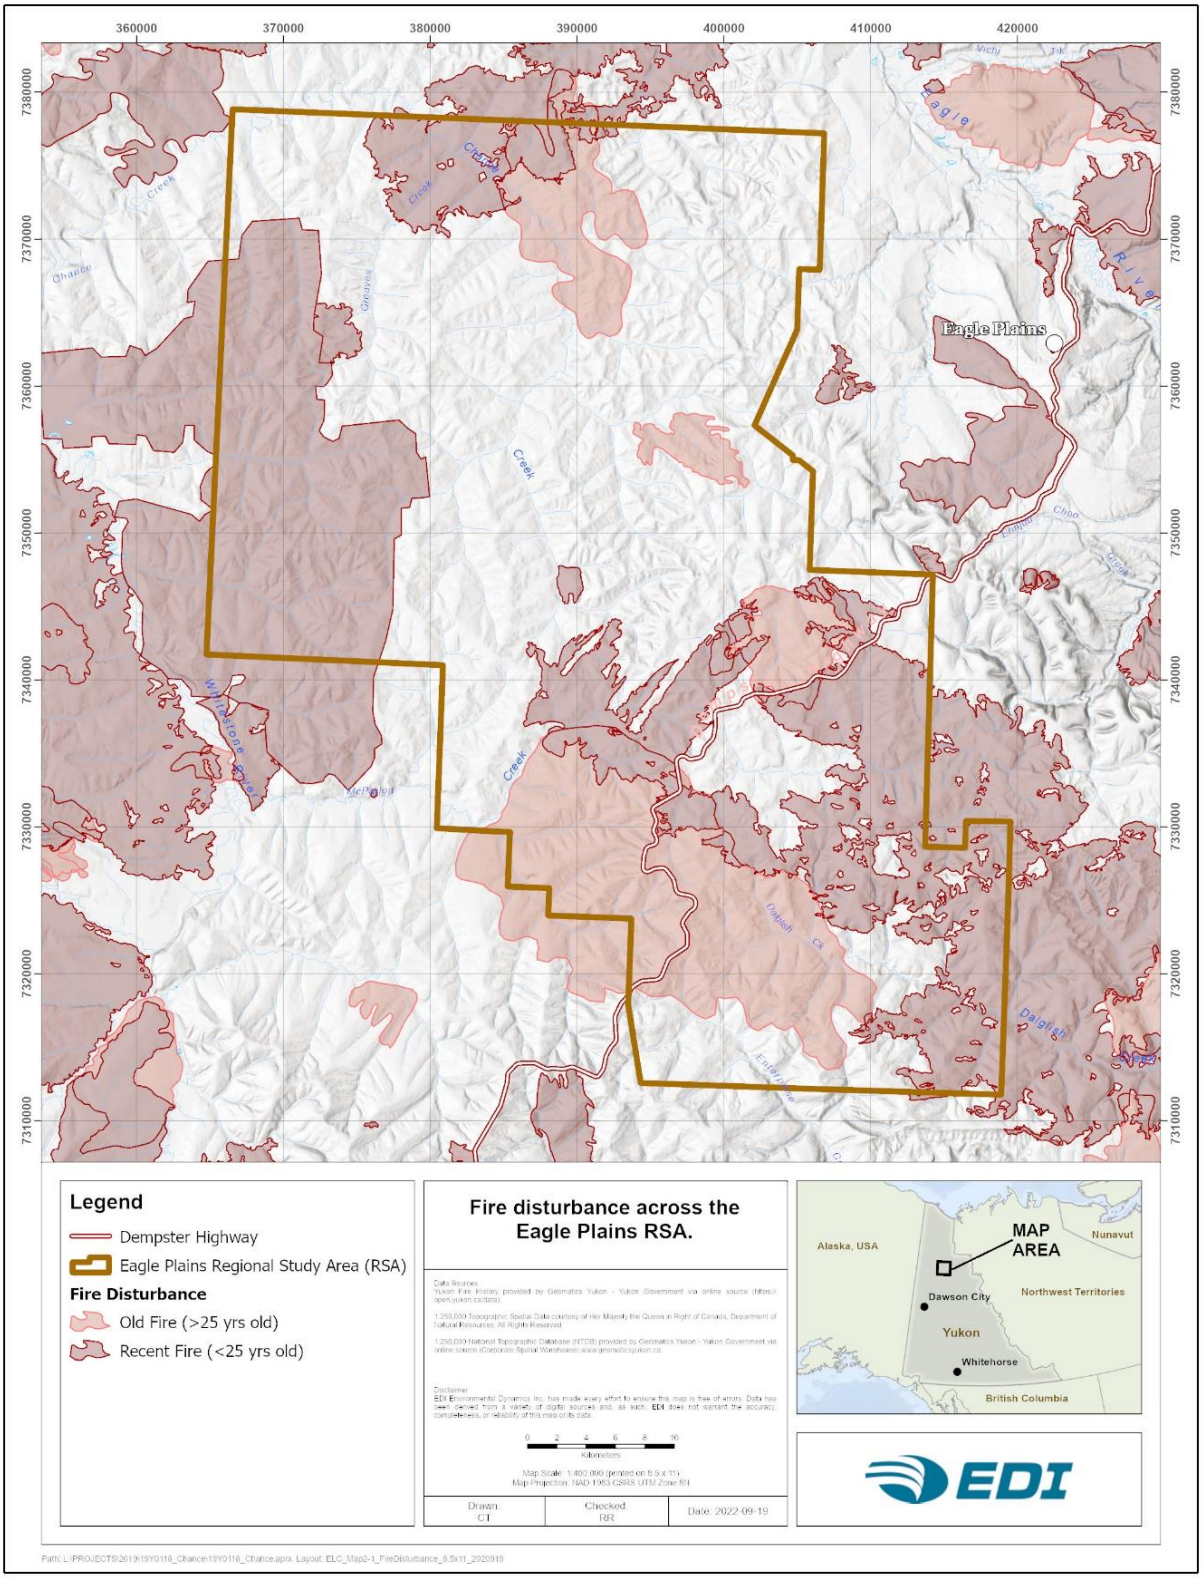
3) all information was completed for every polygon.

The descriptions and codes of assumed and atypical site modifiers, structural stages and stand modifiers used are presented in Attachment A.

After completing the mapping, the ELC database was reviewed through an internal quality assurance process for completeness and correctness, including the correct application of ecosites, structural stages, disturbance types and canopy composition modifiers. Finally, the spatial attributes of the ELC database were reviewed to ensure all deciles sum to 100%, and that no sliver polygons (typically <1 ha) or polygon overlaps remained. A finalized seamless polygon spatial coverage was prepared following database review.

Table 2-2. ELC database fields and descriptions.

ELC Database Field	Field Description
UniqueID	Unique Polygon Identifier
Eco_Reg	Ecoregion
Bio_Zon	Bioclimate Zone
Bio_Subzon	Bioclimate Subzone
SDEC_1	Decile 1 (percentage of the polygon from 4 – 10)
EcositeS1	Ecosite for Decile 1
SiteAM_S1a	Assumed Modifier 1 for Ecosite 1
SiteAM_S1b	Assumed Modifier 2 (if applicable)
SiteAM_S1c	Assumed Modifier 3 (if applicable)
SiteM_1a	Atypical Site Modifier 1 (if applicable)
SiteM_1b	Atypical Site Modifier 2 (if applicable)
Strct_S1	Structural Stage for Decile 1
Strct_M1	Structural Stage modifier
Stand_A1	Stand Composition Modifier: B (Broadleaf), C (Coniferous) or M (Mixedwood)
Distcls_1	Disturbance Modifier: T (Terrain), S (Soil), L (Logging)
Dec_1_Area	Area of Decile 1 (hectares)
SDEC _2	Decile 2 (percentage of the polygon from 0 – 5)
EcositeS2	Same sequence as above for Decile 2; ends at Dec_2_Area
SDEC _3	Decile 3 (percentage of the polygon from 0 – 3)
EcositeS3	Same sequence as above for Decile 3; ends at Dec_3_Area
Area_Ha	Total Polygon Area (hectares)
Interpreter	Initials of ecosystem mapper
Source	Source of Estimate: P (Photo estimate), G (Ground plot), V (Visual plot), A (Aircall/from afar)
Plot_ID	ID of Field plot(s) completed in polygon



Map 2-1. Fire disturbances across the Eagle Plains RSA, 1959–2018.

2.2.4 LIMITATIONS

The type and variety of imagery used for the ELC mapping created several polygon attributions and delineation limitations. Imagery sources across the RSA varied, resulting in differences in the quality of imagery available for a given area. The differences in quality included changes in resolution, sharpness, cloud cover and time of year that the imagery was taken. The mappers were required to "re-calibrate" when encountering each new imagery set. A full range of ELC field plots was not available in all imagery sets, so representative plots were not always available to aid in interpreting the imagery. In these cases, estimations or best guesses were made based on plots found in similar imagery.

Several of the ecosites were challenging to differentiate from each other. Some ecosites may be over or underrepresented in the polygon attribution. This was compounded by the variety of imagery used to complete the mapping. Some ecosites were even more difficult to differentiate in imagery with poor resolution. The most common or likely ecosite found in that location (based on slope, aspect and surrounding ecosites) was chosen for attribution.

Attributing the fire-disturbed polygons was completed based on the expected ecosite for that location (based on slope, aspect and surrounding ecosites). The post-fire successional pathways for many of the ecosites were the same or very similar, making differentiating ecosites based on revegetation difficult. Often the post-fire succession also varied for an ecosite depending on several factors, including: the number and frequency of fires, the intensity of the fire, and the amount of permafrost present before and after the fire. Field observations suggest that hot fires likely melt a larger portion of the permafrost, permanently altering the moisture regime of the affected area; therefore, sites become drier and do not return to the same ecosite that had been established before the fire.

The current structural stage for some of the more recent fire-disturbed areas was difficult to determine due to the range in age and variety of the imagery (Photo 2-1 and Photo 2-2). To be consistent, the mappers assigned a shrub structural stage to all fire disturbed areas unless strong evidence suggested another structural stage (i.e., a plot stating it was graminoid dominant). The structural stage for older fire-disturbed areas was detectable from the imagery.

Photo 2-1. Recent fire through lichen-dominated mesic site.

Photo 2-2. Regenerating moist ecological unit.

3 RESULTS

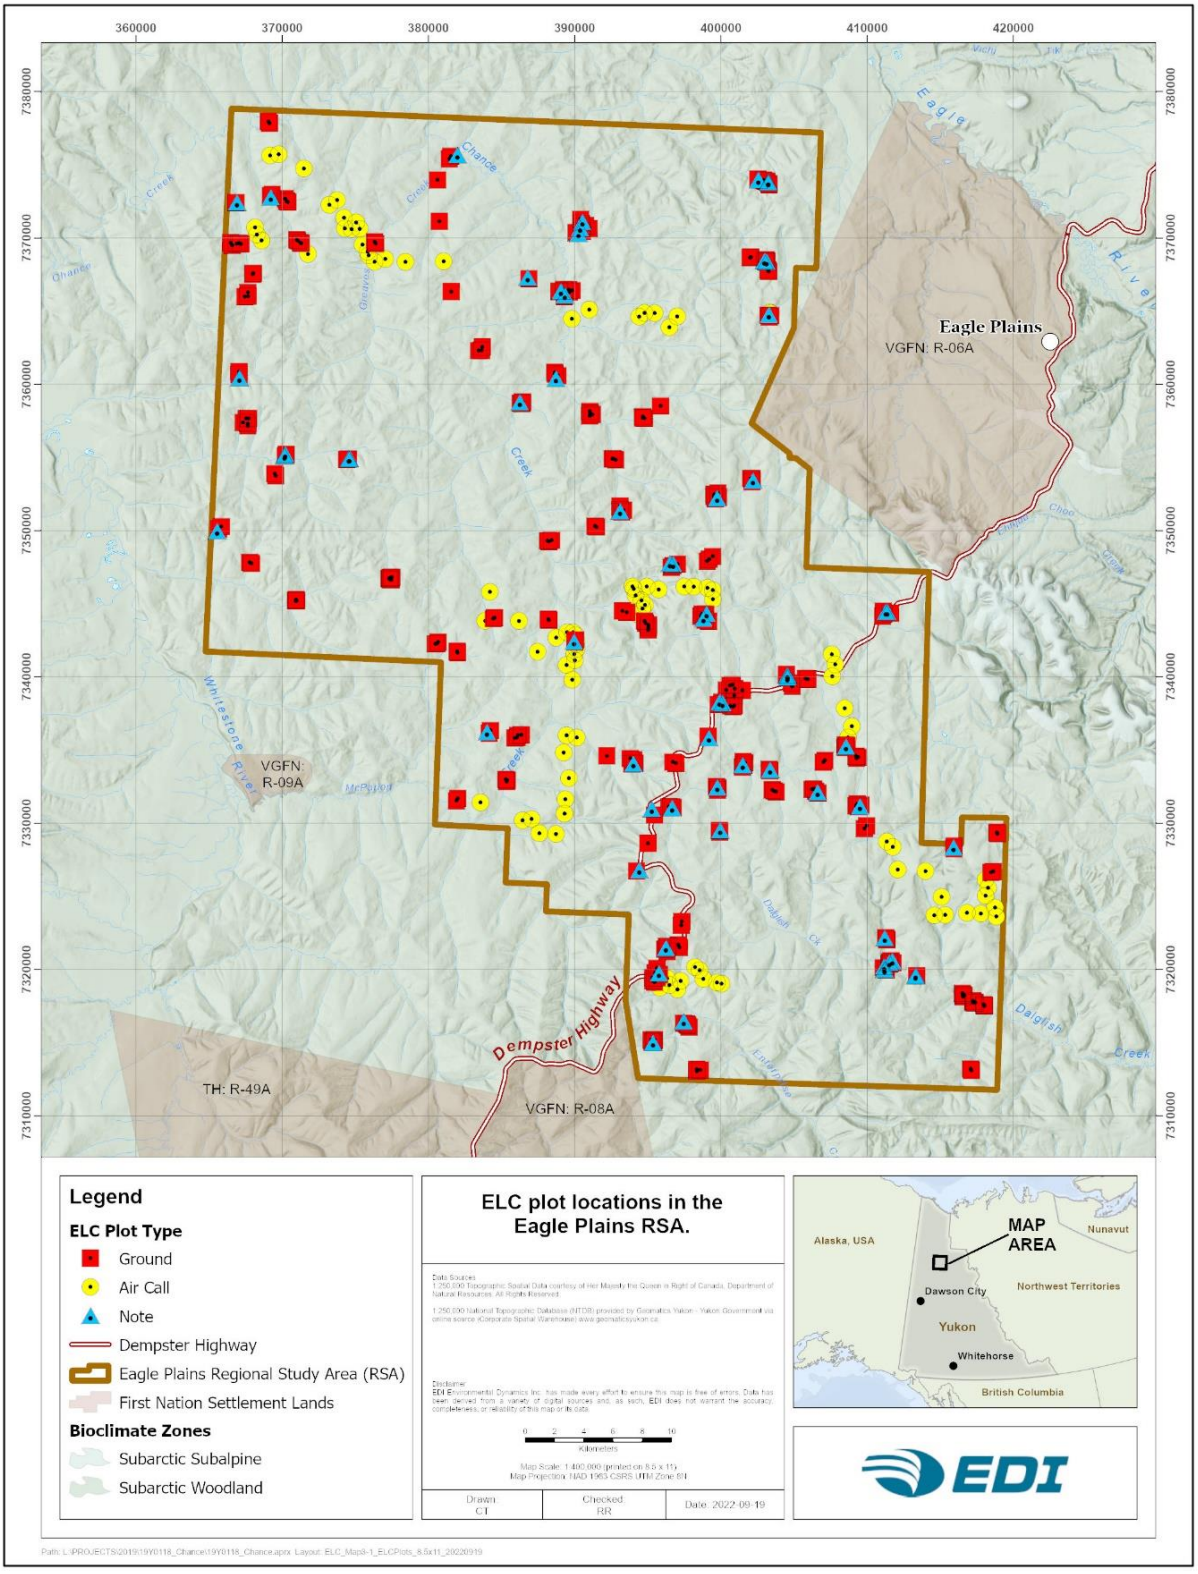
3.1 FIELDWORK

The ELC fieldwork was completed between June 25 and July 7, 2019, and July 26 and August 7, 2019. Sampling was conducted by one crew of two EDI personnel. Field plots were accessed using ground transportation (truck) and helicopter to obtain good area coverage and sample a diversity of ecological communities.

A total of 450 ELC field plots were completed, consisting of 286 ground plots (64%), 63 visual notes (14%), and 101 visual air calls (22%) (Map 3-1). Field surveys documented 126 different plant species, including 6 tree species, 29 shrub species, 48 forb species, 7 ferns and fern allies, 12 graminoid species, 11 lichen species, 10 moss species, and 2 liverwort species (Attachment B).

The terrain and vegetation in the RSA made access difficult for field crews in some areas. Helicopter landing sites had scattered availability, and the Dempster Highway was the only road providing access into the RSA. When on-the-ground field crews could not access a location, air calls were made to complete ELC observations of that area. Achieving the minimum intensity as laid out by the Yukon ELC Mapping Guidelines (Environment Yukon 2016) was impossible. However, due to the landscape's homogenous nature, field crews could obtain an adequate number of field survey plots to provide representative coverage of each ecosite type during the field assessments (Photo 3-1).

Photo 3-1. Photograph showing various plant species present in RSA.



Map 3-1. ELC plot locations in the Eagle Plains RSA.

3.2 ELC MAPPING

A total of 6,617 ELC polygons were delineated and attributed within the RSA. The polygons ranged from 2.3 ha to 248.5 ha, with an average polygon size of 36 ha. All but two polygons were under 168 ha; the two largest polygons represent long, narrow creek habitats. Large polygons generally covered large homogenous slopes and were often in fire-disturbed areas. The smaller polygons delineated small water bodies, wetland, or special wildlife features. A total area of 238,640 ha was mapped (Attachment C).

Forty potential ecosystem units were initially developed for the Project. However, that list was reduced to 31 for mapping purposes. Some ecosystem units had very small extents and did not constitute a large enough component of polygons to map. Some ecosystem units were difficult to differentiate from similar ecosystem units and maybe underrepresented. Refer to Attachment D for ecosystem unit photographs.

Table 3-1 and Map 3-2 shows the general breakdown of ecosystem extents by group. Most of the RSA has a soil moisture regime ranging from moist to wet. Sixty-four percent of the RSA comprises moist ecosystem units, and another 13% comprises wet ecosystem units. The RSA is composed of approximately 2,528 ha of sites officially classified as wetland habitat. However, many moist and wet ecosystems have vegetation associations and structures similar to wetlands (bogs). Bogs were the most common wetland ecosystem unit mapped across the RSA. No swamps were identified during the field program, and no swamps were mapped within the RSA. Seventeen percent of the RSA has ecosystem units within a mesic soil moisture regime. Only 2% of the RSA comprises dry ecosystem units (Table 3-1), typically found on warm steep aspects. Approximately 707 ha was mapped as non-vegetated units (Anthropogenic, Exposed Soil, Flood Active Channel, Lake, Pond, River and Road). The most common non-vegetated unit was associated with Rivers (457 ha).

Fire is a common natural disturbance in the RSA; many forest stands show signs of previous burns. Historic oil and gas exploration disturbances, including seismic lines, winter roads, and well sites were observed throughout the RSA (Photo 3-2). No evidence of recent human activity was observed except within a few hundred metres of the Dempster Highway.

The most common plant species recorded across all soil moisture regimes throughout the RSA are black spruce, scrub/shrub birch, lowbush cranberry, northern Labrador tea (*Rhododendron tomentosum*) and alpine blueberry (*Vaccinium uliginosum*). Prickly rose and crowberry (*Empetrum nigrum*) are typically observed in dry to moist sites and baked apple/cloudberry and Arctic sweet coltsfoot (*Petasites frigidus*) are usually observed in moist to wet sites. Herbaceous forb cover is limited across the RSA.

The most common ecosystem unit mapped in the RSA is Moist Spruce – Labrador Tea (Code 33) (44%) followed by Moist Spruce – Alder – Labrador Tea (Code 34) (12%) and Mesic Black Spruce – Alaska Paper Birch (Code 04) (9%) (Table 3-2). The least common (<0.05%) ecosystem units mapped in the RSA are Dry Sparsely Vegetation (Code 10) and Mesic Birch – Willow (Code 02), and Moist Birch – Willow (Code 36) (Table 3-2). Both Birch – Willow ecosystem units are influenced by anthropogenic disturbances. Other less common ecosystem units that occur more naturally are Dry Aspen (Code 17), Mesic White Spruce – Alaska Paper Birch – Alder (Code 03), and Wet Shrub Scrub Birch – Graminoid (Code 45) (Table 3-2).

In many cases, it was challenging to differentiate some ecosystem units solely based on the imagery: 1) especially between ecosystem units with similar plant species composition but different soil moisture regimes such as Dry Spruce – Lichen (Code 14), Mesic Black Spruce – Labrador Tea (Code 06) and Moist Black Spruce – Labrador Tea (Code 33); or 2) between ecosystem units with slightly different plant species composition in the understory and with similar soil moisture regimes such as Moist Spruce – Alder – Labrador Tea (Code 34) and Moist Spruce – Scrub Birch – Labrador Tea (Code 35).

The Dry Spruce–Lichen (Code 14) ecosystem unit is a spruce dominated conifer stand with an understory composed of 40% shrubs such as scrub/shrub birch, prickly rose, lowbush cranberry, alpine blueberry and crowberry and it can have a small component of Alaska paper birch (*Betula neoalaskina*) in the canopy. This ecosystem unit typically has less than 2% forb cover, has no graminoid cover, and less than 5% moss cover but greater than 50% lichen cover. Lichen cover is usually very diverse and includes the following species: *Cladonia arbuscula* (10–50% cover), *Cladonia rangiferina* (1–20% cover), *Cladonia stellaris* (1–20% cover), *Cladonia* species (5–15% cover), *Stereocaulon* species (5–30% cover), *Flavocetraria* species (1–20% cover and with some *Nephroma arcticum* and *Peltigera aphthosa* presence (1% cover).

The Dry Aspen – Lichen (Code 15) ecosystem unit is an aspen dominated deciduous stand on south facing slopes with an understory composed of lowbush cranberry, crowberry, and bearberry. This ecosystem unit may have greater than 5% forb cover, less than 1% graminoid cover and less than 5% moss cover. The lichen cover is high and mostly composed of *Cladonia arbuscula* (>10%), *C. rangiferina* (>10%), *Stereocaulon* species (>10%) and *Flavocetraria* species (>10%).

The Dry Spruce – Birch – Lichen (Code 16) ecosystem unit is a mixedwood dominated stand composed of spruce and Alaska paper birch, with an understory composed of prickly rose, lowbush cranberry, bearberry (*Arctostaphylos uva-ursi*), less than 2% forb cover and less than 10% moss cover. This ecosystem unit has greater than 30% lichen cover. The lichen cover is composed of *Cladonia arbuscula* (2–25% cover), *Cladonia* species (5–20% cover), *Stereocaulon* species (5–25% cover) and *Flavocetraria* species (1–15% cover).

The Mesic Black Spruce – Alaska Paper Birch (Code 04) ecosystem unit is typically a mixedwood plant community dominated by spruce and Alaska paper birch with an understory composed of more than 60% shrubs such as northern Labrador tea, prickly rose, willow species, scrub/shrub birch, lowbush cranberry, alpine blueberry, and Alaska spiraea (*Spiraea stevenii*). This ecosystem unit also includes Alaska wild-rhubarb (*Aconogonon alaskanum*), and the small presence of horsetails (*Equisetum* species). The ground cover is variable but typically composed of a mix of feathermosses (> 10%) and lichens (>35%). The lichen cover is very diverse but usually consists of the following species: *Cladonia arbuscula* (1–40% cover), *Cladonia rangiferina* (0–20% cover), *Cladonia stellaris* (1–20% cover), *Cladonia* species (0–20% cover), and Flavocetraria cucullate (2–20%) cover. This ecosystem unit may also contain *Stereocaulon* species (0–15% cover), *Cetraria islandica* (0–5% cover), *Nephroma arcticum* (0–15% cover), and *Peltigera aphthosa* (0–5% cover).

The Mesic Alaska Paper Birch (Code 05) ecosystem unit is an Alaska paper birch-dominated deciduous stand with an understory composed of alder (*Alnus viridis*), willow species, prickly rose and wild red currant. This unit has a feathermoss ground cover (5–20%), a graminoid cover greater than 5% composed of Poa species (*Poaceae* species) and no lichen cover.

The Mesic Black Spruce – Labrador Tea (Code 06) ecosystem unit has a black spruce dominated canopy with a small component of Alaska paper birch, with an understory composed of northern Labrador tea, scrub/shrub birch, prickly rose, lowbush cranberry, willow species, wild red currant (*Ribes triste*) and less than 2% forb cover. This ecosystem unit usually has more than 3% Poa species (Poaceae species) and more than 15% of feathermoss cover and lichen cover ranging from none to 75%. The lichen cover mostly comprises Cladonia species such as *Cladonia arbuscula* and *C. stellaris*.

The Moist Spruce – Labrador Tea (Code 33) ecosystem unit has a black spruce-dominated canopy, while the understory species commonly include scrub/shrub birch, tea-leaved willow (*Salix planifolia*), northern Labrador tea, lowbush cranberry, baked apple, crowberry, prickly rose and a few herb species, including Arctic sweet coltsfoot, and narrow-leaved sawwort (*Saussurea angustifolia*). This ecosystem unit can have greater than 5% graminoid cover varying from spruce muskeg sedge (*Carex lugens*) (0–30%), tussock cotton-sedge (*Eriophorum vaginatum*) (0–10%) and Poa species (*Poaceae species*) (0–10%). This unit also has more than 15% of moss cover that can vary from step feathermoss (0–30%) (*Hylocomium splendens*) cover, Sphagnum (0–-35%) cover, glow moss (1–30%) (*Aulacomnium palustre*) and golden fuzzy fen moss (0–50%) (*Tomenthypnum nitens*). The lichen cover is usually similar or higher than the moss cover and dominated by *Cladonia arbuscula* (10–35%), *C. rangiferina* (5–30%) and *Flavocetraria cucullate* (3–20%).

The Moist Spruce – Alder – Labrador tea (Code 34) ecosystem unit also has a black spruce dominated canopy with a shrub understory greater than 45% cover composed of mostly alder, with some scrub/shrub birch, Alaska paper birch, northern Labrador tea, prickly rose, lowbush cranberry, baked apple/cloudberry and Alaska spirea. This unit has less than 10% graminoid species (*Poaceae* species), less than 20% lichen cover and greater than 40% feathermoss cover. The feathermoss cover comprises step feathermoss, red-stemmed moss (Pleurozium schreberi), and Sphagnum in some sites. *Cladonia arbuscula* and *C. rangiferina* and *Flavocetraria cucullate* make up the lichen cover.

The moist Spruce – Scrub Birch – Labrador Tea (Code 35) ecosystem unit also has a black spruce dominated canopy with a shrub understory greater than 40% cover composed of scrub/shrub birch, northern Labrador tea, crowberry (<10%), lowbush cranberry, alpine blueberry, willow species, baked apple/cloudberry and small bog cranberry (*Vaccinium oxycoccos*). Alder and Alaska paper birch are not included in this ecosystem unit. This unit has greater than 10% graminoid species composed of a spruce muskeg sedge and tussock cotton-sedge mixture. The bryophyte layer is mostly composed of Sphagnum moss, and the lichen layer mainly consists of *Cladonia* species such as *C. arbuscula* with some presence of *Cetraria islandica* (<5%).

The Wet Shrub Black Spruce – Tussock Cottongrass (Code 42) ecosystem unit is dominated by a shrub layer greater than 40% cover composed of black spruce, scrub/shrub birch, northern Labrador tea, lowbush cranberry, alpine blueberry, baked apple/cloudberry and small bog cranberry. This unit usually comprises 20 to 50% tussock cotton-sedge cover and less than 20% spruce muskeg sedge with greater than 10% bryophyte cover composed of *Sphagnum* species. The lichen cover is variable but usually composed of *Cladonia* species and *Flavocetraria cucullate*, with a small presence of *Cetraria islandica* (<10%). It also has a very low forb layer species diversity and percent cover (<2%).

The Wet Shrub Black Spruce – Sphagnum (Code 43) ecosystem unit is dominated by a shrub layer greater than 60% cover composed of black spruce, scrub/shrub birch, northern Labrador tea, lowbush cranberry, small bog cranberry and baked apple/cloudberry (>10%). This unit has less than 10% graminoid cover and the species present is usually a sedge species (<5%) and lichen cover is usually variable but composed of *Cladonia* species, *Flavocetraria* species and Arctic tumbleweed lichen (*Masonhalea richardsonii*). The bryophyte layer is generally greater than 30% cover and comprises Sphagnum species. It also has a very low forb layer species diversity and percent cover (<2%).

The Wet Shrub Scrub Birch – Tussock Cottongrass (Code 44) ecosystem unit is dominated by a shrub layer greater than 40% cover composed of scrub/birch, northern Labrador tea, alpine blueberry, lowbush cranberry, willow species (>5%), baked apple/cloudberry (<5%) and occasionally the presence of leatherleaf/Cassandra (*Chamaedaphne calyculata*) (0–10% cover). This unit has less than 10% lichen cover and a bryophyte layer ranging from 10 to 25% cover composed of a mixture of glow moss, Sphagnum species and *Polytrichum* species. The graminoid layer is greater than 40% cover and dominated by tussock cotton-sedge (>30%) with some spruce muskeg sedge (5–40%). This unit has a variable forb layer percent cover and species composition, including *Epilobium* species.

The Wet Black Spruce – Labrador Tea – Cladonia (Code 46) ecosystem unit has a black spruce tree layer greater than 15% and with a shrub layer greater than 60% cover composed of black spruce, scrub/shrub birch, northern Labrador tea, lowbush cranberry, tea-leaved willow, alpine blueberry and baked apple/cloudberry. Arctic sweet coltsfoot can be present in the forb layer. This unit can have a graminoid layer less than 30% cover and composed of a mixture of spruce muskeg sedge and tussock cotton-sedge. The bryophyte layer is variable but usually ranges between 25 to 50% cover and composed of glow moss, step moss, red-stemmed moss and Sphagnum species. The lichen layer can be greater than 30% cover and composed of various *Cladonia* species, *Flavocetraria cucullate* and with a small presence of *Peltigera aphthosa* (<5%).

The Wet Black Spruce – Tussock Cottongrass – Sphagnum (Code 47) ecosystem unit has a black spruce tree layer greater than 10% and with a shrub layer greater than 30% cover composed of scrub/shrub birch, norther Labrador tea, lowbush cranberry and baked apple/cloudberry. The graminoid layer is dominated with tussock cotton-sedge and Sphagnum dominates the bryophyte layer. The lichen layer has less than 20% cover and is dominated by *Cladonia* species.

The Wet Black Spruce – Carex (Code 48) ecosystem unit has a black spruce dominated tree layer with a shrub layer greater than 30% cover composed of black spruce, scrub/shrub birch, northern Labrador tea, prickly rose, lowbush cranberry and willow species. Sweet Arctic coltsfoot is present in the forb layer. The graminoid, bryophyte and lichen layers have variable percent covers. The graminoid layer includes *Carex* and *Calamagrostis* species, and the bryophyte layer comprises Sphagnum species.

Most of the RSA is mapped in a shrub structural stage (74%) with 45% of the RSA in a low shrub structural stage (Table 3-3). Only approximately 1% of the RSA is in an old forest structural stage and 21% is in a mature forest structural stage (Table 3-3) (Map 3-3). A table listing the mapped ecosite by structural stage can be viewed in Attachment E.

Site modifiers codes and descriptions

Modifier	Code	Criteria
Gentle slope	j	site occurs on gently sloping topography (less than 20%)
Cool	k	sites occur on cool, northerly aspects (300°-60°), on moderately steep slopes (20%-65%)
Warm	w	site series occurs on warm, southerly aspects (130°-230°), on moderately steep slopes (20-65%)
Steep cool	q	site series occurs on steep slopes (>65%) with cool, northerly aspects (300°-60°)
Steep warm	z	site series occurs on steep slopes (>65%) with warm, southerly aspects (130°-230°)
Shallow	s	site series occurs where soils are shallow to bedrock
Deep	d	site series occurs on soils are not considered to deep
Coarse-textured	c	site series occurs on soils with a coarse texture, including sand and loamy sand; sandy loam, loam and sandy clay loam with greater than 70% coarse fragment volume
Permafrost	p	Site is influenced by permafrost
Neutral	n	Sites occurs on flat ground (no aspect) or areas considered neither warm nor cool.

Structural stage modifier codes and descriptions

Modifier	Code	Criteria
Non-vegetated	1	No vegetation or less than 5% established vegetation; often due to recent disturbance (e.g., placer mining) or unvegetated rock.
Sparse/cryptogram	2	Either the initial stages of primary and secondary succession or a cryptogram community maintained by environmental conditions; sparsely vegetated or dominated by bryophytes and lichens; may be prolonged where there is little or no soil development (e.g., bedrock).
Sparse	2a	5 – 10% vegetation cover
Bryoid	2b	Bryophyte-dominated
Lichen	2c	Lichen-dominated
Herb	3	Early successional stage or herbaceous communities maintained by environmental conditions or disturbance (e.g., wetlands, post-fire forest succession); herb dominated, including forbs, graminoids and ferns; some invading or residual shrubs and trees may be present but are usually sparse or absent; many herbaceous communities are continually maintained in this stage.
Forb-dominated	3a	Herbaceous communities dominated (greater than 1/2 of the total herb cover) by non-graminoid herbs, including ferns.
Graminoid dominated	3b	Herbaceous communities dominated (greater than 1/2 of the total herb cover) by grasses, sedges, reeds and rushes.
Aquatic	3c	Herbaceous communities dominated (greater than 1/2 of the total herb cover) by floating or submerged aquatic plants; does not include sedges growing in marshes with standing water.
Dwarf shrub	3d	Communities dominated (greater than 1/2 of the total herb cover) by dwarf woody species, such as kinnikinnick or dwarf willows.
Shrub	4	Early successional stage or shrub communities maintained by environmental conditions or disturbance (e.g., wetlands, flooding, post-fire forest succession); dominated by shrubby vegetation; either dominated by shrubby vegetation, including tree seedlings/saplings, or if sparsely vegetated overall, the dominance of shrubs characterizes the community as a shrubland. This may include sites where

Modifier	Code	Criteria
		trees are stunted due to the presence of permafrost, preventing the stand from reaching a higher structural stage.
Tall shrub	4a	Communities dominated by tall shrub layer vegetation - woody plants > 2m tall and ≤ 7 cm dbh; may be a successional stage or may be in this stage perpetually due to environmental conditions or disturbance.
Low shrub	4b	Communities dominated by low shrub layer vegetation - woody plants < 2m tall; may be a successional stage or may be in this stage perpetually due to environmental conditions or disturbance.
Pole sapling	5	Trees > 5m tall and > 7 cm dbh, typically densely stocked. Self-thinning and vertical structure are not yet evident in the canopy. Younger stands are vigorous (usually > 15–20 years old); older stagnated stands (up to 100 years old) are also included; time since disturbance usually < 40 years; up to 100+ years for dense (5000 – 15000+ stems per ha) stagnant stands.
Young forest	6	Self-thinning has become evident, and the forest canopy has begun to differentiate into distinct layers. A more open stand than the pole/sapling stage.
Mature forest	7	Trees established after the last stand-replacing disturbance have matured; a second cycle of shade tolerant trees may have become established; shrub and herb understories become well developed as the canopy opens up.
Old forest	8	Stands of old age with complex structure; patchy shrub and herb understories are typical; regeneration is usually of shade-tolerant species with composition similar to the overstory. Fire maintained stands may have a 'single-storied' appearance. Very old stands having complex structure with abundant large-sized trees, snags and coarse woody debris (CWD); snags and CWD occurring in all stages of decomposition; stands are comprised entirely of shade-tolerant overstory species with well-established canopy gaps.

Stand composition modifiers and stand influencing site disturbance modifiers.

Modifier	Code	Criteria
Canopy Composition		
Coniferous	C	Greater than 3/4 of total tree layer cover is coniferous
Deciduous	D	Greater than 3/4 of total tree layer cover is broadleaf
Mixed	M	Neither coniferous nor broadleaf account for greater than 3/4 of total tree layer cover
Site Disturbance		
Fires	F	Areas influenced by wildfire
Seismic Line	S	Areas disturbed by seismic line, associated with oil and gas exploration.

ATTACHMENT B LIST OF PLANT SPECIES OBSERVED DURING ELC SURVEYS

List of plant species observed during baseline ELC plot surveys in the Eagle Plains Exploration RSA.

Scientific Name	Common Names	Synonym	Type	Tracked or Watched[1]
Diphasiastrum alpinum (L.) Holub	alpine clubmoss	*Lycopodium alpinum*	Fern and Fern Allies	Do Not Track

EXECUTIVE SUMMARY

The Eagle Plains Exploration Project (the Project) is an oil and gas exploration project located in north Yukon. Chance Oil and Gas Ltd. (Chance) intends to conduct exploratory activities to confirm the quality, quantity, and extent of hydrocarbons over ten years. Work will include seismic exploration and exploratory wells supported by an expanded winter road network. Oil and gas exploration activities create long, narrow clearings through natural vegetation, such as seismic lines and roads, collectively known as 'linear features.' Linear features can be a management challenge because they can affect how people and animals move and plants disperse within a landscape. For example, in southern parts of the boreal forest, linear features appear to affect predator-prey dynamics that can result in increased caribou mortality by wolves. The North Yukon and Peel Watershed Regional Land Use Plans identify mitigations to minimize the potential effects of linear features, including cautionary (0.75 km/km^2) and critical (1.0 km/km^2) indicator levels of linear disturbance.

Intermittent exploration activities in the Eagle Plains area from the 1950s to 2014 have created a network of winter roads, 2D seismic lines, and, most recently, 3D seismic lines in parts of the Regional Study Area (RSA). However, the extent of liner features that currently occur in the RSA, the structural, vegetation, and functional characteristics of different linear feature types, and their degree of regeneration are unknown. EDI Environmental Dynamics Inc. conducted a linear features study to characterize the structural, vegetation, and functional aspects of linear features in the RSA to address these information gaps. The study addressed three objectives: (1) comprehensive mapping and classification of existing linear feature footprints within the RSA; (2) quantification of structural aspects (e.g., widths) and functional aspects (ease of travel and sightlines) of linear features; and (3) quantification of regeneration pathways and structural stages of linear features. This combined information supports assessing potential effects of linear features in the Project application and refinement of mitigation measures for linear features to minimize possible effects.

The linear features inventory was compiled from multiple spatial datasets and was verified and supplemented using satellite imagery in a Geographic Information System. Linear feature densities were estimated for each linear feature type. Estimates were adjusted to account for (i) overlap with open habitats, such as recent burns, where vegetation heights were similar on and off the line, and (ii) for average rates of regeneration determined from field studies.

Site selection used a stratified random design to obtain a representative sample of different feature types across the RSA. Ground and aerial surveys measured specific structural, vegetation, and functional characteristics across the different line types. Measures included width, successional class, structural stage, vegetation composition and height, and sightline distances. A 'walk test' was used to index ease of movement for large mammals. A driving survey documented the visibility of seismic lines from the Dempster Highway (i.e., as an index of potential human access onto the seismic lines). An aerial winter track survey was conducted in March 2020 to assess ungulates' relative use of different linear feature types.

Four primary types of linear features occur in the RSA, totalling 4,269 km: 2D seismic (34%), 3D seismic (51%), winter roads (14%), and the Dempster Highway (1%). The unadjusted linear feature density for the RSA totalled 1.79 km/km^2. After accounting for burns, natural openings and regeneration, the adjusted linear

feature density for the RSA totalled 0.52 km/km², below the cautionary and critical indicator levels in the North Yukon and Peel Watershed Regional Land Use Plans.

Structural, vegetation, and functional characteristics differed substantially among linear feature types. 3D seismic accounts for the largest extent of linear features in the RSA and had the narrowest widths and limited functional effects (e.g., the proportion of features used by ungulates in the winter was less than a third of the rates of use on 2D and winter roads). Winter roads had the widest average widths and the greatest functional effects except for the Dempster Highway. However, a substantial portion (39%) had also regenerated into or past the Tall Shrub stage (which this study suggests may be the best criterion for functional recovery). Most 2D lines had substantial vegetation regeneration, resulting in the shortest average sightlines and slowest movement speeds. However, ungulates still appeared to select them to travel on during winter.

Except for the Dempster Highway, where walking speeds were near twice the rate of other linear feature types, there was relatively little difference in movement rates among linear feature types and control areas. The density of shrubs and trees primarily limited movement rates. 2D lines, which had the highest density of shrubby regeneration, had the slowest average movement rates. For other linear feature types, the combination of vegetation regeneration on linear features and the naturally open nature of most adjacent undisturbed areas did not convey a substantial increase in movement rates on linear features compared to undisturbed areas.

Sightline distances on 2D lines and winter roads were also affected mainly by the degree of vegetation regeneration. Where regeneration was limited, sightlines on 2D lines and winter roads regularly exceeded 150 m. On 3D lines, which have not had enough time since their creation for vegetation to regenerate to the height that restricts vision, sightlines were limited by meanders purposely constructed to reduce sightlines. The meanders employed on 3D lines were also effective in reducing the detectability of the lines from the Dempster Highway. In the blind test, where observers did not know the location of the 3D lines, only 5% (4 out of 74) crossings were spotted. With a map showing the crossing locations, only two additional 3D lines were detected.

These results provide information to assess the potential effects of linear features in the Project application and refine mitigation measures.

ACKNOWLEDGEMENTS

EDI Environmental Dynamics Inc. (EDI) completed the work within the traditional territories of the Vuntut Gwitchin First Nation (VGFN), First Nation of the Na-Cho Nyäk Dun, and the Tetlit Gwich'in Council (Secondary Use Area). Tyrel Kassi, a VGFN citizen, played an active role in the field components of the project. We thank him for his diligence and shared perspectives during the project.

AUTHORSHIP

1 INTRODUCTION

1.1 PROJECT OVERVIEW

The Eagle Plains Project (the Project) encompasses a 2,386 km² area in north-central Yukon, approximately 605 km north of Whitehorse and 40 km south and west of Eagle Plains hotel, along the Dempster Highway (Map 1-1). The Project occurs within the Eagle Plains petroleum basin, north of the Ogilvie River and west of the Richardson Mountains. The basin contains proven natural gas and oil reserves (Peel Watershed Planning Commission 2019), including 4.6 billion m³ of gas and 3.2 million m³ of oil (Hannigan 2014).

The Regional Study Area (RSA) has had intermittent periods of oil and gas exploration since the 1950s. That activity has developed winter roads, seismic lines, and exploratory wells across parts of the current RSA. Approximately 40 exploration wells have been drilled at Eagle Plains. Eight wells are maintained in suspended status, and the remaining wells have been plugged and abandoned. Seismic exploration has included approximately 10,000 km of two-dimensional (2D) lines (mainly before 1985), and about 325 km² of three-dimensional (3D) seismic was conducted in 2013–2014 (Northern Cross (Yukon) Ltd. 2014).

The current exploration program will build on past exploration to better define the extent, amount and quality of oil and gas deposits. Under the current program, Chance Oil and Gas Ltd. proposes conducting additional 3D seismic over large extents of the RSA and drilling up to 30 exploratory wells. Depending on the drilling program results, extended flow testing over several months may be conducted at a subset of the wells to determine the quantity and quality of the oil and gas deposit. The existing winter road network will be expanded to support the seismic and drilling programs. Most work is expected to be conducted in the winter (e.g., seismic line clearing and drilling); however, seismic recordings and extended flow testing may also occur during summer.

Oil and gas exploration activities create long, narrow clearings through natural vegetation, such as seismic lines and roads, collectively known as 'linear features.' Linear features can be a management challenge because they can affect how people and animals move and plants disperse within a landscape. For example, in southern parts of the boreal forest, linear features appear to affect predator-prey dynamics that can result in increased caribou mortality by wolves. The North Yukon and Peel Watershed Regional Land Use Plans identify mitigations to minimize the potential effects of linear features. The Plans also include cautionary (0.75 km/km²) and critical (1.0 km/km²) linear density indicator levels.

1.2 PURPOSE AND OBJECTIVES

Intermittent exploration activities in the Eagle Plains area from the 1950s to 2014 have created a network of winter roads, 2D seismic lines, and, most recently, 3D seismic lines in parts of the RSA. However, the extent of liner features that currently occur in the RSA, the physical and functional characteristics of different linear feature types, and their degree of regeneration are unknown.

EDI Environmental Dynamics Inc. (EDI) conducted a linear features study to characterize the physical and functional aspects of linear features in the RSA to address these information gaps. The three objectives of this study were to: (1) conduct comprehensive mapping and classification of existing linear feature footprints within the RSA; (2) determine physical aspects (e.g., widths) and functional aspects (ease of travel and sightlines) of linear features; and, (3) quantify regeneration pathways and stages of linear features. The combined information forms the basis for assessing the potential effects of linear features in the RSA and refining mitigation measures for linear features.

1.3 STUDY AREA

The RSA for the Eagle Plains Project is approximately 2,386 km² (238,566 ha), centred in the Eagle Plains Ecoregion in north Yukon (Map 1-1). The area consists of subdued topography of rolling hills and sloping plains. The RSA is centred on a major watershed divide (denoted by the location of the Dempster Highway), with the northwestern two-thirds of the RSA draining into the Porcupine River watershed to the north, via Chance Creek, and west, via McParlon Creek and the Whitestone River. The southeastern third of the RSA drains into the Peel River watershed via Dalglish Creek.

Development in the RSA and the surrounding Eagle Plains is low. The Dempster Highway is the primary vehicle access corridor, running from approximately Dawson City, Yukon in the south to Inuvik, Northwest Territories in the north, and transiting the RSA. The Eagle Plains settlement is on the Dempster Highway, approximately 40 km northeast of the RSA and includes the Eagle Plains Hotel and the Government of Yukon's Highway Maintenance camp. The Eagle Plains area has had intermittent periods of oil and gas exploration since the 1950s. That activity has created winter roads, seismic lines, and exploratory wells across parts of the RSA. Approximately 40 exploration wells have been drilled at Eagle Plains. Eight wells are maintained in suspended status, and the remaining wells have been plugged and abandoned. Approximately 10,000 km of 2D lines have been developed across the Eagle Plains Ecoregion, mostly between 1961 and 1984 (Access Consulting Group and EBA Engineering Consultants Ltd. 2001, GEOTIR 2014). More recently, approximately 2,200 km of 3D LIS exploration was conducted in a 325 km² area between November 2013 and April 2014 (GEOTIR 2014). This 3D exploration grid is near the centre of the RSA, spanning north and south of the Dempster Highway.

1.3.1 REGIONAL ECOLOGICAL SETTING

The Eagle Plains Ecoregion is a 20,400 km² portion of the Taiga Cordillera Ecozone in north Yukon between the Richardson and Ogilvie Mountains. Unlike much of the mountainous Taiga Cordillera, most of the Eagle Plains Ecoregion occurs as low altitude rolling topography between 300 m and 600 m above sea level (masl), with few scattered peaks above and around 1,000 masl (Ecological Stratification Working Group 1995). Most of the ecoregion is unglaciated terrain, with surficial features formed due to permafrost and frozen ground-related processes, including thermokarst subsidence, soil creeps, cryoturbation, solifluction, and active layer detachment slides on shale (Yukon Ecoregions Working Group 2004).

The Eagle Plains Ecoregion experiences moderate precipitation, with annual amounts around 400 mm. Most precipitation falls as rain throughout the summer, averaging 50 to 80 mm per month, June through August. Precipitation is lighter through September to April and falls as snow, with average winter snowpacks of 80 cm peaking in April. The climate is strongly affected by latitude, with extended winter conditions from October to early May. There is a substantial variation in seasonal temperatures in the Eagle Plains, with cool short summers and long cold winters. Average winter temperatures are between −30°C and −25°C, with extremes as low as −60°C. Average summer temperatures are around 13°C, with extremes as high as 30°C. Due to the northern latitude, this region experiences continuous sun above and below the horizon, in summer and winter, respectively.

Most of the Ecoregion, including the northeast portion of the RSA, drains north into the Yukon River via the Whitestone, Porcupine and Eagle rivers. That part of the RSA includes the headwaters of the Eagle River and several other tributaries of the Porcupine River, along with the Chance and McParlon Creek subdrainages of the Whitestone River. The southeast corner of the Ecoregion drains east to the Mackenzie River via the Peel, Wind and Ogilvie Rivers. Dalglish and Enterprise creeks flow directly into the Peel River. The few lakes in the Ecoregion are generally oxbow or thermokarst lakes (Yukon Ecoregions Working Group 2004). Several wetland complexes are associated with larger creeks in the RSA.

The Eagle Plains Ecoregion is within the continuous permafrost zone where permafrost can be found up to 200 m thick. The Eagle Plains Ecoregion is dominated by the Cryosolic soils that occupy much of the northern third of Canada, characterized by near-surface permafrost. Turbic Cryosols predominate, exhibiting patterned ground formations and hummocks, and are often associated with open stands of black spruce (*Picea mariana*), tamarack (*Larix laricina*) and birch (*Betula* spp.). The active permafrost layer in these ecosystems generally ranges between 20 cm and 90 cm below the surface. The active layer depth is generally deeper directly under hummocks and shallower under inter-hummock areas (Yukon Ecoregions Working Group 2004).

The RSA is entirely within the Subarctic Bioclimate Zone (Environment Yukon 2014). Vegetation in the RSA is characterized by open-canopy, spruce-dominated habitats where permafrost and short cool growing seasons limit tree growth and often result in stunted, disclimax vegetation communities (Environment Yukon 2016). Hummocky, black and white spruce (*Picea glauca*) woodlands with well-developed shrub communities are common in upland areas. White spruce and ground lichens increase in abundance in well-drained sites. Areas with low slope gradients and fine-textured soils often have ground cover dominated by cottongrass tussocks beneath a shrub layer of birch, black spruce, Labrador tea (*Rhododendron groenlandicum*), and occasionally tamarack (*Larix laricina*) (Yukon Ecoregions Working Group 2004).

Forest fires are a common disturbance agent in the region, and burns of various ages occur throughout the RSA. Fires increase the depth of the active permafrost layer and changes in soil moisture and productivity, affecting vegetation regeneration and resulting in terrain disturbances, such as slope failures and erosion. Regenerating burns are dominated by shrubs, such as scrub birch (*Betula glandulosa*), willows (*Salix spp.*) and alder (*Alnus spp.*), with Alaskan paper-birch (*Betula neoalaskana*) often the first tree species to colonize burn areas. As burns regenerate into young and mature forest, black and white spruce typically become the dominant forest species. Residual Alaskan birch in spruce-dominated stands often defines the extent of old burns (Yukon Ecoregions Working Group 2004).

Mammal diversity is relatively low in the Eagle Plains Ecoregion due to its northern location and low productivity. Voles (*Microtus* spp., *Myodes* spp., *Phenacomys* spp.), American marten (*Martes americana*), ermine (*Mustela erminea*), and red fox (*Vulpes vulpes*) are common smaller mammals. Wolves (*Canis lupus*), wolverines (*Gulo gulo*), and both black and grizzly bears (*Ursus americanus* and *U. arctos*.) are present at low densities. Moose (*Alces alces*) inhabit the region year-round. The RSA overlaps a small portion of the winter range of the Porcupine caribou herd (PCH), a subpopulation of the barren-ground caribou (*Rangifer tarandus granti*). The PCH is an iconic species in north Yukon, with high cultural, social, economic, and ecological values. The PCH's population has been increasing over the last several decades and is currently estimated to consist of 202,106 to 234,808 caribou (Caikoski 2017, Porcupine Caribou Technical Committee 2018). The PCH is known to occupy portions of the Eagle Plains Ecoregion in fall and winter when they tend to occur in smaller groups over a larger area than during other seasons.

1.3.2 REGIONAL LAND USE PLANNING

The RSA overlaps four First Nation Traditional Territories. Most of the RSA is within the Traditional Territory of the Vuntut Gwitchin First Nation. The southeastern portion is in an area of overlapping Traditional Territories of Vuntut Gwitchin First Nation, the Tetlit Gwich'in Council, the First Nation of Na-cho Nyäk Dun, and Tr'ondëk Hwëchin. Although the RSA is located outside of any First Nation Settlement Lands, it does abut Vuntut Gwitchin First Nations Settlement Lands on parts of its east and southwest borders. Each First Nations government has provided input to, and approved of, the Regional Land Use Plan(s) on their Traditional Territory under the respective First Nation Final Agreements.

1.3.2.1 North Yukon Regional Land Use Plan

The RSA lies mainly within the North Yukon Planning Region and is subject to the North Yukon Regional Land Use Plan (NYRLUP) (Map 1-1). The NYRLUP was created to protect the natural and cultural resources of the region while allowing sustainable economic development opportunities (Vuntut Gwitchin Government and Yukon Government 2009). It provides management direction for using public and settlement lands based on four principles: sustainable development, precautionary principle, conservation, and adaptive management. The NYRLUP divides the Planning Region into 23 land management units classified into three categories: protected area, integrated management area (IMA), and community area. IMAs are further classified into four zones: Zone 1 (lowest development), Zone II (low development), Zone III (moderate development), and Zone IV (highest development). IMA zones are classified based on the area's sensitivity to landscape disturbance, ecological and cultural values, risk of significant impacts, and level of acceptable change. The RSA is a Zone IV IMA with lower ecological and cultural values in a moderately sensitive biophysical setting. Subsequently, Zone IV IMAs allows for the highest development level to occur.

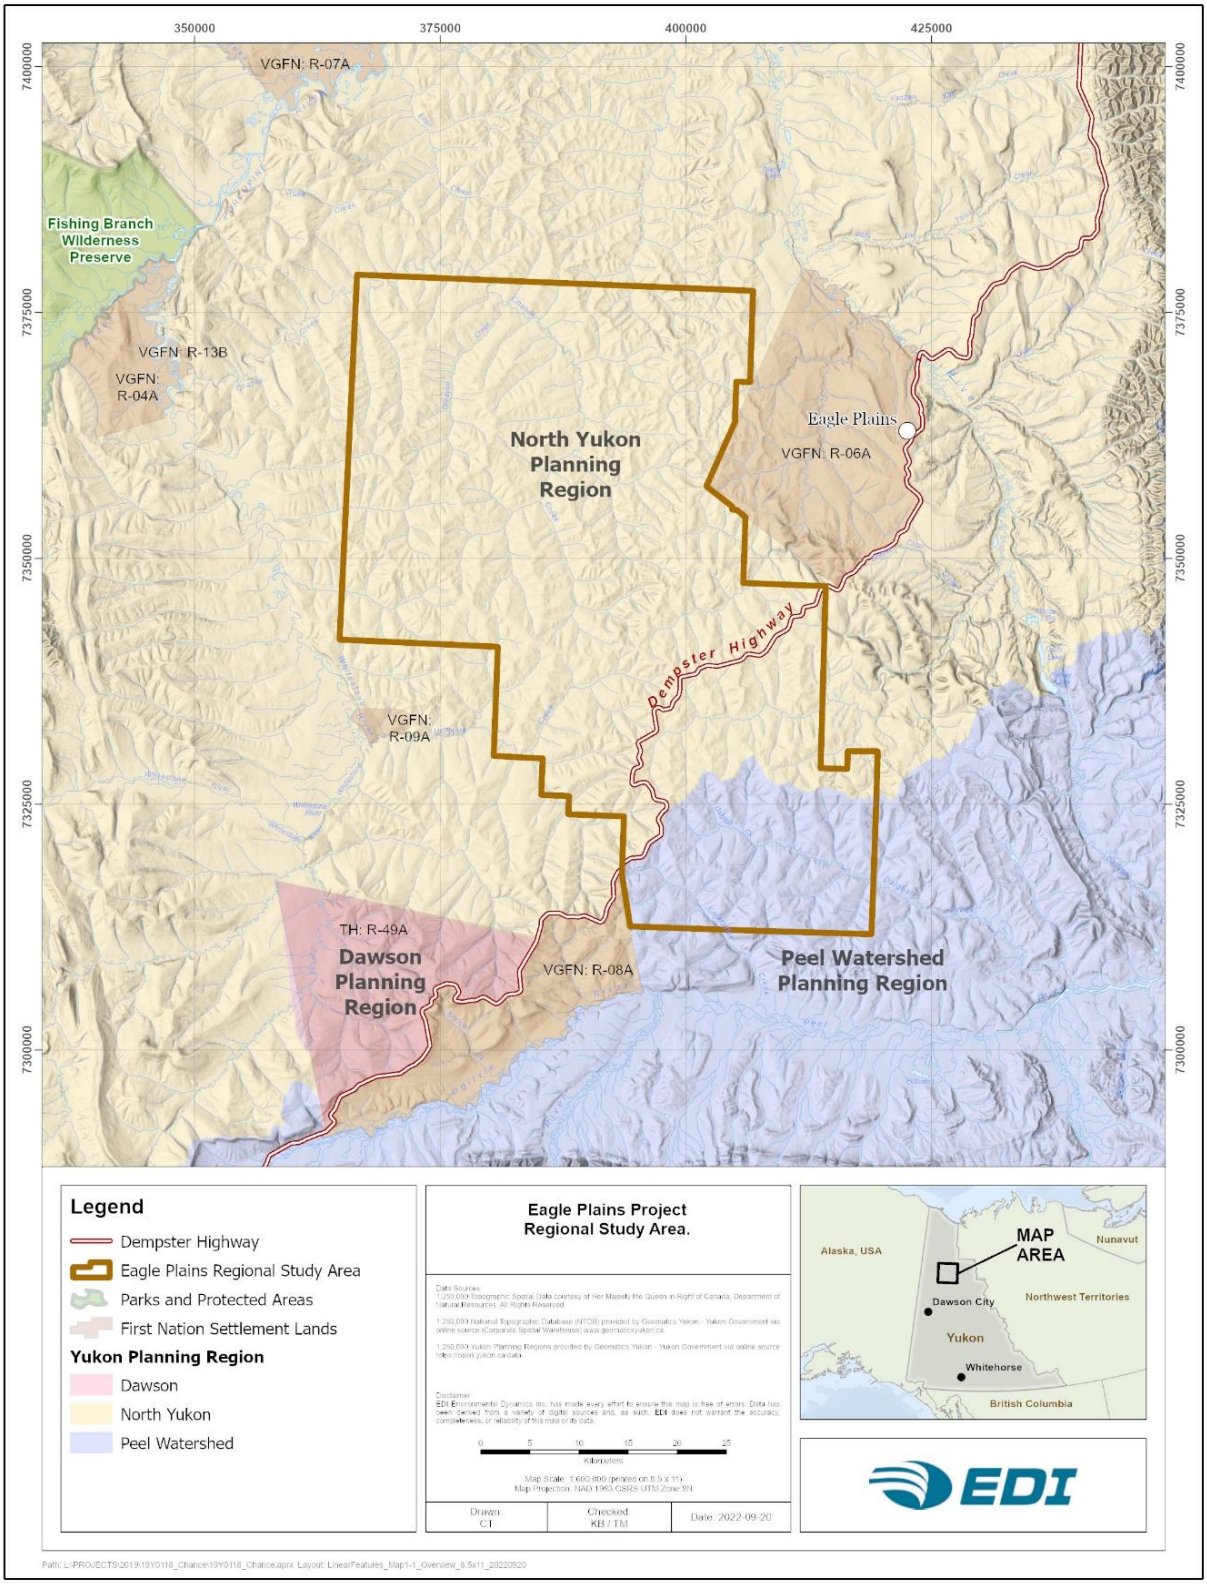
The NYRLUP encourages results-based management and uses cumulative effects indicators to determine if goals and objectives are met. Results-based management allows for innovation and creativity in land-use strategies and approaches. The two cumulative effects indicators included in the NYRLUP are direct surface disturbance and linear density. The NYRLUP guidelines for Zone IV IMAs are 0.75–1.0% surface disturbance and 0.75–1.0 km/km² linear density (Vuntut Gwitchin Government and Yukon Government 2009).

However, as surface disturbances and linear features reach a level of functional recovery and become part of the continuous landscape, they can be subtracted from the total amount of disturbed area (Vuntut Gwitchin Government and Yukon Government 2009). The NYRLUP suggests using a height of 1.5 m for woody vegetation in forested areas, as vegetation above this height would likely no longer allow for travel or access by humans or wildlife and is, therefore, considered functionally recovered. Activities considered exempt from functional disturbance restrictions are (1) new linear features less than 1.5 m wide; (2) land-use activities that occur on frozen water bodies; (3) winter work with no required clearing of trees; and (4) winter work that uses existing disturbances and linear features.

1.3.2.2 Peel Watershed Regional Land Use Plan

The southeastern corner of the RSA lies within the Peel Watershed Planning Region (PWPR) and is subject to the Peel Watershed Regional Land Use Plan (PWRLUP) (Peel Watershed Planning Commission 2019) (Map 1-1). Like the NYRLUP, the PWRLUP was established to provide management direction and ensure long-term sustainable development in the Planning Region. The PWRLUP was founded on three main themes: environmental protection, social considerations, and economic development. It follows a similar framework as the NYRLUP. The PWPR is divided into 16 Landscape Management Units (LMU), which each share similar ecological characteristics, planning issues, and management intent. Each LMU is categorized by a land-use designation system. Conservation Areas are managed to protect ecological and cultural resources, while IMAs are 'working' landscapes where new development and surface disturbance may be allowed. IMAs are further classified into Zones, which correspond to the level of allowable development with comparable justification as the NYRLUP. The RSA is part of LMU 7 (Dalglish Creek), classified as an IMA Zone IV, allowing for the highest level of development.

Like the NYRLUP, the PWRLUP encourages results-based management and uses the same cumulative effects indicators, surface disturbance and linear density to inform decisions. The PWRLUP cautionary and critical indicators are identical to those of the NYRLUP: 0.75–1.0% surface disturbance and 0.75–1.0 km/km² linear density. As surface disturbances reach a level of functional recovery and no longer enable travel or access by wildlife and people, they can be subtracted from the total amount of disturbed area. The PWRLUP suggests using a 1.5 m woody vegetation height as a threshold for functional recovery in forested or shrubland areas. In areas dominated by low-growing vegetation, a feature could be considered functionally recovered when covered by native species roughly the same height and composition as the surrounding vegetation. To be considered as "functionally recovered," features must have similar sediment and run-off compared to background levels, roughly match original contours, and have no human-brought materials on the site. Exceptions to the linear density calculation are identical to those outlined in the NYRLUP.



Map 1-1. Eagle Plains Project Regional Study Area.

2 BACKGROUND

The term "linear feature" refers to any narrow, linear clearings of vegetation on the landscape. They include roads, seismic lines, power lines, and pipelines. Seismic lines are the dominant linear feature class in northern Canada, accounting for approximately 46% of all linear features in the Canadian boreal region (Pasher et al. 2013). Seismic exploration detects underground oil and natural gas reservoirs by analyzing sound waves reflected from the underlying geology (Yukon Energy Mines and Resources 2006). Sound waves are emitted by detonating small charges in a series of drilled shot holes (up to 20 m deep) or by vibrating a heavy metal plate on the ground's surface using a truck-mounted vibrator (Yukon Energy Mines and Resources 2006). Both methods require cleared travel corridors for equipment transportation, which results in a network of seismic lines across the landscape where seismic exploration has occurred.

Until the late 1990s, conventional 2D was the primary form of seismic exploration used in North America. 2D seismic lines were created using bulldozers to clear all vegetation in straight swaths, approximately 5–10 m wide in their earliest form. These wide, straight lines were necessary to enable large, heavy equipment movement. This process resulted in significant physical disturbance, often removing most surface vegetation and roots and the top layer of soil (Bliss and Wein 1972). Progressive improvements in 2D seismic exploration methods reduced the environmental impact, such as clearing in winter instead of summer and raising and adding mushroom shoes to the bulldozer blade to reduce soil disturbance. Despite these improvements, many of the 2D seismic lines created in the 1960s and 1970s in northern Canada remain disturbed, with little evidence of ecological recovery (Lee and Boutin 2006, van Rensen et al. 2015).

3D seismic exploration provides more accurate subsurface geological structure data than 2D technology. 3D seismic exploration techniques were developed in the mid-1990s, and their use became widespread in the early 2000s (Dabros et al. 2018). At the same time as the transition to 3D, the seismic industry was transitioning to smaller and more specialized equipment that reduces cost, improves efficiency and reduces environmental impacts. Modern seismic equipment and methods typically use what is referred to as Low Impact Seismic (LIS) methods that minimize line widths and site disturbance and compaction. Typical 3D seismic lines are 2–3 m wide, constructed in 100–500 m spaced grids, and follow meandering rather than straight routes. There have been substantial improvements in the equipment used for 3D seismic line creation: low ground pressure mulchers, lighter equipment, ATV-mounted equipment, mushroom shoes and smear blades, and 'envirodrills' greatly reduce physical and vegetation disturbance (Dabros et al. 2018). These methods often leave the ground vegetation intact and only remove trees and tall shrubs, reducing overall disturbance and facilitating faster regeneration. The location of the seismic line can be adjusted on the fly in the field to minimize impacts, such as avoiding the cutting of large trees.

Continuous advancements in seismic exploration technology have improved geophysical accuracy while simultaneously reducing environmental impact. Numerous studies have examined the effects of linear disturbances on soil, hydrology, vegetation, regeneration, and wildlife responses (see Dabros et al. 2018 for a comprehensive review). Although the bulk of literature focuses on 2D seismic lines, as they have been part of the landscape for over 60 years, there have been several recent studies investigating the effects of LIS and 3D seismic lines (e.g., Kemper and Macdonald 2009a, Kansas et al. 2015, Golder Associates 2016).

Linear features have been associated with various environmental effects, including permafrost thaw, soil compaction and rutting, increased soil moisture and pooling, altered snow cover, temperature and wind patterns, and varied vegetation and wildlife responses (Dabros et al. 2018). In addition to the immediate loss of vegetation, linear features can create extensive edge effects, facilitate non-native or disturbance-induced species establishment, alter species composition, and positively and negatively affect wildlife (Dabros et al. 2018).

One of the most extensively studied effects of linear features in the southern boreal forest is the indirect effects that linear features can have on mortality risk to woodland caribou (*R. tarandus caribou*). Linear features can result in complex effects on populations dynamics that include (i) increases in secondary prey (moose and deer), which elevate wolf populations (apparent competition) and (ii) more efficient hunting by predators along linear features (facilitated predation) (Wittmer et al. 2007, Latham et al. 2011, Dickie et al. 2017a, Keim et al. 2019b, 2021). Research has also documented the responses of birds to linear features (Bayne et al. 2005, Machtans 2006, Lankau et al. 2013), bears (Tigner et al. 2014, Finnegan et al. 2018), and furbearers (Tigner et al. 2015).

Most studies investigating impacts and recovery of seismic lines and other linear features were conducted in southern boreal forest ecosystems (i.e., Boreal Plains Ecozone; e.g., Lee and Boutin 2006, Kansas et al. 2015, van Rensen et al. 2015, Dickie et al. 2017a). There are fundamental differences in the climate, vegetation communities, wildlife communities, and ecological processes in taiga ecosystems that may result in different patterns and responses to linear features. For example, regeneration patterns of linear features in taiga ecosystems over permafrost can follow different successional trajectories than those of southern boreal regions (Simpson 2008). The few studies that have examined linear features in taiga regions have found similarities and differences to southern studies revegetation (Kemper and Macdonald 2009, Dabros et al. 2018). One of the key objectives of this study was to collect local information from Eagle Plains that can be used to better contextualize or adapt the findings from other studies to the Eagle Plains Project.

3 METHODS

A GIS analyses and field surveys were conducted to characterize linear features within the RSA. The inventory of linear features in the RSA was developed in a GIS by compiling available spatial data and then verifying and updating that against satellite imagery. Field studies quantified the width, vegetation characteristics, ecological function (line-of-sight, large mammal ease of movement assessment), and visibility of lines from the Dempster Highway.

3.1 LINEAR FEATURES INVENTORY

The inventory of existing linear features in the RSA was developed in a GIS by compiling available spatial data and then verifying and updating that against satellite imagery. A preliminary linear feature database was first developed that was used to support field surveys (described below in this section). A second step linked the field data to the linear feature database and conducted a more thorough review and verification process using satellite imagery to produce a final linear feature dataset for the RSA (see details in section 3.5.1).

Linear feature spatial data were obtained from the following sources:

- Yukon Government Energy, Mines and Resources "Oil and Gas Seismic Lines" dataset (a combination of less detailed National Energy Board data pre-1999 and the more detailed company-submitted data post-1999) (Yukon Government 2019)
- Natural Resources Canada CanVec "Roads," "Trails," and "Cut Lines" 1:50,000 scale datasets (Natural Resources Canada 2019)

The two datasets were merged into one dataset of all linear features documented in Yukon and clipped to the RSA. Key attribute data included (if available) the linear feature type (i.e., 2D and 3D seismic lines, winter roads, trails, Dempster Highway), width, year of establishment, and data source. This preliminary linear feature dataset was compared against satellite imagery at a (minimum) 1:10,000 scale to verify its accuracy. Any linear features that did not correspond with features visible in satellite imagery were either corrected or deleted based on satellite imagery interpretation. In the case of duplicate features across datasets, the 'best' data were attributed to a single feature by considering the spatial accuracy and the amount and accuracy of attribute data, as assessed against satellite imagery. Where duplicate widths occurred in the two source datasets, the wider width was retained.

3.2 LINEAR FEATURE CHARACTERISTICS SURVEY

Field studies quantified the width, vegetation characteristics, line-of-sight, and large mammal ease of travel assessment across the linear feature types identified from the GIS inventory. One aspect of the field study was to compare vegetation, line-of-sight, and ease of movement on the linear features to undisturbed areas adjacent to the cleared lines. Three types of surveys collected data for the linear feature study: ground surveys

(finest level of detail), air surveys (medium level of detail), and air calls (coarsest level of detail). EDI crews collected field data between July 28 and August 8, 2019.

3.2.1 SITE SELECTION

All ground surveys and aerial surveys occurred at predetermined, random sites. Sample sites were selected using a clustered, random sampling approach. This approach balanced obtaining a random, representative sample across linear feature types with survey efficiency (i.e., without clustering sites, the travel time between points would have been substantially greater and resulted in smaller sample size). Survey sites were drawn from 5,000 points distributed randomly across the set of mapped linear features (minimum spacing of 200 m between points). Each point was randomly assigned a unique number.

Each survey cluster included options for both ground and air surveys. For ground surveys, the cluster used a 2 km radius designed to accommodate approximately four ground survey sites, intended to be surveyed within a half-day of work (and close enough so crews could walk between sites). The objective was that two ground clusters could be surveyed by a crew each day. For air surveys, a 4 km radius was used that generally provided at least ten random survey site options. The objective for air survey clusters was that they could be surveyed while transiting between ground survey clusters.

Survey sites were selected via a two-stage process. The first stage was randomly drawing 100 points from the 5,000-point dataset. These points defined the survey clusters and served as actual survey sites. In this first stage, site selection was stratified to obtain an approximately equal sample across 2D, 3D and winter roads. This overweighted sampling of 2D and winter roads, relative to their extents in the RSA, but those features had the highest uncertainty in terms of their widths, vegetation characteristics, and functional characteristics. Stratification was necessary to obtain sufficient sample sizes across these less-common features. The second site-selection stage selected additional random points from the 5,000-point dataset in proximity to the first point, using the 2 km radius for ground surveys and the 4 km radius for aerial surveys.

The RSA was divided into 10 work areas to implement the sample design, each corresponding to a day of surveys. Each day the survey crew selected clusters to survey using the ascending order of the random identification number of the first point used to define each cluster. Similarly, points within each cluster were prioritized in ascending order of the random identification number. Normally, at least two ground clusters and two air clusters were sampled each day. However, that varied somewhat depending on the number of sample sites available in each cluster and the availability of the helicopter.

3.2.2 LINEAR FEATURE CHARACTERISTICS AND SURVEY METHODS

3.2.2.1 Linear Feature Characteristics

A range of structural, vegetation, human use, and functional characteristics was assessed in the field. A list of the various characteristics examined, with a description of each, is provided in Table 3-1. Successional classes and structural stages of vegetation are defined in Table 3-2 and Table 3-3, respectively.

Table 3-1. Description of physical, ecological and function characteristics assessed in the Eagle Plains linear feature study.

Parameter	Description	Survey Measured [1]
Plot location	Latitude and longitude using WGS 1984, measured by Garmin GPS units to ~4 m accuracy.	G, AS, AC
Linear feature type	Dempster Highway, winter road, 2D, 3Dc (conductor lines), 3Dr (receiver lines), and 3D5 (3D lines used both for seismic and local equipment/vehicle travel.	G, AS, AC
Linear feature width	During ground surveys, measured to the nearest 0.05 m and replicated four times. During aerial surveys, they were visually estimated to the nearest 1 m.	G, AS
Percent mulch	Percent cover of mulch (wood chips) on the seismic line, estimated to the nearest 1% using visual estimates. In areas with dense trees or large shrubs, the thick mulch layer produced during line clearing can hinder vegetation regeneration.	G, AS
Successional class	Refers to the successional trajectory of vegetation regeneration on the linear feature. Includes normal, magnified, stagnated, retrogressive, no succession, or recent disturbance class following Simpson (2008)[1].	G, AS, AC
Burn status	Burnt or not burnt; based on visual assessment (i.e., burned trees, charred ground vegetation).	G, AS, AC
Structural stage	Categorical descriptor of the dominant vegetation life form in the plot following the *Field Manual for Describing Yukon Ecosystems* criteria (Environment Yukon 2017). Structural stage categories are defined in Table 3-3.	G, AS
Height and species of tallest vegetation	Measured to the nearest 0.1 m for the tallest vegetation layer, approximated by the 90th percentile height to exclude extreme heights of individual plants.	G
Cover and species of dominant trees	Percent cover was recorded to the nearest 1% if less than 10%, and to the nearest 5% if over 10%. One or two dominant tree species were recorded.	G, AS
Cover and species of dominant shrubs	Percent cover was recorded to the nearest 1% if less than 10%, and to the nearest 5% if over 10%. Up to five co-dominant shrub species were recorded. Ground shrubs were excluded.	G, AS
Ecosite	Ecosite was recorded using Predictive Ecosystem Mapping (PEM) Units, available at the time of the survey. However, separate vegetation surveys indicated that the accuracy of the PEM mapping was poor, and ecosites were not used in subsequent analyses.	G
Permafrost activity/degradation	Present or absent. Additional comments (i.e., type of activity, percent cover) were recorded if applicable.	G
Wildlife trails	Present or absent. If present, rated as poorly, moderately, or well defined.	G
Potential for Off-Highway Vehicle (OHV) passage	Present or absent. Based on professional judgment, a 4x4 side-by-side is summer, considering obstructing vegetation, ground conditions (e.g., wetlands, peatlands), and graminoid tussocks.	G, AS
Signs of human activity	Present or absent. If present, applicable comments were recorded.	G
Ground disturbance	Percent cover of visibly disturbed ground. If present, type and additional descriptive comments were recorded.	G

[1] G=Ground Survey, AS=Aerial Survey, AC=Air Call.

[2] Between 2006 and 2008, Yukon Government, Department of Energy, Mines, and Resources investigated the recovery status of linear features in the Eagle Plains, British Mountains, and Peel River Plateau Ecoregions (Simpson 2008). They found that linear features typically regenerated into one of six categories: normal succession, magnified succession, retrogressive succession, successional stagnation, no succession, and recent disturbance (Table 3-2).

Table 3-2. Descriptions of successional classes on linear features in the Eagle Plains area (following Simpson 2008).

Successional Class	Description
Normal succession	Vegetation is similar to the adjacent undisturbed area but often in an earlier seral stage. E.g., often young trees surrounded by early successional shrubs and forbs. The disturbance was likely limited to removing trees and shrubs, with little to no disturbance to soil or permafrost.
Magnified succession	Vegetation on the feature is taller than the adjacent undisturbed area. Deciduous species often dominate tree and shrub layers, but a similar pattern was also observed for coniferous trees on some sites. The response is likely due to increased site productivity (including increased soil moisture, nutrients, and temperature) due to soil disturbance or increased depth to permafrost. Most frequently, but not exclusively, observed in burns.
Retrogressive succession	Sites are typically moss or sedge-dominated (rarely forb or low shrub), with high moisture content, often including standing water (i.e., micro wetlands), that contrast to upland conditions in adjacent undisturbed areas. The condition appears to result from permafrost melting and water pooling associated with vegetation removal and removal/compaction of the peat layer and mostly associated with winter roads.
Successional stagnation	Vegetation is typically dominated by graminoids or shrubs and not progressing to more advanced successional stages. Disturbance to soil or permafrost is likely. The ground may have been compacted. Almost exclusively associated with winter roads.
No succession	No ecological differences between the linear feature and adjacent undisturbed areas except that there is no or very little tree or shrub regeneration on the line, other than what was left after creation of the feature. Disturbance appears to be limited to the removal of trees and shrubs, with little to no disturbance to ground vegetation, soil, or permafrost.
Recent disturbance	Newer seismic line where successional patterns could not be determined. Features in this class were most likely trending to 'normal succession' or 'no succession', but the degree of regeneration was too limited to classify confidently.

Table 3-3. Structural stage categories used in ground and air surveys for the Eagle Plains linear feature study.

Structural Stage Code	Structural Stage Name	Description
1	Non-vegetated	Very recent disturbance (e.g., fire or flood) and no vegetation or less than 5% vegetation.
2	Sparse/Cryptogram	Either the initial stages of primary succession or a cryptogram community maintained by environmental conditions (e.g., bedrock, talus). Sparse tree, shrub and herb cover. Either sparsely vegetated overall (low cover of vascular plants and cryptograms, if present) or dominated by cryptograms.
2a	Sparse	5–10% vegetation cover.
2b	Bryoid	Bryophyte-dominated.
2c	Lichen	Lichen-dominated.
3	Herb	Early successional stage (e.g., post-fire forest succession) or a herb community maintained by environmental conditions or disturbance. Vegetation is dominated by herbs, although if the site overall is sparsely vegetated, herb cover can be low as long as herbs characterize the vegetation. Trees and shrubs are usually sparse or absent; however, shrub cover and stature (compared to herb cover and stature) determine whether the site is considered herbaceous.
3a	Forb-dominated	Includes non-graminoid herbs and ferns.

Structural Stage Code	Structural Stage Name	Description
3b	Graminoid-dominated	Includes grasses, sedges, reeds, and rushes.
3c	Aquatic	Floating or submerged plants dominate.
3d	Ground shrub-dominated	Dominated by dwarf woody species such as kinnikinnick (*Arctostaphylos uva-ursi*) or dwarf willows.
4	Shrub	Early successional stage of a forest or a shrub community maintained by environmental conditions or disturbance. Dominated either by shrubby vegetation, including tree seedlings or saplings; or, if sparsely vegetated overall, dominated by shrubs, which characterize the community as a shrubland.
4a	Tall Shrub	Dominated by woody plants >2 m tall with diameter at breast height (dbh) ≤7 cm.
4b	Low Shrub	Dominated by woody plants <2 m tall.
5	Treed: Pole/Sapling	Trees >2 m tall and with dbh >7 cm, typically densely stocked. Self-thinning and vertical structure are not yet evident in the canopy. Younger stands are vigorous (usually >15 to 20 years old); older stagnated stands (up to 100 years old) are also included; time since disturbance usually <40 years; up to 100+ years for dense (5,000–15,000+ stems per ha) stagnant stands.
6	Treed: Young Forest	Self-thinning has become evident and the forest canopy has begun to differentiate into distinct layers. A more open stand than at the pole/sapling stage.
7	Treed: Mature Forest	Trees established after the last stand-replacing disturbance have matured; a second cycle of shade-tolerant trees may have become established; shrub and herb understoreys become well developed as the canopy opens up.
8	Treed: Old Forest	Stands of old age with complex structure; patchy shrub and herb understoreys are typical; regeneration is usually of shade-tolerant species with a composition similar to the overstorey. Fire-maintained stands may have a single-storey appearance.
9	Treed: Very Old Forest	Very old stands with complex structures, abundant large trees, snags and coarse woody debris (CWD); snags and CWD occurring in all stages of decomposition; stands are comprised entirely of shade-tolerant overstorey species, with well-established canopy gaps.

3.2.2.2 Survey Methods

Three types of surveys assessed linear feature characteristics: ground surveys (finest level of detail), air surveys (medium level of detail), and air calls (coarsest level of detail). The reason for using different survey types was to maximize the sample size obtained, recognizing that the ability to collect certain types of data, or the level of measurement precision, decreased from ground surveys to aerial surveys to air calls. The characteristics that were measured during each survey type are noted in Table 3-1. Surveys were conducted between July 28 and August 8, 2019.

Ground surveys collected the most information and had the highest measurement precision of the three survey methods. All parameters listed in Table 3-1 were recorded. Field measurements generally followed methods in *Field Manual for Describing Terrestrial Ecosystems* (BC MFLNRORD and BC MOE 2010) with parameter specific details noted in Table 3-1. Photographs were taken of representative on-line and off-line plots.

Air surveys collected moderate resolution data on linear features. Air surveys efficiently collected a larger quantity of more generalized data than ground surveys. The subset of parameters recorded for aerial surveys is noted in Table 3-1. The survey methods generally followed procedures outlined for helicopter-based 'visual checks' in *Standard for Terrestrial Ecosystem Mapping in British Columbia* (Resources Inventory Committee 1998). Data were collected by hovering in a helicopter approximately 30 m over the sample sites for approximately three minutes while field crews recorded data for the reduced set of variables. Like ground surveys, relevant data were collected for both on-line and off-line plots. Photographs were taken at representative air survey plots (Attachment A).

Air calls collected data at the coarsest resolution of the three survey types, and no off-line data were collected. The data collected during air calls were limited to linear feature type, successional class, and burn status. Air calls were opportunistically conducted when EDI crews were flying through the RSA and linear features were encountered.

A fundamental aspect of the field study was to compare linear feature characteristics to adjacent undisturbed areas. Hence, field surveys included paired on-line and off-line plots at each sample site (excluding sites assessed via air calls). Off-line plots were located 50 m off the linear feature, with the direction off the feature selected randomly at each site using a coin toss. Data collected for each sample site were recorded on tailored survey forms (Attachment B).

3.2.2.3 Line-of-Sight and Ease of Travel

In addition to the structural and vegetation measures noted above, line-of-site and ease-of-movement were assessed as functional characteristics of the linear features at each ground plot. The sightline, measured to the nearest metre, was calculated as the farthest line that could be sighted using a range finder at the height of 1.5 m off the ground. Two measurements were recorded, one in each direction along the linear feature. Sightline measurements were repeated using the same bearings in the off-line plot.

Ease of travel was assessed using a 'walk test,' as Keim et al. (2019a) described in a study assessing the functional recovery of linear features. They found that ease of travel, as measured by a walk test conducted by human researchers, positively correlated with the intensity of use by several wildlife species. One EDI crew member timed themselves to the nearest second for the walk test while walking an approximately 75 m transect, measured to the nearest metre using a hip chain. This walk test was repeated in both the on-line and off-line plots, the paired transects spaced in parallel, approximately 50 m apart. The same observer conducted both walk tests to minimize observer bias at each site.

3.3 VISIBILITY OF LINEAR FEATURES FROM THE DEMPSTER HIGHWAY

One of the management concerns associated with seismic exploration is that seismic lines create travel routes that humans use. The probability of human use of seismic lines to access the surrounding landscape likely increases if the seismic line is visible and accessible from roads. The intersections of seismic lines and winter roads with the Dempster Highway are the primary locations where this could originate. Driving surveys were conducted along the 47 km section of the Dempster Highway within the RSA to determine the number and

type of linear features that could be located and accessed by the public from the Dempster Highway. Two types of surveys were conducted: a blind search where the location of the linear features was unknown and a 'map search,' where the observers had a map of the linear features that showed where they occurred. Both surveys were conducted on August 8, 2019.

The blind search approximated the proportion and type of linear features that the public could locate and access without prior knowledge of their locations. An EDI field crew drove along Dempster Highway at 35 km/h and attempted to identify linear features by visual inspection alone, unaware of where they intersected the highway. When a linear feature was identified, the crew stopped to record the following parameters:

- linear feature type;
- sight line distance;
- evidence of human use;
- evidence of wildlife use; and
- potential for OHV passage.

Photographs were taken, and relevant comments were recorded for each linear feature intersection where applicable.

The map search was a targeted search designed to approximate the proportion and type of linear features the public could spot from the Dempster Highway with prior knowledge of their locations. Using a map of linear features present in the RSA, an EDI field crew drove along the Dempster Highway, slowing to 10 km/h and attempting to identify the linear features when passing a point where the map showed they intersected the highway. When a linear feature intersection was reached, the crew recorded whether the line was visible or not and the parameters listed above for the blind search where a line was detected.

3.4 WINTER TRACK SURVEY

An aerial survey was conducted to assess the relative frequency of use of different liner feature types by ungulates and humans in late winter (March 2020). The survey consisted of 11 transects spanning the width of the RSA. Three of the transects were established parallel to the Dempster Highway at 50 m, 1 km and 5 km off the highway. The remaining transects were spaced approximately 5 km apart across the remainder of the RSA.

Before the field survey, each transect was established in a GIS. Each intersection with a linear feature was given a unique identification point and used to generate a field form (i.e., with a row for each linear feature intersection). The field survey involved flying along each transect and recording the presence of ungulate tracks or human tracks (e.g., snowmobile tracks) at each linear feature that was traversed. Surveys were conducted via helicopter at approximately 70 km/h, 50 m above the ground, with one navigator/data recorder and one primary observer. The surveyors classified tracks to species and counted the number of unique tracks. However, overlapping tracks and dustings of new snow made track identification and counts uncertain in over

half the detections. Therefore, analyses defaulted to the simple presence/absence of ungulate tracks. The primary metric examined was the proportion of linear features with ungulate tracks.

The original survey plan was also to count tracks in undisturbed areas between linear features. However, tracks were so numerous that surveying the entire area between linear features would have required substantially reducing the aircraft speed. This would have reduced the number of transects that could have been surveyed. As a compromise, field crews subsampled the area between lines by surveying an approximate 200 m band of an undisturbed area adjacent to each linear feature.

In conjunction with winter fish habitat assessments, the transects were surveyed over six days (March 7–13, 2020). Each day, one or two transects were surveyed while transiting to/from the study area. No track-erasing snowfalls occurred during the survey period. Snow depths ranged from 65 to 80 cm.

3.5 DATA PREPARATION AND ANALYSIS

3.5.1 SPATIAL DATA

The project generated two primary spatial datasets — a point database corresponding to all field survey sites and the linear feature database. The Linear Feature Survey Point Database (ArcGIS point feature class) contains all location-specific (point coordinate) field data collected at sample sites in summer 2019. Several fields were added to this database based on calculations and spatial joins (e.g., year of linear feature establishment and most recent fire). Paired on-line and off-line plot data were recorded as part of the same sample site coordinate.

The Linear Feature Inventory (ArcGIS polyline feature class) is a compilation of all documented linear features within the RSA, verified by comparing the preliminary linear feature inventory to aerial and satellite imagery and ground-truthing results.

Several modifications were made to improve the accuracy and detail of the Linear Feature Inventory:

- Linear features were classified into the following categories:
  - 2D (historical seismic lines, typically >3m wide),
  - 3D5 (including 4–5 m wide 3D lines that were used for both seismic and local vehicle/equipment travel);
  - 3Dc (3 m wide 3D seismic conductor lines);
  - 3Dr (2 m wide 3D seismic receiver lines);
  - winter roads (any trails or limited use roads used by vehicle or equipment, generally wider than 5 m and often with an obviously curving path); and,
  - Dempster Highway.
- Overlapping features (within a 3 m tolerance) were addressed according to the following rules:

- If two linear features of the same or unknown age overlapped, the wider feature was saved and the narrower feature deleted.
- If two linear features of the same or unknown width overlapped, the more recent feature was saved and the older feature deleted.
- If a 3D line overlapped with a 2D line, both lines were saved. This is because the older 2D lines were often still evident on the landscape in some state of regeneration, as were the 3D lines. However, both were saved since it was unknown at what state each line was in (i.e., if the 2D line was still evident, or only the 3D line, or both in varying states of regeneration). This occurred for 33 km of linear features within the RSA.

The preliminary linear feature inventory within the RSA was compared against a recent high-resolution satellite or aerial imagery (generally, 0.5–1 m resolution) at a 1:10,000 (or finer) scale to verify the accuracy of the source data. Any features that were visibly offset from georeferenced imagery were corrected to match the imagery.

Some older (1960s and 1970s) 2D seismic lines included in the source databases did not appear in satellite imagery. These 2D lines were compared against the imagery along the length of the feature to search for any sign of linear disturbance and then cross-referenced with field surveys conducted along the line, if present. These unverified linear features were classified as 'not applicable' and excluded from analysis if there was no evidence of linear disturbance along the feature's length in the imagery, which could often be verified with associated surveys noting that the feature was 'not present,' 'not visible,' or 'completely regenerated.' Unverified linear features were retained if there was evidence of linear disturbance along any feature's length in the imagery or if associated surveys had noted that the feature was present and in some state of regeneration, even if the feature was not visible in the imagery. A total of 199,473 m of erroneous or regenerated linear features were deleted from the linear feature inventory within the RSA.

Some linear features were visible on the imagery that had not been included in any of the source databases. In these cases, the linear features were manually digitized and classified into linear feature types based on visual assessment and attributes of adjacent connecting features, if present. Digitized linear features were assigned a year if they were obviously a continuation of a documented feature or if they were surrounded by features of the same type and year. Otherwise, the year was not included. High-resolution imagery was not available for the southernmost portion of the RSA (approximately 25 km by 15 km). This area was compared against lower quality Google Earth imagery, but this was not detailed enough to detect undocumented linear features if any existed (Google Earth 2019). However, existing linear features were verified using this method. A total of 202,945 m of linear features were digitized within the RSA.

After the Linear Feature Inventory was verified and corrected to be consistent with imagery and field observations, it was spatially joined to the Linear Feature Survey Point Database. In cases where the survey point did not correspond with any nearby linear feature, or if a linear feature was deleted (following the methods described above), the data were retained in the survey point database, but the linear feature type was updated to 'not applicable' and excluded from data analysis. Ten survey plots were identified as 'not applicable' and excluded from analyses; thus, the corrected sample size for survey plots is n = 210.

3.5.2 FIELD DATA

After completing field sampling, data forms and field notes were reviewed for completeness and accuracy during an internal data quality-assurance process. All associated digital photographs and GPS coordinates were reviewed to correspond to the appropriate field plots. A summary of field plots by linear feature type and survey type is provided in Table 3-4. All recorded data were entered into MS Excel databases (Microsoft 2019). Spatial data were uploaded to the ArcGIS platform (ESRI 2019).

Field-collected data were summarized primarily using Excel spreadsheets (Microsoft 2019). More detailed statistical analyses were performed on select data using R Statistical Software (R Development Core Team 2020). For example, the variation in ease of travel and vegetation cover as a function of linear feature types, burn history, successional stage, or ecosite were explored. During formal analyses, standard assumptions of normality and homogeneity of variance were assessed, and variance-covariance structures were applied to model heterogeneity (of residuals) if required. For instance, the sightline distance (m) was fourth-root transformed to meet normality. In certain models, random effects were included to account for variance among different subjects. For example, observers were included as a random variable to account for observer bias (i.e., a random intercept model; package "nlme", Pinheiro et al. 2016). Corrected Akaike's Information Criteria (AICc) scores were used to compare sets of candidate models. Models with the lowest AICc score were selected because they yielded the best balance (parsimony) between explained variance and level of complexity.

Table 3-4. The number of sites surveyed using ground surveys, air surveys, and air calls for each linear feature type in the Eagle Plains RSA.

Linear Feature Type	Survey Type			
	Ground Survey	Air Survey	Air Call	Total
2D	31	32	44	107
3D-5m wide	5	0	0	5
3D-Conductor	26	3	0	29
3D-Receiver	23	1	0	24
Winter Road	18	17	8	43
Dempster Highway	2	0	0	2
Not Applicable	3	2	5	10
Total	108	55	57	220

3.5.3 LINEAR FEATURE DENSITY CALCULATION

Linear feature densities were calculated in two ways: (1) using the total linear feature extents, and (2) adjusting the extents to account for (a) lines through 'open' habitats, such as wetlands and recent burns, where the vegetation on the line did not differ from vegetation off the line, and (b) functionally recovered linear features such as 2D lines from the 1960s and 1970s that had advanced regenerated at least to the Tall Shrub structural stage. Adjustments were determined by intersecting the Linear Feature Inventory with a recently developed

Ecological Landscape Classification (ELC) map of the RSA (a companion Eagle Plains Project baseline report). The ELC map documented the type and structural stage of vegetation communities across the RSA. The extent of linear features in open habitats was determined by the lengths of linear features overlapping Low Shrub, Herb and Bryoid structural stages in the ELC maps. This includes seral habitats regenerating from burns and ecosystems that are maintained in those stages over time, such as wetlands and shrub-carrs. The extent of regenerated linear features was determined by integrating the proportion of regenerated lines observed from the field surveys (e.g., 61% for 2D lines) with the length of lines through non-open vegetation types in the ELC map. Adjustments were applied to generate functional linear feature densities for each linear feature type individually (i.e., to compare the relative extents of different feature types) and combined to provide an overall density for all linear feature types. For example, the linear feature density for 2D lines was calculated by starting with the total length of 2D lines in the RSA, reducing that by the length of lines through open vegetation types, then reducing the remaining extent by the average proportion of 2D lines that were observed to be regenerated, and then dividing the remaining total length of lines by the extent of the RSA.

4 RESULTS

4.1 LINEAR FEATURE INVENTORY AND DENSITIES

A total of 4,269 km of linear features were mapped and verified in the RSA (Map 4-1, Table 4-1). Winter roads and 2D seismic occur in varying densities across much of the RSA. The extent of 3D seismic is limited to the one area straddling the Dempster Highway in the centre of the RSA.

The total linear feature density in the RSA was 1.79 km/km², based on a total length of 4,269 km and the RSA area of 2,386 km². 3D seismic lines accounted for approximately half of the total length of linear features in the RSA, 2D seismic lines accounted for about one-third, followed by winter roads and the Dempster Highway (Table 4-1). Adjusting for open habitats (i.e., areas in structural stages Low Shrub, Herb, and Bryoid) and vegetation regeneration[1] resulted in substantially lower densities of 0.52 km/km² (Table 4-2). Relatively large extents of recent wildfires were the greatest factor reducing linear feature densities. The relative proportions of the different linear feature types were similar after adjustments, though the proportion of 3D increased and 2D decreased. This was mainly due to the greater degree of vegetation regeneration on 2D lines, consistent with their age since disturbance.

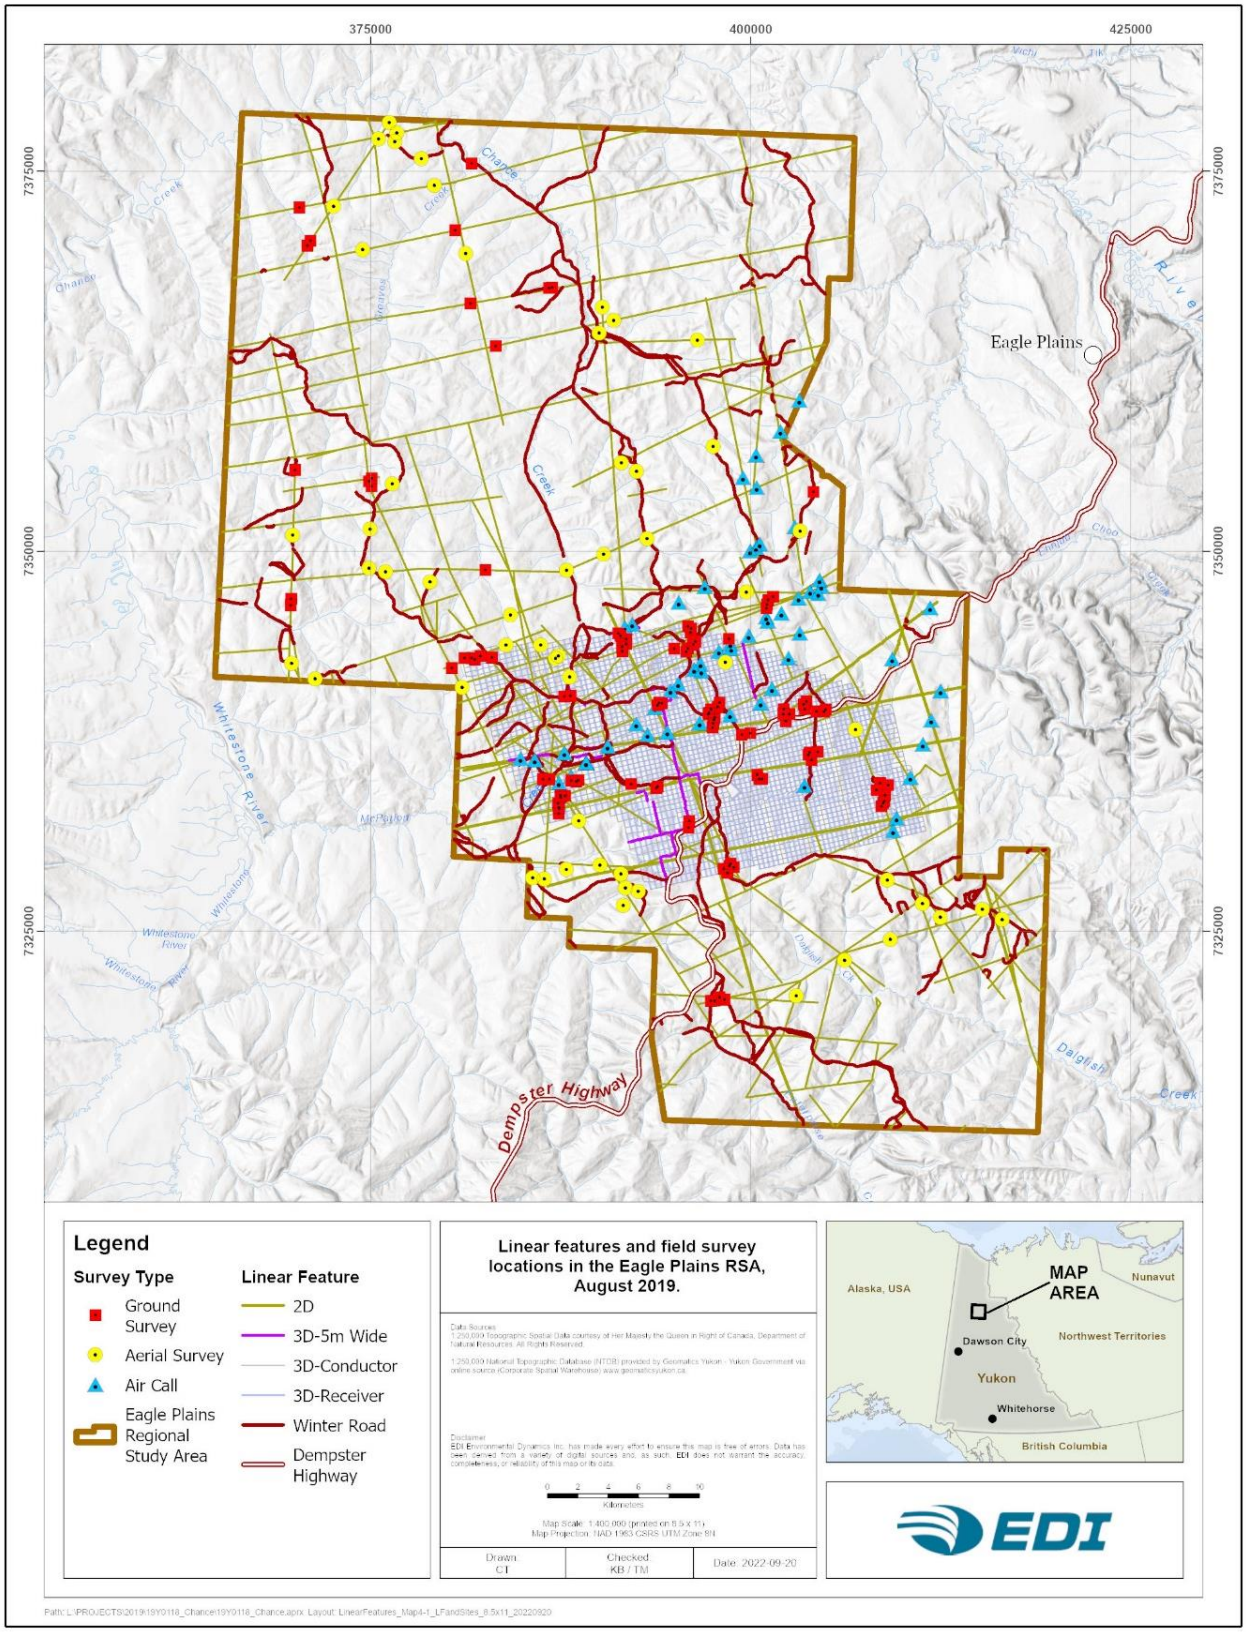
Table 4-1. Summary of total length and density of linear features documented in the Eagle Plains RSA.

Linear Feature Type	Total Length (km)	The Proportion of Total Length	Linear Feature Density (km/km²)
2D	1,452	34%	0.608
3D (combined)	2,165	51%	0.907
3D-5m wide	48	1%	0.020
3D-Conductor	1,189	28%	0.498
3D-Receiver	928	22%	0.389
Winter Road	596	14%	0.250
Dempster Highway	47	1%	0.020
Unknown	8	<1%	0.003
Total	**4,269**	**100%**	**1.788**

[1] See Section 5.5 Functional Recovery of Linear Features for details about vegetation regeneration criteria.

Table 4-2. Summary of total effective length and density of linear features in the Eagle Plains RSA adjusted for open habitat and vegetation regeneration.

Linear Feature Type	Total Length (km)	Proportion of Total Length	Linear Feature Density (km/km²)
2D	289	23%	0.121
3D (combined)	750	60%	0.314
3D-5m wide	21	<1%	0.009
3D-Conductor	401	32%	0.168
3D-Receiver	328	26%	0.138
Winter Road	171	14%	0.072
Dempster Highway	26	<1%	0.011
Unknown	8	<1%	0.003
Total	1,243	100%	0.521



Map 4-1. Linear features and field survey locations in the Eagle Plains RSA, August 2019.

4.2 LINEAR FEATURE CHARACTERISTICS

4.2.1 LINE WIDTHS

Line width varied by linear feature type. Mean line widths ranged from 1.96 m for the narrowest line type (3D receiver lines) to 33.75 m for the Dempster Highway (Table 4-3). Standard error around mean estimates were smallest for 3D seismic lines, which were cleared in the same season using the same equipment and methods, and greatest (by a large margin) for winter roads. The average difference in widths between 3D conductor (wider) and 3D receiver lines was 1.2 m.

Table 4-3. Widths of different linear feature types in the Eagle Plains RSA.

Linear Feature Type	n	Minimum mean width (m)	Maximum mean width (m)	Overall mean width (m)	Standard Error (m)
2D	107	3.97	8.5	5.42	0.11
3D-5m wide	5	5.30	6.40	5.68	0.22
3D-Conductor	29	2.50	4.80	3.17	0.13
3D-Receiver	24	1.63	2.53	1.96	0.04
Winter Road	43	2.53	17.97	7.42	0.66
Dempster Highway	2	33.00	34.50	33.75	0.75

4.2.2 MULCH COVER

Mulching of woody vegetation is common during seismic line clearing activities and was used in the 2013/14 3D program. In areas with thick tree or shrub cover, mulching can create a thick blanket of wood chips that inhibits vegetation regeneration (Golder Associates 2016). There was no evidence that this was an issue with any of the seismic lines within the RSA. On average, the percent cover of mulch was <1% on all line types.

4.2.3 HUMAN USE

No sign of human use was detected along linear features during the summer ground surveys (e.g., OHV tracks, ruts, water crossings, vegetation trampling/scarring, tree blazes, trap sets, garbage, and campsites), except for the two sites on the Dempster Highway.

On average, 42% of on-line sites were deemed passable to an OHV (a 4x4 side-by-side) during summer, considering obstructing vegetation, ground conditions (e.g., wetlands or peatlands), and the presence of graminoid tussocks (Table 4-4).

Table 4-4. Proportion of survey sites deemed passable to OHV in summer across different linear feature types in the Eagle Plains RSA.

Linear Feature Type	No. Survey Sites	% Passable
2D	55	9%
3D-5m wide	5	80%
3D-Conductor	29	59%
3D-Receiver	24	75%
Winter Road	29	55%
Dempster Highway	2	100%
Total	144	42%

4.2.4 SUCCESSIONAL CLASSES

Linear features surveys in the Eagle Plains RSA observed five of the six of the successional classes documented by Simpson (2008): normal succession, magnified succession, stagnated succession, no succession, and recent disturbance (Figure 4-1) (Attachment A). No retrogressive succession sites were observed at official survey sites. However, a small number of retrogressive sites were incidentally observed on winter roads while travelling through the RSA.

Most sites surveyed (79%) were undergoing normal succession. The next most common successional class was magnified succession, occurring in 11% of sites, followed by stagnated succession, occurring in 5% of sites. All 3D seismic lines surveyed followed a normal successional trajectory, except for one site that was classed as recently disturbed. Magnified succession was most common in 2D seismic lines (21%), while stagnated succession was most common in winter roads (19%). Successional classes were defined as 'not present' if the linear feature was not present in the field or had regenerated to a stage that was not discernable from the adjacent areas. The Dempster Highway was classified as recently disturbed due to the regular maintenance of the road.

Fire history appeared to influence some successional classes. Magnified succession was more common at burnt sites (19 burnt versus 5 unburnt). In contrast, stagnated succession was more common at unburnt sites (3 burnt versus 7 unburnt). Sites on a normal successional trajectory did not appear to have any relationship to burnt status. The remaining successional classes were too uncommon to draw any conclusions.

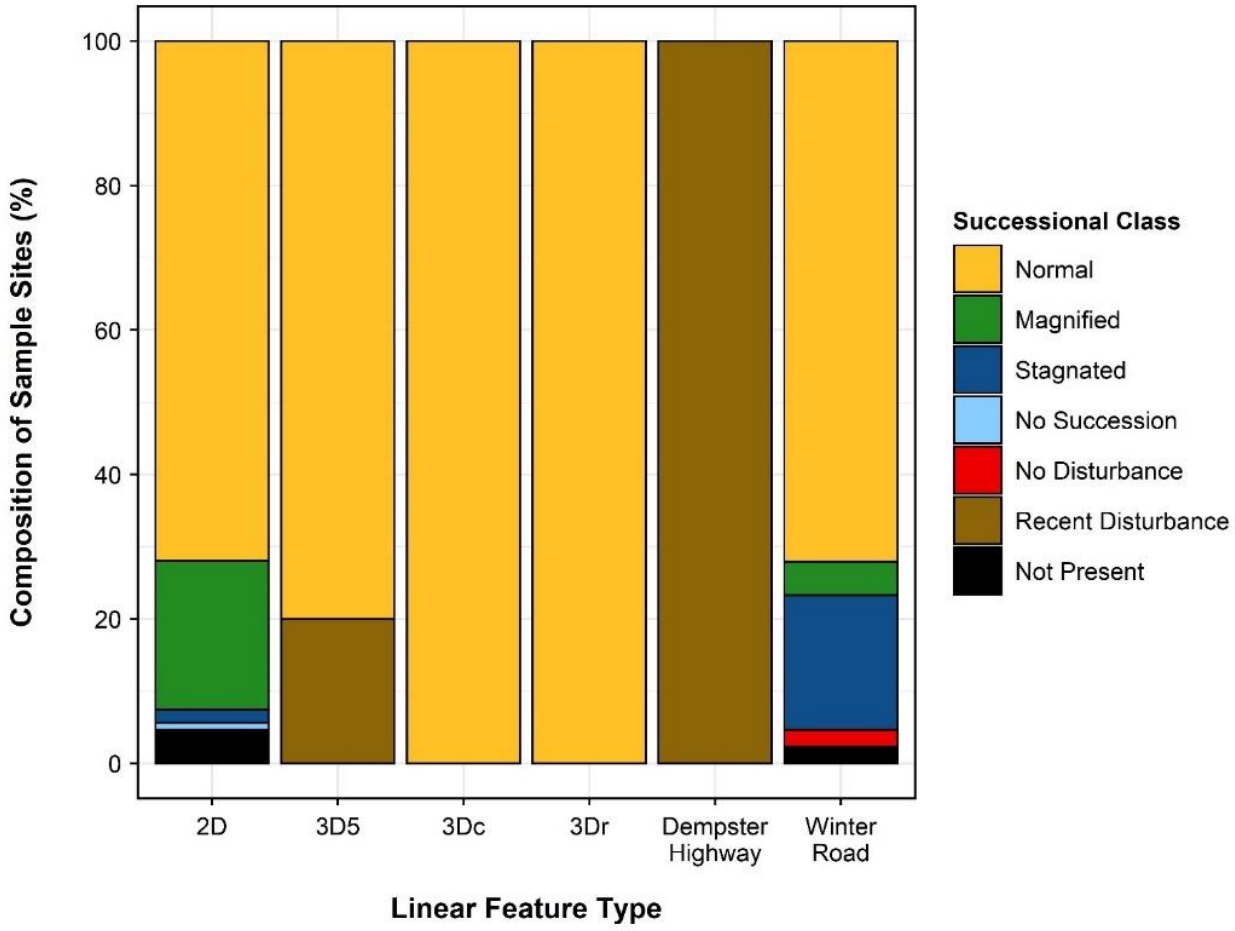


Figure 4-1. Summary of successional classes observed across different linear feature types in the Eagle Plains RSA.

4.2.5 STRUCTURAL STAGE

Most linear features were in a Low Shrub (56.1%) or Tall Shrub (29.0%) structural stage. However, the distribution of structural stages varied substantially across linear feature types (Table 4-5). Although herbaceous and forested stages occurred at some on-line plots, they were not common (less than 5%each). Nearly all forested structural stages were observed on 2D seismic lines and winter roads, reflecting the long time since they were created. Tall Shrub stages were almost twice as frequent in 2D seismic lines than any other linear feature type. Conversely, 83% of 3D linear features were in the Low Shrub structural stage, with most of the remaining in the Tall Shrub stage. The differences in structural stages between 2D and 3D lines appear to be primarily due to the time since disturbance. Winter roads were less consistent in their structural stages; herbaceous, shrubland and forested stages were all observed with moderate frequency. The two Dempster Highway plots were the only non-vegetated stages recorded.

Off-line plots were also mostly in Low Shrub and Tall Shrub stage, but they also included a higher proportion of Young Forest and Mature Forest compared to on-line plots (Table 4-5; Photos A-15 to A-20 in

Attachment A). For off-line plots, the Low Shrub sites were mostly burned areas, and the Tall Shrub sites were mostly stunted, open-canopy, black spruce forest 2–8 m tall.

Fire had a strong effect when comparing structural stages between paired on-line and off-line plots (Figure 4-2). The top two charts in Figure 4-2 show that the pattern of structural stages for burnt areas was very similar between on-line and offline plots. The bottom two charts show that the pattern of structural stages differs substantially between on-line and offline plots in unburnt areas. In unburnt areas, off-line plots had much lower numbers of sites in Low Shrub and much higher numbers of sites in Young Forest and Mature Forest than on-line plots. For burnt areas, the on-line and off-line plots at the same site were the same structural stage in 72% of cases, and within one structural stage of each other 91% of the time (e.g., Tall Shrub vs Pole Sapling). For areas that were not burnt, the on-line and off-line plots at the same site were the same structural stage in only 29% of cases. These results demonstrate that in the absence of fire, pronounced differences between linear disturbances and the surrounding community are evident in both recent (3D) and legacy (2D and winter road) linear feature types. But following a fire, the vegetation structure on-line and off-line are likely to be similar (Photos A-22 to A-24 in Attachment A).

Table 4-5. Vegetation structural stages observed on different linear feature types as a proportion of all plots sampled (n = 156) in the Eagle Plains RSA.

Linear Feature Type	No. Sites	Structural Stage[1]								
		Non-vegetated	Bryoid	Herb	Low Shrub	Tall Shrub	Pole-Sapling	Young forest	Mature forest	Old Forest
2D	62	0%	0%	2%	37%	47%	2%	8%	3%	2%
3D-5m wide	5	0%	0%	20%	80%	0%	0%	0%	0%	0%
3D-Conductor	29	0%	0%	0%	83%	14%	0%	3%	0%	0%
3D-Reciever	24	0%	4%	0%	83%	13%	0%	0%	0%	0%
Dempster Highway	2	100%	0%	0%	0%	0%	0%	0%	0%	0%
Winter Road	33	0%	0%	12%	48%	27%	3%	3%	6%	0%
Off-line	155	0%	1%	1%	33%	29%	1%	18%	17%	1%

[1] See Table 3-3 for structural stage codes and descriptions.

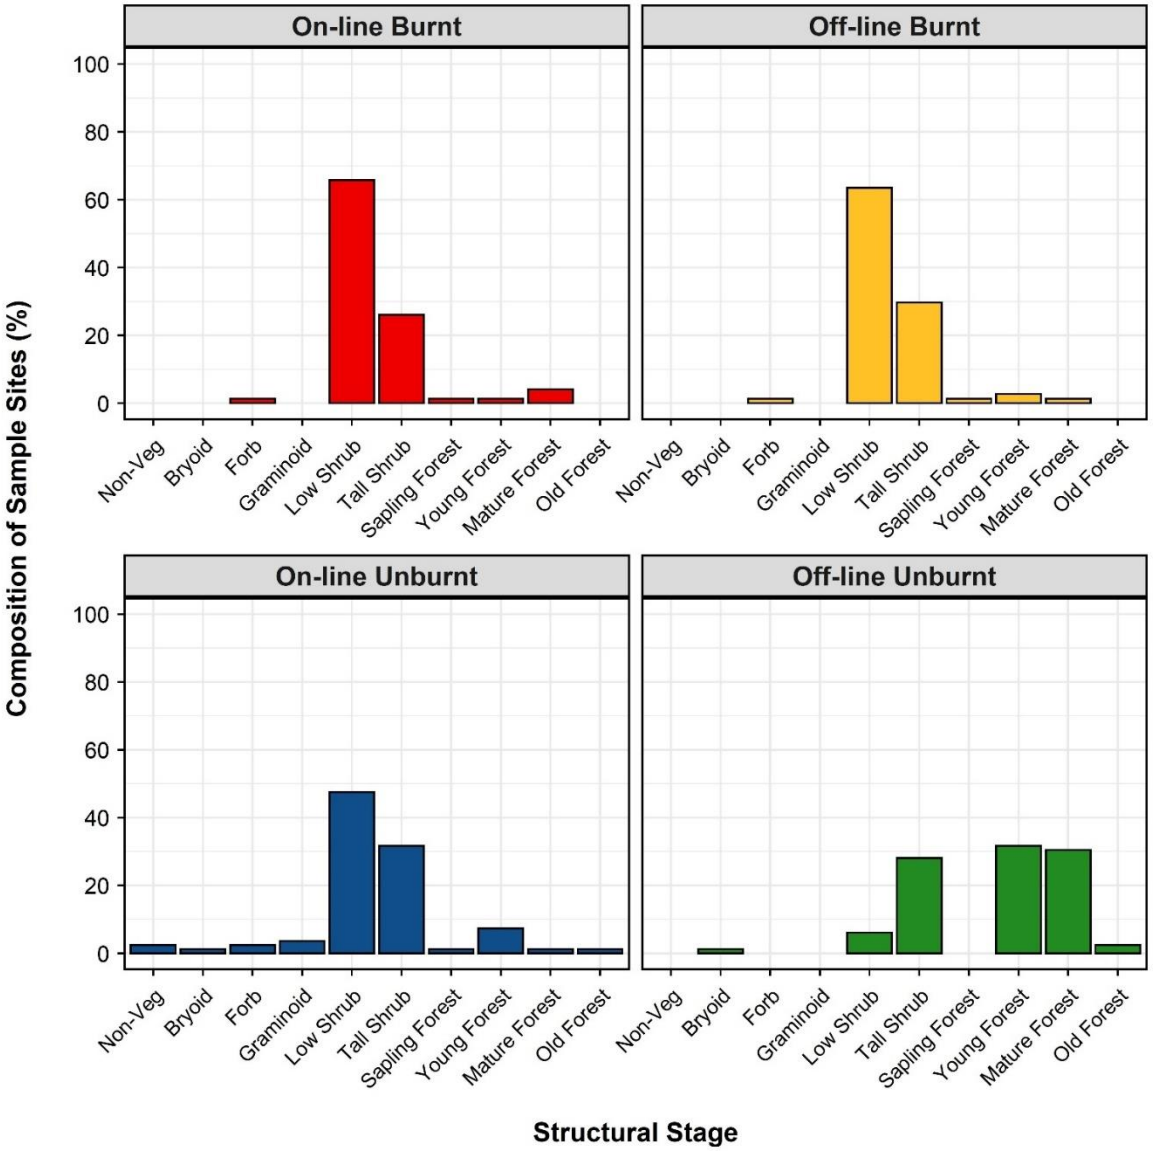

Figure 4-2. Comparison of structural stages on linear features to off-line plots in burnt and unburnt areas, in the Eagle Plains RSA.

4.2.6 VEGETATION HEIGHT

Based on the similarity of patterns in vegetation composition and structure, linear feature types were combined into two groups for assessment of patterns in height: (i) 2D and winter roads and (ii) 3D. A wide range of vegetation heights was recorded at both on-line and off-line plots in the RSA, from 0.3 m to 16 m. Collectively, off-line plots had a normal distribution of vegetation heights between 0 m and 4 m, and then a scattered distribution across heights up to 16 m (Figure 4-3). Plots with ≥4 m tall vegetation accounted for approximately 40% of all off-line reference plots.

In comparison, recovering 2D seismic lines and winter roads shared a relatively uniform distribution between 0 m and 4 m but with a peak occurring at vegetation heights measuring 1.5–2 m tall (Figure 4-4). Only 21% of 2D and winter roads contained dominant vegetation ≥4 m, and only 5% were ≥8 m tall. 3D seismic lines were rarely composed of vegetation ≥2 m, and most of the vegetation (67%) recovering on 3D lines was less than 1 m (Figure 4-5). This is very different from the off-line undisturbed height distribution. However, 3D lines were all only five years old at sampling, and shorter vegetation was expected.

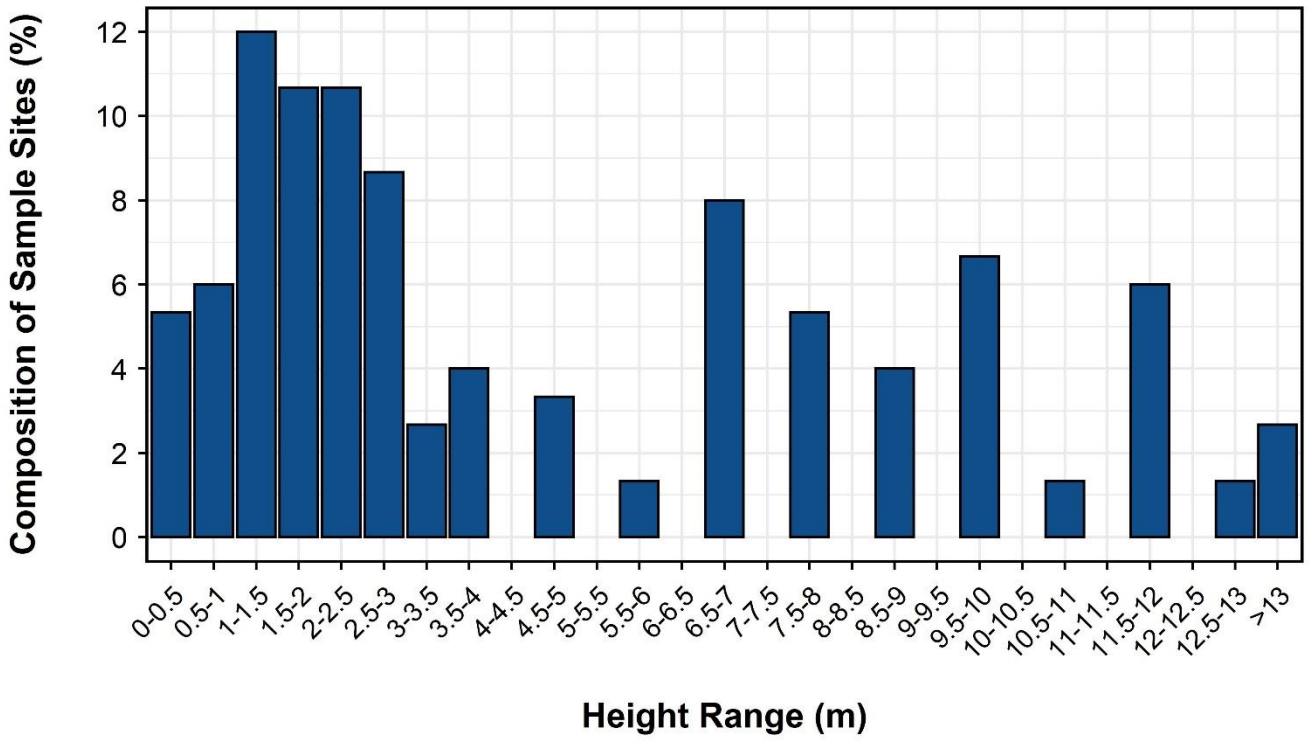

Figure 4-3. Vegetation height distribution of off-line reference plots in the Eagle Plains RSA.

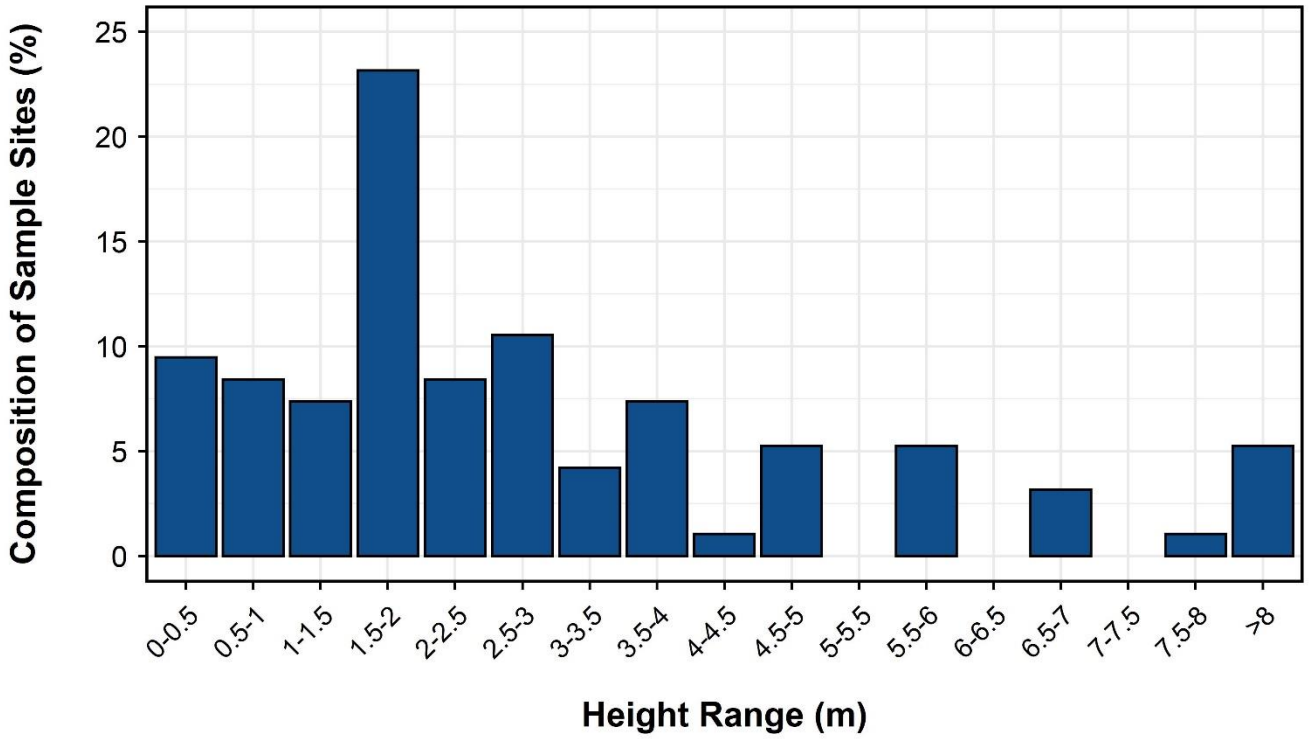

Figure 4-4. Vegetation height distribution of on-line 2D and winter road plots in the Eagle Plains RSA.

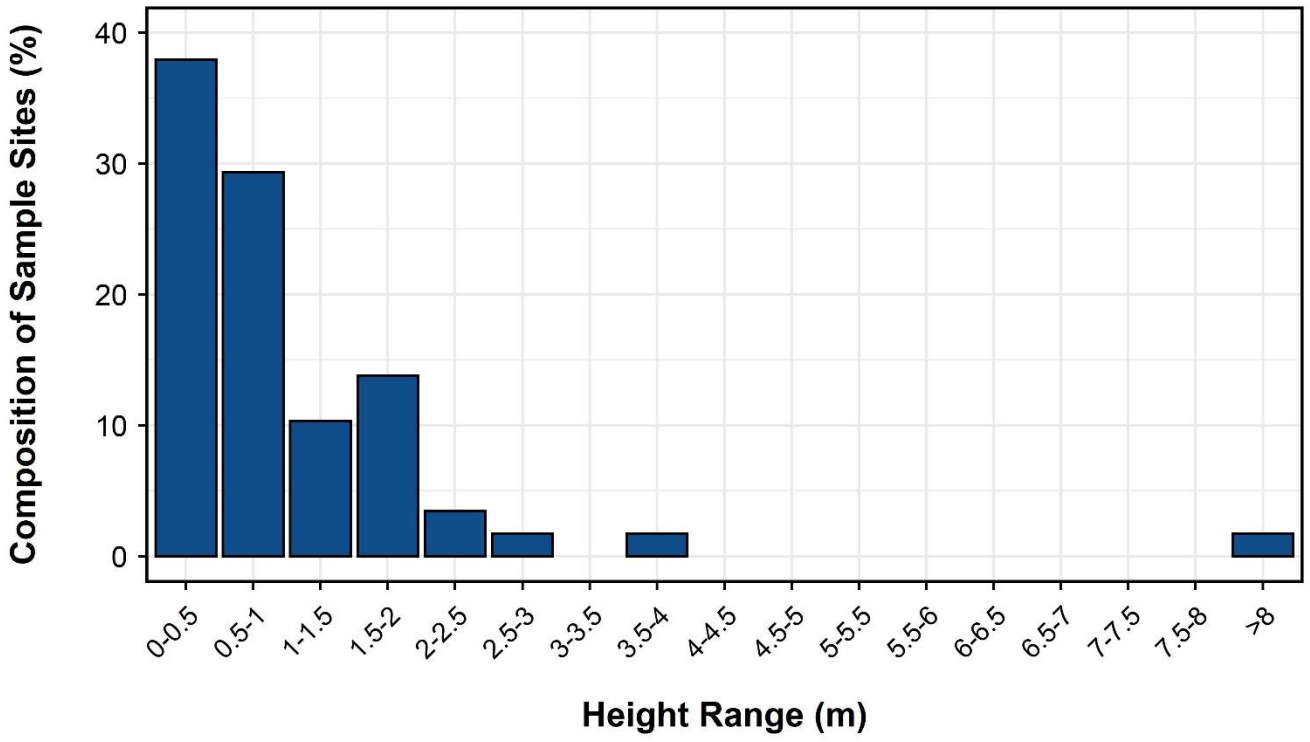

Figure 4-5. Vegetation height distribution of on-line 3D plots in the Eagle Plains RSA.

4.2.7 VEGETATION COVER

Tree and shrub cover varied between linear feature types and burn status (Table 4-6). Generally, tree cover was low on undisturbed reference plots (mean tree cover of 8% on unburnt and 2% on burnt sites). This is typical of the taiga cordillera landscape — forests are generally stunted and sparse due to poor nutrient regime and continuous permafrost conditions (Smith et al. 2004). Of the on-line plots, tree cover was greatest on 2D seismic lines and burnt winter roads (5% to 8%) and lowest on 3D seismic lines and the Dempster Highway (0%), regardless of burn status. This is likely due to the recently disturbed 3D seismic lines that are too young for trees to have re-established. Burnt 2D seismic lines and winter roads had greater tree cover than unburnt lines.

Shrub cover was much greater than tree cover overall. Shrub cover was typically 30–40% on unburnt off-line plots and 40–50% on burnt off-line plots. Shrub cover was highest on 2D seismic lines (~54%), regardless of burn status. Shrub cover was moderate on winter roads (38–45%) and lowest on unburnt 3D seismic lines (8–22%). Burnt 3D seismic lines had approximately twice as much shrub cover as unburnt 3D lines.

Table 4-6. Summary of the mean tree and shrub cover (%) between on-line and off-line, and burnt and unburnt plots surveyed in the Eagle Plains RSA.

Linear Feature Type	Burn Status	Mean Tree Cover (%)		Mean Shrub Cover (%)	
		On-line	Off-line	On-line	Off-line
2D	Burnt	7.0	3.5	54.0	36.0
	Unburnt	5.5	13.4	53.2	32.8
3D5	Burnt	0.0	0.3	41.7	60.0
	Unburnt	0.0	0.5	7.5	42.5
3Dc	Burnt	0.0	0.2	40.4	46.1
	Unburnt	0.4	6.0	21.5	34.3
3Dr	Burnt	0.0	0.7	35.0	51.9
	Unburnt	0.0	5.5	20.6	32.5
Winter Road	Burnt	7.7	1.0	45.0	43.8
	Unburnt	1.3	4.0	37.5	32.3
Dempster Highway	Unburnt	0.0	1.0	0.0	37.5

4.2.8 LINE-OF-SIGHT AND EASE OF TRAVEL

Line-of-sight (sightline) distance was examined primarily as a function of line type; however, vegetation height (the primary factor affecting sightlines) was also examined for on-line and off-line plots for each linear feature type using multiple linear regression. Mean sightlines varied significantly by linear feature type (Table 4-7, $F_{4,187} = 3.3$, $P = 0.01$). For reference, the average sightline distance for offline controls was 46.7 m. This relatively far distance reflects the open stand structure on most sites in the region. Burn status had little influence on sightlines (e.g., burnt off-line=50.2 m, unburnt offline=43.6 m). 2D lines had the shortest average sightline distances at 41.2 m. This was mainly due to the advanced stage of regenerating vegetation on the lines. Where regenerating vegetation was limited, sightline distances on 2D lines frequently exceeded 150 m.

On 3D lines, the time since clearing was too recent for regenerating vegetation to obscure sightlines. Instead, sightline distances on 3D lines were generally controlled by bends in the lines, which were specifically designed as mitigation measures to reduce sightlines. For 3D lines, sightline distances decreased from 3D5 to 3Dc to 3Dr lines. The reduction in sightline distances resulted from differences in line width and the average distance between bends across the feature types.

The regression analysis also found a significant interaction between on-line versus off-line occurrence and vegetation height ($F_{1,187}$ = 13.0, P = 0.0004), whereby on-line plots had, on average, more negative slopes than off-line plots. In other words, sightlines at on-line plots decreased more drastically than off-line plots with each incremental increase in vegetation height. This is consistent with the qualitative observations of field crews that the regenerating vegetation on lines was thicker than the vegetation off lines.

Similar to sightline distances, determining differences in ease of travel among line type the primary factor of interest for the walking speed tests. However, burn status, and the percent cover of trees and shrubs were expected to be the most important explanatory variables related to walk speeds, so they were included as secondary variables using a mixed-effects linear regression. Walking speeds across linear feature types and the differences between on- and off-line plots within linear feature types varied significantly (Table 4-8, $F_{5,170}$ = 3.4, P = 0.006). However, the magnitude of the difference between on-line and off-line plots was modest. Even the Dempster Highway only conveyed a 35% increase in walking speed over off-line plots. Other researchers, in other areas, often observed walk speeds on linear features were often at least twice as fast as off-line transects (Keim et al. 2019a).

Notwithstanding the modest magnitude of faster walking speeds on-lines, there were clear patterns in walking speed differences across linear feature types. 2D lines were the one feature type where walking speeds were slower on lines than off lines. This reflected the thick, shrub stage vegetation that had regenerated on most 2D lines, which impeded travel (similar to the effect that regenerating vegetation had on sightline distances in the previous section). Walk speeds decreased across the other feature types in relation to line width and the degree to which ground cover was levelled or compacted.

Statistical analyses indicated that both burn status ($F_{1,170}$ = 17.85, P < 0.0001) and percent cover of shrubs and trees (hereafter woody vegetation; $F_{5,170}$ = 5.29, P = 0.0002) affected walking speeds, both on and off lines. On average, walk speeds in burns were approximately 10% slower than in unburnt areas. This is partly related to thicker woody cover in most burns, which hinders walking speed because of the time it takes to push through or walk around it. Walking speeds significantly decreased, on average, by 0.04 (CI = 0.02–0.06) km/h and with every 10% increase in the percent of woody cover off-line and 0. 11 (0.07–0. 15) km/h on 2D lines.

Table 4-7. Average sightline distances along different linear feature types in the Eagle Plains RSA.

Linear Feature Type	n	Average Sightline Distance (m)	Comments
2D	30	41.2	Sightlines are frequently reduced by regenerating vegetation >1.5m tall
3D-5m	5	105.6	Has fewer bends than 3Dc and 3Dr
3D-Conductor	26	75.9	Sightlines limited by bends in lines; too recent for regenerating vegetation to impede sightlines
3D-Receiver	23	60.2	Sightlines limited by bends in lines; too recent for regenerating vegetation to impede sightlines
Dempster Highway	2	814.8	
Winter Road	17	106.2	
Off-Line Controls	103	46.7

3Dr	23	3.2	2.9	10%
Dempster Highway	2	5.6	4.1	35%
Winter Road	16	3.6	3.1	17%
Off-Line Controls	97	n/a	2.9	

4.3 VISIBILITY OF LINEAR FEATURES FROM THE DEMPSTER HIGHWAY

Overall, the blind search identified 11 of 100 possible linear feature intersections with the Dempster Highway (Table 4-9). Five of the features were roads that were classified as winter roads in the GIS inventory, but most (four) were actually short, all-season roads leading to gravel pits or well sites. Two of the observed features were human truck/OHV trails that led to camp sites 100–200 m off the Dempster Highway, and four were 3D seismic lines. The map search detected two more 3D lines, one 2D line, and one old winter road. The 2D line and the old winter road had regenerated into Young Forest structural stages. Excluding the four short secondary roads into gravel pits and well sites, and the two human trails, only 8% of linear features that intersected the Dempster Highway were visible during the two driving surveys.

Only 6 of the 74 3D lines that crossed the Dempster were detected. The combination of construction design (i.e., creating a bend in the 3D line adjacent to the highway) and regenerating vegetation in the right-of-way made it difficult to detect the 3D lines. Evidence of human use (e.g., packed vegetation, tire tracks, rutting, garbage, campfire remnants, tree stumps, or tree blazes) was observed on four of the short, all-season roads

and the two trails. No evidence of human use was noted on any of the 2D or 3D seismic lines, or the three winter roads (including the Chance and Blackie winter roads). However, some types of human use do not leave sign during the snow-free season (e.g., snowmobile use in the winter).

Table 4-9. Summary of linear features identified and intersecting the Dempster Highway during a blind search test.

Linear Feature Type	No. Features Intersecting the Dempster	No. (%) Observed Blind Search	No. (%) Observed Map Search	Total No. (%) Observed	OHV Accessible	Sign of Human Use
2D	18	0 (0%)	1 (6%)	1 (6%)	0	0
3D	74	4 (5%)	2 (5%)	6 (8%)	4	0
Secondary Roads	8	5 (63%)	1 (13%)	6 (75%)	5	4
Trail	n/a	2 (n/a)		2	2	2
Total	100	11 (11%)	4 (4%)	15 (15%)	11	6

4.4 WINTER TRACKS

In total, 462 linear features were surveyed for winter tracks over 358 km along the 11 transects. No human sign was observed on any linear features, except the Dempster Highway. Ungulate tracks were frequently observed travelling along linear features. The proportion of linear features with tracks decreased with decreasing linear feature widths, from 29% on winter roads, 24% on 2D lines, 8% on 3D conductor lines, and 6% on 3D receiver lines (Figure 4-6).

The frequency of use in adjacent undisturbed areas, corrected to account for different survey extents between the linear features and the undisturbed areas, was 1%. As discussed in the methods, it was difficult to compare the frequency of use along linear features to use in undisturbed areas. The issue is that for the comparison to be relevant, the survey design needs to account for the size of the sample units (i.e., the extent of the undisturbed area needs to be comparable to the width of the linear features), and the two samples should be independent. These conditions were not achieved under the current survey design (i.e., the extent of the survey area in the undisturbed area was much larger than the width of the linear feature, and the location of the undisturbed area was spatially correlated to the linear feature). The estimated relative use rate of 1% in undisturbed areas adjusts the total counts within the 200 m survey area to 5 m (i.e., the average linear feature width); however, the adjustment fails to account for spatial correlation between the two samples. Therefore, the estimate of use in undisturbed areas could be biased. Notwithstanding this limitation in the estimate of travel rates in undisturbed areas, it is supported by qualitative observations of the survey crew that travel rates on even the least used linear features (i.e., 3D lines) are higher than undisturbed areas.

The relative use of linear features by ungulates also appeared to vary with distance from the Dempster Highway, with features within 1 km of the highway receiving lower use than features equal to or greater than 5 km from the highway (Figure 4-7). It is worth noting that the Highway and 1 km transects were completed on the first and second day of surveys, respectively, and the other transects were surveyed one to six days later, providing more time for tracks to accumulate. Snowfall data prior to the crew's arrival on site was not

available; however, road crews at Eagle Plains reported that there had not been a major snowfall in the area for at least a week. Based on this information, the issue of time since last snow has less potential to bias results than if a track-erasing snow event had recently occurred.

Off-line Controls	N/A	46.67	2.95	N/A	N/A	N/A	N/A	N/S

[1] as characterized by reaching a tall shrub stage, or greater.
[2] including stagnated and disturbed successional patterns.
[3] accounting for burns, natural openings, and regeneration.
[4] percent of lines with ungulate tracks during March 2020.

2D Seismic — 2D lines are, on average, the oldest features in the area and have had the longest time to regenerate. Most features were cleared before 1985, but some were developed in the early 2000s. Historical 2D lines were generally long and straight, with moderate widths of 4–8 m. Lines were typically constructed with bulldozers that cut into the moss layer and often included some patches of soil disturbance. The combination of site disturbance and wider widths generally resulted in a successional reset to pioneering vegetation (including early seral graminoids, forbs, and shrubs). Most sites were following a normal successional pathway (73%). However, 27% of sites exhibited atypical pathways, dominated by magnified succession (21%, mostly in burns), stagnated succession (3%) or no succession (1%). Sixty-one percent of the 2D sites had regenerated to a Tall Shrub or more advanced structural stage. 2D lines had the shortest sightlines and slowest walk test speeds of all feature types (including off-line controls), reflecting the regenerating vegetation's effect on these functional metrics. During winter, ungulates regularly used 2D lines to travel along.

3D Seismic — All 3D lines were created during the last exploration period, during the winter of 2013/14. 3D lines constitute the most extensive combined lengths of the different linear feature types, but their areal extent is limited to a relatively small portion of the RSA along the Dempster Highway. Due to their basic design, as well as specific mitigations, 3D lines minimize environmental effects compared to other linear feature types. They are narrow (averaging 3.2 m and 2.0 m for conductor and receiver, respectively), often

narrower than average tree spacing in the region. They were constructed during winter, over snow, using low-ground pressure equipment, which avoids ground disturbance and maintains vegetation in the moss, herb and low shrub layers. The lines were constructed with a meandering path, and strategically placed sharp angle dogleg bends to reduce the visibility of the lines from roads, reduce sightlines along them, and hamper travel by OHVs. All 3D lines that were surveyed were undergoing a normal successional pathway and were dominated by the same vegetation as in adjacent undisturbed areas. Regenerating vegetation was mostly in a Low Shrub structural stage, consistent with the relatively short six-year period since they were cleared. Sightlines and movement speeds were intermediate compared to other linear feature types, with sightlines primarily controlled by dogleg bends purposely designed to reduce sightline distances. Ungulates occasionally used 3D lines to travel on in winter, but at less than a third of the rate as 2D lines and winter roads.

Winter Roads — A network of winter roads across much of the RSA results from the historical exploration programs that have occurred. Although many of the winter roads were initially developed during the earliest exploration programs, vegetation has not had the same opportunity to regenerate as on 2D lines because the vegetation was re-cleared on several roads during subsequent exploration programs. The average width of winter roads was 7.4 m, but major roads, like the Chance road, were often 10–12 m wide. Historical winter roads were typically cleared with a bulldozer, and then snow was packed and graded to create a road surface. Similar to historical 2D seismic, the combination of site disturbance and wider widths (i.e., that increases solar exposure) generally resulted in a successional reset to pioneering vegetation (including early seral graminoids, forbs, and shrubs). Most sites were following a normal successional pathway (72%), but 26% of sites exhibited atypical pathways, dominated by stagnated succession (19%), magnified succession (6%) and no succession (1%); 2% of the sites were classified as no disturbance (indistinguishable from vegetation community off the road). Thirty-nine percent of the winter road sites had regenerated to a Tall Shrub or older structural stages. Winter roads had the longest sightlines and fastest walk test speeds of all feature types, other than the Dempster Highway, reflecting the variable levels of regenerating vegetation that occurred on winter roads. During winter, ungulates regularly used 2D lines for travel.

Dempster Highway — The Dempster Highway is the only all-season road in the RSA (except for short spurs off the Dempster to well sites and gravel pits). It is fundamentally different from all other linear features in the area in terms of wide width, surface material and maintenance, long sightlines, regular traffic, and base of access for human land use activities such as hunting, camping, and trapping.

5.2 LINEAR FEATURE CHARACTERISTICS

5.2.1 FIRE

The presence or absence of recent forest fires affected several linear feature characteristics, including linear feature width, successional class, structural stage, and vegetation height and cover. Mean measured linear features widths were 0.2–0.6 m wider at burnt sites than at unburnt sites. This may be due to the already shorter vegetation at burnt sites, which would reduce overgrowth occurring from forest edges and decrease the measured width between driplines (branches extending into the linear feature from either side of the line).

Magnified succession was nearly four times more common in burnt plots than unburnt plots, and stagnated succession was half as common. Fire likely facilitates magnified succession by increasing soil temperatures, accelerating decomposition, and releasing stored water and nutrients to promote vegetation growth (Seccombe-Hett and Walker-Larsen 2004, Simpson 2008). Stagnated succession is likely less common at burnt sites because the associated nutrient and water increase allows woody plant species to colonize more easily and advance through successional stages.

Overall structural stage distribution was very similar between burnt on-line and off-line plots, but was markedly different between unburnt on-line and off-line plots. Furthermore, when the structural stages were compared between paired on-line and off-line plots, they matched two to four times more frequently at burnt sites than at unburnt sites and were mismatched two to six more frequently at unburnt sites than at burnt sites. Nearly all burnt plots were in a low shrub, or tall shrub structural stage, which is expected as fires tend to remove overstory trees, and shrubs generally colonize rapidly post-fire (Seccombe-Hett and Walker-Larsen 2004).

Vegetation height was 4.4 m shorter in burnt than unburnt reference plots, and tree cover was approximately 6% less. These modest differences reflect the stunted and open nature of the taiga forest. There was little change in vegetation height between burnt and unburnt linear features, likely because there were very few linear disturbances in a forested structural stage; most of them, even in unburnt conditions, were already in a shrub-dominated stage due to the clearing of trees. For shrub cover, except for 2D seismic lines, the mean was approximately 10% to 20% greater at burnt plots than at unburnt plots. The increase in shrub cover at burnt sites was most prominent in 3D seismic lines due to their comparatively lower pre-fire shrub cover.

Post-burn vegetation was, on average, shorter and shrubbier than unburnt off-line plots, but taller and shrubbier than unburnt on-line plots. Furthermore, burnt paired plots were more similar in vegetation characteristics than unburnt paired plots. This evidence supports the theory that forest fires in taiga ecosystems resets the landscape to some extent and effectively erase signs of anthropogenic disturbance (Seccombe-Hett and Walker-Larsen 2004, Simpson 2008). Forest fire in the taiga returns ecosystems to an early successional stage (i.e., low shrub) and synchronizes baseline biophysical conditions on a landscape scale, allowing previously disturbed and undisturbed areas to recover at equal rates, as has been documented by Seccombe-Hett and Walker-Larsen (2004). Thus, most linear features that have experienced forest fires no longer create different ecological conditions or functional disturbances than the surrounding landscape.

5.2.2 SUCCESSIONAL CLASS

The idea that vegetation regeneration on linear features could follow different successional trajectories came out of work by the Yukon Government in the early 2000s (Simpson 2008). That work described six successional trajectory classes observed in the Eagle Plains area. However, that study did not quantify the relative extents of linear features that followed the different trajectories. This study used the classes that the Yukon Government work developed and quantified the proportion of linear features in each successional class across a random sample of linear features.

Successional classes in the Eagle Plains RSA varied according to linear feature type and burn status. However, one of the key findings was that normal succession was the dominant trajectory observed for all linear features except the Dempster Highway. All 3D seismic lines followed a normal successional trajectory, except for one recently disturbed site. This was likely attributable to the low impact methods used in 3D line creation that minimize ground and vegetation disturbance, creating conditions more likely to result in a normal successional trajectory (Yukon Energy Mines and Resources 2006, Golder Associates 2016). Magnified and stagnated succession were only observed in 2D seismic lines and winter roads. These linear features were generally wider and were created using methods that cause greater disturbance to soils, hydrology, and vegetation, leading to these alternative successional trajectories (Simpson 2008, Jorgenson et al. 2010, Dabros et al. 2018). Magnified succession is unique among the classes in that it results in accelerated vegetation regeneration. Magnified succession was most common on burned 2D seismic lines where the combination of site disturbance associated with the 2D lines and fire is suspected of causing accelerated soil warming, moisture availability, and nutrient flush, which increase on-line vegetation growth (Simpson 2008). Successional stagnation was most common on unburnt winter roads. Stagnation tends to occur on features that have experienced ground disturbance or have been seeded to agronomic species, which may have happened on winter roads in the RSA (Simpson 2008). Repeated disturbance associated with multiple exploration programs over time may also limit successional advancement and contribute to successional stagnation (Lee and Boutin 2006, Jorgenson et al. 2010).

Although some alternative successional pathways were observed in this study, most linear features in the Eagle Plains RSA are following a normal successional trajectory. This implies that most of these disturbances will recover to an ecological condition like that of the surrounding community with adequate time.

5.2.3 STRUCTURAL STAGE

The taiga forest in Eagle Plains presents a unique situation where the Tall Shrub stage is applied to two very different stand conditions. One condition, the more traditional, is of regenerating stands following a natural or anthropogenic disturbance. In this setting, the vegetation consists of deciduous shrubs and 2–8 m tall, 10–30 years old trees. The stage is transitional, with the vegetation expected to advance to the Pole-Sapling stage over time. The second condition where the Tall Shrub stage is applied is to stunted, old, black spruce stands in a disclimax state. In this setting, the vegetation consists of open, stunted, black spruce stands that are typically ≥50 years old and 2–8 m tall. Stands in this condition are expected to remain in the same condition over time(i.e., a disclimax state). Structurally, the stunted black spruce trees function more like shrubs than trees. Both Tall Shrub conditions (referred to as disturbance and disclimax forms hereafter) are widespread across the RSA in off-line sites. Only the disturbance form was observed on linear features.

The structural stage on linear features was predominantly Low Shrub or Tall Shrub, determined mainly by the time since line clearing and burn status. Less than 4% of surveyed features were in forested stages (Pole-Sapling or greater). Off-line plots had a higher proportion of forested structural stages (37%). However, they were still predominantly Low Shrub and Tall Shrub, resulting from extensive burns across the RSA and large extents in the disclimax form for Tall Shrub in un-burned areas.

The structural stage of on-line plots was also influenced by successional class. The small number of forested structural stages observed on features only occurred on sites undergoing normal succession. Stagnated succession was associated with only the Herb structural stage, which was expected as stagnation is defined by its high herbaceous species cover (among other factors) that limits the establishment of other structural groups. Magnified succession was the one atypical successional class with accelerated vegetation growth. Most structural stages on sites with magnified succession were in Tall Shrub and, occasionally, Pole/Sapling. Often the structural stage on magnified succession sites was one stage greater than the off-line plot.

5.2.4 VEGETATION HEIGHT

This study observed a range of vegetation heights across different feature types. Except for the 3D lines, the linear features' age was unknown, so it was impossible to estimate growth rates. Although some regenerating vegetation on 2D seismic lines and winter roads reached 8 m high, most were between 1.5 m and 2 m. Though the ages of specific features were mostly unknown, the minimum age for most was at least 35 years. Having most vegetation heights at only 1.5–2.0 m after this long period suggests regeneration growth rates on linear features may be quite slow. This pattern of slow vegetation growth on linear features may partly reflect the generally poor growing conditions in the taiga region. Still, it is also a pattern that has been observed on linear features in other studies in the southern boreal forest.

Interestingly, the vegetation heights on linear features in Eagle Plains are greater than reported in several other studies. For example, approximately 65% of sites on linear features in northeast Alberta had not advanced beyond a cover low forbs after 35 years (Lee and Boutin 2006). Key factors that have been linked to slow vegetation regeneration on linear features were continued human disturbance (e.g., OHV travel), ecosystem type (bogs and fens regenerated much slower than upland sites), competition from early seral and invasive graminoids and forbs, and soil or site degradation associated with feature construction (Lee and Boutin 2006, van Rensen et al. 2015, Finnegan et al. 2018).

There is limited data on vegetation regeneration in the taiga. A study from NWT found that vegetation regeneration on conventional seismic lines was affected by both a time lag for seedling establishment (as long as 17 years for black spruce) and slow growth rates (83 years to reach 5 m) (Seccombe-Hett and Walker-Larsen 2004). In burned areas, the seedling establishment delay was reduced to five years.

Although the 3D lines in Eagle Plains were only six years old when they were surveyed, a combination of field survey results and information from other studies suggests that vegetation recovery on 3D lines could be much faster than the previous examples for conventional 2D lines. This is because the undisturbed ground conditions and maintenance of the vegetation community in the moss, forb and low shrub layer provide both plants and growing conditions that support faster shrub and tree growth compared to sites beginning primary succession. In northeast British Columbia, Golder Associates (2016) found that in the first year following 3D seismic line creation, there were already black spruce seedlings exceeding 0.5 m in height. These seedlings were plants that were initially present on the site and that had survived line clearing. This is consistent with the results of this study, where nearly all of the 3D plots contained black spruce seedlings. Despite their relatively young age, most 3D seismic lines in Eagle Plains included shrubs and trees between 0.5 m and 1 m

tall. Although growth rates in Eagle Plains are not known, similar species that occur in Eagle Plains were observed to grow 5–10 cm per year on 3D lines in the boreal forest in northeastern British Columbia (Golder Associates 2016). If similar growth rates occur in Eagle Plains, regeneration on the 3D lines can be 2 m over the next 5–20 years.

5.3 HUMAN USE AND ACCESS ALONG LINEAR FEATURES

The NYRLUP and the PWRLUP indicate that one of the primary concerns about linear features is that they can increase human access into remote areas. This has been demonstrated in southern regions, and that access can have secondary effects of inhibiting vegetation regeneration (Lee and Boutin 2006) and, in winter, packing snow that can affect predator-prey dynamics (Latham et al. 2011, McKenzie et al. 2012, Keim et al. 2019a). In the boreal forest in northern Alberta, OHV travel was common on most conventional 2D seismic lines. After 35 years, approximately 20% of the lines were considered to have been converted to tracked access routes (Lee and Boutin 2006). In the same study, about 65% of the lines remained cleared after 35 years, and OHV use along the lines was identified as one factor contributing to the lack of vegetation regeneration. In contrast, there is little evidence of human use along linear features in the Eagle Plains RSA. No sign of human use was detected along linear features during the summer ground surveys (e.g., OHV tracks, ruts, water crossings, vegetation trampling/scarring, tree blazes, trap sets, garbage, campsites, etc.) or the winter track survey (e.g., snowmobile tracks). Although these surveys provided limited snapshots in time, and that some types of human activity leave little sign (e.g., evidence of snowmobile tracks have limited persistence during winter and leave no sign behind after snow melt), the results suggest that human use of the area is very limited outside of the Dempster Highway corridor. This is consistent with general comments from highway workers, staff at the Eagle Plains Hotel, pilots, and some First Nation residents that most areas beyond the Dempster Highway corridor receive very little human use. Specific instances of use of the area outside the Dempster Highway corridor include intermittent activity on the community trapline that occurs in Eagle Plains and occasional forays by hunters (First Nation and non-First Nation), mostly in winter.

People's limited use of the Eagle Plains area is likely due to its far distance from any human settlements and the difficulty of travel off the Dempster Highway. The network of winter roads in the area does provide access via specific types of OHVs in summer and snowmobiles in winter. However, there was no evidence observed that this occurs regularly. Travel along seismic lines, though possible in specific locations, would be hampered over any substantial distance by vegetation regeneration along the historical 2D lines, the narrow widths of and frequent dogleg bends in 3D lines and, during summer, difficult terrain (extensive peatlands and graminoid tussocks).

5.3.1 EFFECTIVENESS OF MITIGATION MEASURES FOR 3D SEISMIC LINES

In addition to the narrow widths of 3D lines, which hampers OHV travel, the 3D lines included regular bends in the lines, which were designed to limit the visibility of the lines at intersections with roads and other seismic lines, and to hamper OHV along the lines further. The driving survey along the Dempster found that this mitigation was very effective in reducing the visibility of the 3D lines from the road (i.e., only 6 of the 74 3D

lines intersecting the Dempster Highway were visible). Incidental observations during ground surveys observed similarly reduced visibility of 3D lines crossing winter roads. Regular bends in the 3D lines away from roads were also designed to limit human access by reducing sightlines and making travel more difficult along the line (i.e., needing to reduce speed to navigate the tight turns of a dogleg bend approximately every 70 m).

5.4 FUNCTIONAL CHARACTERISTICS OF LINEAR FEATURES

In addition to human travel, linear features can also affect how wildlife move within a landscape. Several studies in western Canada have documented the effects of linear features on the movements and population dynamics of large mammals, such as caribou, moose, deer, wolves and bears (Latham et al. 2011, McKenzie et al. 2012, Dickie et al. 2017b, Keim et al. 2019a). EDI focused on two established indicators of human and wildlife access and travel on linear features: sightline distance and ease of travel. These measurements act as a proxy for the functional recovery of disturbed areas. They are mainly dependent on vegetation height, cover, and terrain.

5.4.1 LINE-OF-SIGHT

Line-of-sight or sightline distance is how far one can see under normal conditions and was compared between linear features and paired reference plots. It has been proposed that humans and predators select linear disturbances because it is easier to travel and detect prey using those features (Finnegan et al. 2018). As vegetation grows taller and denser, sightlines diminish, and the use of linear features decreases (e.g., for wolves, Dickie et al. 2017a). This study found that average sightlines were farther on-line versus off-line for most linear feature types, but that sightlines varied substantially across line types. Sightlines were shorter on seismic lines than on roads, especially 2D lines which had more advanced vegetation regeneration than other feature types. On 3D lines, sightlines averaged approximately 30 m farther on lines than off lines. However, this difference probably provides little advantage to predators or human hunters because the increase is still within the olfactory and auditory detection zone for most large prey species. Average sightlines were 60 m farther on winter roads than surrounding forest, which may begin to confer more advantage to predators and hunters.

The range of sightlines observed on most linear features probably do not provide an advantage to detect prey species visually. For 2D lines and winter roads, sightline distances were primarily driven by the height and density of regenerating vegetation. The recovery period for 2D seismic lines appears to be sufficient to support vegetation that reduces visibility to a similar level as the surrounding habitats. The reason for longer sightlines on winter roads is that they are subject to intermittent re-activation, where the vegetation is cleared once again, which resets vegetation recovery and maintains longer sightlines. In contrast to 2D lines and winter roads, where sightlines were largely determined by vegetation regeneration, the sightlines on 3D lines were presently limited by the bends purposely constructed into the lines. Sightlines along all feature types will continue to diminish over time as vegetation regeneration continues.

5.4.2 EASE OF TRAVEL

Ease of travel is a fundamental indicator of functional recovery of linear features. Wolves, bears, and humans have been documented to select linear features with greater ease of travel, which is generally associated with lower and more sparse vegetation and stable, even terrain (Dickie et al. 2017b, Keim et al. 2019a). Access and travel resistance are the main determinants of predator and human use of linear features and the key concern of linear disturbances in the RSA (Vuntut Gwitchin Government and Yukon Government 2009, Peel Watershed Planning Commission 2019).

The walk test used in this study, as an index of ease of travel, found differences among linear feature types and between linear features and controls. However, the magnitude of the differences for both comparisons was modest. Even the Dempster Highway only conveyed a 35% increase in walking speed over off-line plots. Other researchers, in other areas, often observed walk speeds on linear features were often at least twice as fast as off-line transects (Keim et al. 2019a). Two conditions associated with the Eagle Plains area appear to limit the advantage of travelling on linear features. One is that the vegetation in most ecosites and structural stages is relatively open and has a limited effect on impeding movement. The second factor is that ground conditions limiting movement, including soft, thick peat and graminoid tussocks, were similar on both on-line and off-line plots for most linear feature types.

Notwithstanding the modest magnitude of faster walking speeds on-lines, there were clear patterns in walking speed differences across linear feature types. 2D lines were the one feature type where walking speeds were slower on lines than off lines. This reflected the thick, shrub stage vegetation that had regenerated on most 2D lines, which impeded travel (similar to the effect that regenerating vegetation had on sightline distances in the previous section). Walk speeds decreased across the other feature types in relation to line width and the degree to which ground cover was levelled or compacted. 3D seismic lines allowed slightly easier travel than paired off-line plots. They usually had lower vegetation cover and clearer route selection. As linear feature width decreased in 3D lines, walking speed also decreased. This implies that width may be related to functional recovery, with narrower lines having smaller impacts than wider lines, even within an already narrow linear feature type. Although ease of travel was greater in 3D seismic lines than surrounding community, it is expected that this will decrease in future years as vegetation increases in height and density.

5.5 FUNCTIONAL RECOVERY OF LINEAR FEATURES

Functional disturbance is defined in the NYRLUP and PWRLUP as "*physical land use disturbance that results in disruption of soil or hydrology, or that requires the cutting of trees*." One of the main concerns with linear disturbances under these land use plans is that such features can technically allow increased access to previously remote areas, potentially leading to a greater harvest of wildlife and fish, higher predation rates, and a change in how people and wildlife use the land (Vuntut Gwitchin Government and Yukon Government 2009). A disturbance can be considered functionally recovered and subtracted from the overall linear density when it no longer facilitates access or travel by humans or wildlife (Vuntut Gwitchin Government and Yukon Government 2009), or otherwise no longer functions as a surface disturbance (Peel Watershed Planning Commission 2019). Both plans use 1.5 m vegetation height as a threshold for functional recovery in forested communities. The

PWRLUP includes the following additional criterion for recovery "*in non-forested areas (dominated by vegetation under 1.5 m), when the disturbed area is covered by native species roughly the same height and composition as the surrounding dominant vegetation*" (Peel Watershed Planning Commission 2019):

One limitation of using height alone as a functional recovery criterion is that it does not consider vegetation density. Although regeneration may meet the recommended height criteria, if it is very sparse (as is often the case in the Eagle Plains Ecoregion), it may still facilitate access and travel by humans and wildlife. Attachment Photo A-25 provides an example in the Eagle Plains RSA where tall but sparse regeneration meets the 1.5 m criteria but does not inhibit access or travel.

The combined results of this study indicate that using regeneration to the Tall Shrub structural stage may be a more appropriate criterion for functional recovery. Attachment Photo A-3 and Attachment Photo A-10 provide examples of linear features that have regenerated to a tall shrub structural stage. Using the Tall Shrub criterion, 38% of all linear features in the RSA would be considered functionally recovered compared to 53% using the 1.5 m height criterion. For this study, the more conservative criterion of reaching the Tall Shrub structural stage was used to adjust (reduce) linear feature densities.

5.6 LINEAR FEATURE INVENTORY AND DENSITY

This study was successful in mapping all linear features within the RSA. The combined results of the mapping exercise and the field studies found that the extent of open habitats (burns and naturally open habitats like wetlands and shrublands), and the degree of vegetation regeneration, played a significant role in the effective density of linear features across the RSA. Before accounting for open areas and regeneration, the total linear feature density was 1.79 km/km². After accounting for open areas and vegetation regeneration (to the Tall Shrub structural stage), the effective linear feature density was 0.52 km/km². The NYRLUP and PWRLUP suggest cautionary levels for linear density of 0.75 km/km² and critical levels of 1.0 km/km² (Vuntut Gwitchin Government and Yukon Government 2009, Peel Watershed Planning Commission 2019).

The Yukon Land Use Planning Council (YLUPC) was conducting a pilot study of surface disturbance across the broader Eagle Plains Ecoregion (Skinner 2021) at the same time as this study. The methods they used consisted of mapping and attributing human-caused disturbances solely using high-resolution satellite imagery. The YLUPC classified vegetation into eight broad classes based on whether the surrounding area was forested or non-forested, the similarity of vegetation on-line to off-line, and the presence or absence of woody cover (i.e., shrubs or trees). The features were then classified as recovered or not-recovered based on the presence of woody cover (recovered) or, if woody cover was not present, the similarity to surrounding vegetation (i.e., if similar then recovered, if not similar, then not-recovered). Historical field data and photographs from the area (Simpson 2008) were used to verify interpretations.

The spatial data from the YLUPC work was not available to compare in detail to the linear feature inventory compiled in this study. However, the mapping linework is expected to be very similar because satellite imagery was used to verify and supplement the linear feature geospatial data compiled in this study (presumably the same satellite imagery that YLUPC used because the imagery was obtained from Yukon Geomatics). One

difference between the two products is that the YLUPC completed the inventory for the entire Eagle Plains Ecoregion, while this study was restricted to the RSA. Another difference is that the attribute data in this study is expected to be more detailed and more precise than the YLUPC data because (i) the original geospatial data includes some information, like date of creation, that would be impossible to estimate from imagery, and (ii) because this study linked field surveys to the mapping exercise to determine line widths and other characteristics more precisely.

Although it is impossible to directly compare the linear feature density estimates between the two studies, due to the different study extents, the general pattern of results is similar. The YLUPC estimated the linear density (accounting for recovery) to be 0.38 km/km² across the entire Eagle Plains Ecoregion. This is consistent with the estimate from this study for the RSA of 0.52 km/km² because the portion of the Ecoregion outside the RSA has lower linear feature density than the RSA.

6 CONCLUSION

This study successfully mapped all linear features within the RSA and measured a suite of structural, vegetation, and functional characteristics across different feature types. Generally, the effects associated with linear features (i.e., differences between conditions on-line and adjacent off-line areas) correlated to feature width and the degree of ground disturbance. In terms of combined effects across the range of feature types that occur in the Eagle Plains RSA, the ranks were:

Dempster Highway >>> Winter Roads > 2D Seismic > 3D-5m >> 3D Conductor > 3D Receiver[2]

The effects of 3D lines (both conductor and receiver lines) appear to be substantially lower than other feature types. This reduced magnitude of effects is important because 3D lines have the longest combined length of exiting linear features. They are also the predominant feature planned for the next exploration program. Important findings for 3D lines include:

- Relatively narrow line widths of 2–3 m are often smaller than natural tree spacing and minimize the potential for changes to microsite conditions (e.g., solar radiation, air and ground moisture) reported in other studies.
- Minimal ground disturbance and maintenance of the moss, herb, and low shrub layers, which retains the natural vegetation community and accelerates vegetation regeneration.
- Successful application of mitigations, notably dogleg bends that minimize sightlines, ease of human travel, and visibility of lines from roads.
- Ungulate use of 3D lines in winter was less than a third of the rate observed on 2D lines and winter roads.

The adverse effects of linear features in other areas are often caused or exacerbated by human use after the lines are initially constructed, including effects on vegetation regeneration and predator-prey dynamics. Human use does not appear to be a significant factor in Eagle Plains. No sign of human use was observed outside the Dempster Highway corridor.

Substantial vegetation regeneration has occurred on existing features in the Eagle Plains RSA. Previous work by the Yukon Government identified the potential for atypical successional trajectories to occur on linear features in the region. Although atypical succession occurred to a limited extent, this study determined that 81% of the sites exhibited a normal succession (100% on 3D lines). Only 5% exhibited inhibited regeneration trajectories (mostly stagnated succession on winter roads). Regarding functional recovery, 53% of sites met the NYRLUP and PWRLUP criterion of vegetation reaching 1.5 m, and 38% of sites met the criterion of attaining a Tall Shrub structural stage. Using the Tall Shrub structural stage as a criterion of functional recovery may be a more ecologically appropriate criterion to meet LUP objectives.

The extent of open habitats (e.g., burns, wetlands and shrublands) and the degree of regeneration on existing linear features (mostly the older 2D lines and winter roads) play an important role in calculating effective linear

[2] Relative magnitudes of effects: >>> large effect, >> moderate effect, > small effect.

feature density in the RSA. Before accounting for open areas and regeneration, the total linear feature density was 1.79 km/km². After accounting for open areas and vegetation regeneration (to the Tall Shrub structural stage), the effective linear feature density was 0.52 km/km².

EXECUTIVE SUMMARY

The Eagle Plains Project (the Project) is an oil and gas exploration program in north-central Yukon, approximately 605 km north of Whitehorse along the Dempster Highway. Chance Oil and Gas Ltd. intends to conduct exploratory activities over a 10-year period to confirm the quality, quantity, and areal extent of hydrocarbons. Project activities will include seismic exploration and exploratory wells supported by an expanded winter road network.

The Project's Regional Study Area (RSA) is approximately 2,400 km² and is spatially bounded by the Peel River and Ogilvie River to the south and the northern reaches of Chance Creek to the north. The Project is within the Eagle Plains ecoregion, an intermontane basin underlain by sedimentary rock. The regional land cover comprises subarctic coniferous forest with mixed forest and arctic/alpine tundra while also lying within a continuous permafrost zone.

For the Project to proceed, it must be evaluated under the *Yukon Environment and Socio-Economic Assessment Act*, which requires baseline wildlife information. As such, wildlife baseline studies were conducted to provide information about birds, American marten, grizzly bear, moose, and caribou to meet the information requirements to support a project proposal to the Yukon Environmental and Socio-economic Assessment Board. The following subsections provide an executive summary of each baseline study completed for the Project.

Birds

The purpose of the birds baseline study was to document the potential occurrence, relative abundance, and habitat associations of birds across the Project's RSA. This study consisted of a combination of a desktop assessment and field surveys. The desktop assessment included identifying ecosystem units across the RSA using predictive ecosystem mapping, collecting, and cleaning historic bird survey data in the broader area, and developing a comprehensive list of bird species with the potential for occurrence based on range and habitat requirements. Two types of field surveys were conducted, each targeted at broad habitat associations in the Project area: point count surveys (transects for terrestrial habitats) and wetland/pond surveys. The survey design followed a targeted, stratified habitat design to provide representative survey coverage across the range of habitat types that occur in the RSA. Point count stations were established along walking transects for efficient survey implementation, and sites were selected using a targeted, stratified habitat design. Ecosystem units for predictive ecosystem mapping were reclassified with field data to produce 32 ecosystem units that captured site-specific differences in vegetation. An average of 23 survey stations were located in each ecosystem unit, with a minimum of eight stations in uncommon habitats. Field surveys were conducted during the 2019 breeding season (June 25 to 30) by two experienced biologists.

To better explain broad patterns of habitat occupation by species of birds in the RSA, the initial 32 ecosystem units were consolidated into ten broad avian habitat types: Herb, Deciduous/Mixed Shrub, Tall Shrub – Black Spruce, Deciduous/Mixed Forest, Spruce Forest, Riparian/Wetland Deciduous Shrub, Riparian Coniferous Shrub, Riparian Spruce Forest, Open Water, and a classification ("Unknown") for distant (>100 m) or flyover observations that prevented associating birds with habitat.

Based on range and habitat, 128 bird species potentially occur in or adjacent to the RSA. Forty-eight bird species were recorded in adjacent areas during North American Breeding Bird Surveys. Possible species include eight listed either under the federal *Species at Risk Act* or identified in the Yukon *Wildlife Act*, and 67 are considered a priority and management concern under the federal *Bird Conservation Region 4 Plan*. Species listed in the *Species at Risk Act* include (with those in bold observed in the RSA): Horned Grebe (*Podiceps auritus*), Peregrine Falcon (*Falco peregrinus*), Short-eared Owl (*Asio flammeus*), **Red-necked Phalarope** (*Phalaropus lobatus*), **Common Nighthawk** (*Chordeiles minor*), **Olive-sided Flycatcher** (*Contopus cooperi*), Bank Swallow (*Riparia riparia*), and **Rusty Blackbird** (*Euphagus carolinus*).

During field surveys, nine hundred and seventy-nine birds from 53 species were observed in the RSA. Point counts identified 743 birds of 42 species, and wetland surveys identified 231 birds of 37 species. Five Swainson's Hawk (*Buteo swainsoni*) were also identified as incidental observations. Patterns of species relative abundance and richness (number of species) varied among the different habitat types. These patterns were consistent with regional habitat and known bird range-use and habitat requirements. Average relative abundance and species richness were greatest in Spruce Forest, Deciduous and Mixed Shrub, and Riparian/Wetland Deciduous Shrub habitats; and lowest in Herb and Tall Shrub – Black Spruce habitats. These patterns were generally related to the structural complexity and productivity of these different habitat types. However, the number of unique species in a given habitat did not depend on structural complexity. Many unique species were found in the Herb and Open Water habitats.

The general patterns of bird occurrence and habitat associations observed in this study are consistent with the limited information available for birds in the area.

Marten

Marten were selected as a Valued Component for the Project due to their value as a furbearer to the Vuntut Gwitchin First Nation and as an indicator species for mature and old forest values. Marten are a good species for assessing potential effects on habitat because they are more closely associated with habitat (mature forest) than many other species of medium-sized carnivore. However, little is known about basic marten ecology in northern boreal forest and taiga ecosystems. The RSA is located entirely within the Eagle Plains Ecoregion, where tree growth is limited by the presence of permafrost and short cool summers that limit the structural development of forests. The most common climax forest community is black spruce woodlands with open canopies and relatively small trees. The size and number of mature forest structures that marten use, such as large trees, snags, and coarse woody debris is much smaller than in forests used by marten in more southern latitudes. Therefore, indices of marten habitat suitability were evaluated in a relative context in this northern setting.

A habitat suitability index model was developed for marten to examine the amount, quality, and habitat distribution for the species in the RSA. Habitat was assigned a suitability ranking of High, Moderate, Low, or Nil/Very Low, relative to the range of habitat quality across the RSA. The rating categories correspond to qualitative predictions of the relative suitability of the habitat for supporting five life requisites of marten: reproduction, thermal cover, escape cover, foraging, and dispersal. High-quality habitat supports all five life requisites. Moderate-quality habitat supports escape cover, foraging, and dispersal. Low-quality habitat only

supports limited foraging and dispersal. Nil/Very Low-quality habitat does not contribute significantly to any life requisites; however, herb/shrub structural stages and stunted disclimax forest areas likely function as permeable barriers and allow intra-territorial movements within marten home ranges. Key habitat associations include selection for mature/old conifer structural stages and avoidance of herb/shrub structural stages (mostly resulting from fire), natural openings, wetlands, and stunted black spruce stands. The model also accounts for avoiding anthropogenic linear features, with greater rating reductions for wider linear features. The model uses two types of source information to provide a spatially explicit quantification of marten habitat across the RSA: vegetation mapping (Ecological and Landscape Classification mapping) and human disturbance, including the Dempster Highway, winter roads, and two types of seismic lines.

The model indicates a patchwork of High (16%), Moderate (23%), and Low (60%) quality marten habitats across the RSA. High-quality marten habitat is associated with mesic, spruce-dominant ecosites in mature to old structural stages. Concentrations of High-quality habitat include the southern portion of the study area, in the Enterprise and Dalglish Creeks watersheds, a band running east-west, north of the Dempster Highway, and the western portion of the northern half of the RSA. Moderate-quality habitat is associated with wetter and/or younger ecosystem units than High-quality habitat and is widespread across the RSA. High and Moderate quality habitat is also concentrated in narrow strips of mature/old riparian forests along some of the major watercourses in the RSA, including Chance and Greaves Creeks in the northwest and McParlon Creek west of the Dempster Highway. Low-quality habitat is associated with regenerating burns, wetlands, and stunted, open, black spruce areas. Concentrations of Low-quality habitat include recent burns on both sides of the Dempster Highway and wetlands and open, stunted spruce areas in valley bottoms in the lower reaches of the Chance watershed in the northwestern portion of the RSA. Nil/Very Low habitat constitutes only 1% of the RSA.

Linear features had a relatively minor effect on overall quality, amount, and distribution of potential habitat for marten in the RSA. This was due to the narrow width of linear features and small overall extent they comprise relative to the overall RSA. Though existing linear features result in reduced habitat quality at the site-level, their effects on habitat supply for marten at the home range scale are very limited.

Grizzly Bear

Grizzly bears (*Ursus arctos horribilis*) were selected as a Valued Component for the Project due to their conservation status and social, cultural, and economic value. Grizzly bears are Special Concern on Schedule 1 of the federal *Species at Risk Act*. The grizzly bear section provides baseline information about population trends, distribution, sources of mortality, diet, and habitat selection within the RSA. This section draws from multiple sources, including published and unpublished literature, personal communications with biologists, and traditional knowledge where available. Few studies on grizzly bears have been conducted in the Project area. Literature from surrounding regions was consulted when local information was not available.

Grizzly bear densities are thought to be low throughout the RSA. The most current grizzly bear population estimate for the broader Eagle Plains Ecoregion (which encompasses the RSA) is 184 individuals, based on expert opinion of grizzly bear habitat capacity from the 1980s. Little is known about seasonal grizzly bear distribution and movements within the RSA and surrounding areas. However, the Richardson and Ogilvie

Mountains (north and south of the RSA, respectively) are thought to have higher grizzly bear densities than the comparatively flat Eagle Plains Ecoregion. Grizzly bears congregate at the Fishing Branch River (20 km west of the RSA) in the fall to feed on spawning salmon. Grizzly bears may also follow the spring and fall migration of the Porcupine caribou herd to take advantage of the seasonal abundance of caribou as a food source.

Key threats to grizzly bear populations in the Yukon are human-wildlife conflict and harvest mortality. Licenced grizzly bear harvest rates are low in the RSA relative to other parts of the Yukon. Annual grizzly bear harvest in Game Management Zone 1 (which encompasses the RSA) has historically varied from zero to three bears per year. Other potential sources of grizzly bear mortality in the RSA include the defence of life and property kills, collisions with vehicles, and predation from other bears or large carnivores.

Seasonal grizzly bear diets reflect the phenological progression of key food resources such as herbaceous plants, roots, ungulate calves, berries, and fish. Terrestrial wildlife are likely an important food source for grizzly bears in northern Yukon, particularly barren-ground caribou (*Rangifer tarandus groenlandicus*) and arctic ground squirrels (*Spermophilus parryii*). The distribution of available food strongly influences habitat selection by grizzly bears during spring, summer, and fall seasons and the supply of suitable den sites in winter. Grizzly bears in the RSA may select habitats with abundant herbaceous vegetation, roots, or berries, such as riparian valleys and slopes. Grizzly bears may also travel to nearby mountain ranges to feed on ground squirrels, particularly in fall, as berry availability declines. Grizzly bears may follow caribou during spring and fall as they migrate to and from their calving grounds, targeting calves or opportunistically preying on adults.

Grizzly bears in northern Yukon hibernate in winter from approximately October to May. They prefer to den in mountainous regions; however, in areas with relatively flat topography (such as the RSA), grizzly bars will select small topographic features such as hills, steep riparian banks, or lakesides to excavate their dens. Grizzly bears in the taiga of northern Yukon have large home range sizes (females: 442–750 km^2, males: 760–1,250 km^2). They travel long distances to find suitable winter denning habitats in the mountains.

Moose

Moose (*Alces alces*) were selected as a Valued Component for the project's environmental assessment due to their value as a game species and their cultural values to local First Nations. The purpose of the moose study was to summarize existing baseline information for moose and develop a habitat model for the species within the Eagle Plains RSA. The habitat model quantifies the suitability, amount, and distribution of potential habitat for moose in the RSA. This information can be used to assess the Project's potential effects on moose and develop measures to mitigate effects if required.

There is limited incidental knowledge about moose population levels, distribution and habitat use within the Eagle Plain RSA. Formal population surveys of moose have not been conducted, but local knowledge suggests that, while moose densities in Eagle Plains are relatively low compared to areas in southern Yukon, they are relatively high compared to other areas in North Yukon. Information from two historical aerial surveys examining the distribution of moose (and other large mammals) indicates that moose occur across the RSA throughout the year, consistent with the relatively low elevation, subdued topography, and moderate

snowpacks that occur in the area. Several large, regenerating burns and smaller extents of riparian and wetland shrublands offer shrubby browse that moose depend on during winter.

The habitat model was developed specifically for the winter season because winter is the most limiting season for moose — forage is most limited, and energetic demands are greatest due to cold temperatures and the extra effort required to travel through snow. The model explicitly focussed on forage availability, which was believed to be the most significant factor affecting habitat selection in winter. During winter, moose feed almost exclusively on the stems and branches of certain shrubs. Vegetation surveys in the area found that several species of willows (*Salix spp.*) were the most abundant potential forage species and the species with the most frequent evidence of browsing by moose.

The habitat model included three variables, ecosystem type, structural stage, and fire disturbance status, all from recent vegetation mapping (Ecological and Landscape Classification mapping) conducted in the RSA. Habitat suitability ratings were developed for each combination of ecosystem type, structural stage, and fire disturbance based on the observed or potential abundance of willow. The highest-rated areas included natural shrublands, regenerating burns in riparian areas, and small extents of deciduous and mixed-wood ecosystems on mesic and moist sites. Moderate-rated areas were predominantly regenerating burns on mesic to wet sites. Low-rated sites were mostly undisturbed stands of open, stunted spruce on mesic to wet sites, ranging from tall shrub to old forest structural stages. Differentiating ratings between Moderate and Low areas was often difficult. Many burned and unburned sites had an average willow cover less than 15%, with high variation in cover among sites in the same ecosystem units. Generally, 7% willow cover was used as the threshold to differentiate between Moderate and Low sites. This is a relatively low value of willow cover but using a higher threshold would have resulted in large areas of regenerating burn being classified the same (Low) as undisturbed areas.

The habitat model indicates that High-suitability moose winter habitat is quite limited across the RSA, and Moderate habitat is widespread: High (12%), Moderate (43%), Low (44%), and Nil/Very Low (1%). Due to the scattered occurrence of High-suitability habitat across the RSA, some moose are expected to occur across the RSA in winter. However, local densities are likely to vary with the portions of Low and Moderate suitability habitats that form the matrix of habitat at a larger scale. This pattern of having extensive areas in Moderate suitability winter habitat is different than occurs in other parts of Yukon, especially in more mountainous regions, where suitable winter habitat (i.e., High and Moderate) are often constrained by elevation and broad vegetation patterns to a relatively small proportion of the landscape (e.g., <25%). In Eagle Plains, a substantial amount of winter forage occurs within large areas with relatively low willow cover (i.e., the Moderate suitability areas).

Caribou

The Porcupine Caribou Herd (PCH) is a subpopulation of barren-ground caribou (*Rangifer tarandus*), known for large population aggregations, dramatic population fluctuations, lengthy migrations, and significant cultural and social value to northern Indigenous peoples. Within the North Yukon Land Use Plan, the PCH is considered "the most significant and culturally important wildlife resource in the planning region." The PCH has been assessed as Threatened by the Committee on the Status of Endangered Wildlife in Canada, but the

subspecies is not listed on Schedule 1 of the federal *Species at Risk Act*. Within Yukon, barren-ground caribou are considered Vulnerable/Apparently Secure.

The specific objectives of this study were to:

- summarize existing information about the ecology of the PCH,

and, use telemetry data and analysis outputs from the Porcupine Caribou Technical Committee to:

- quantify the degree of seasonal range overlap by the PCH with the Eagle Plains Oil and Gas Exploration Project RSA during late fall and winter, when seasonal range use overlaps the RSA.
- quantify habitat use patterns and selection by the PCH during late fall and winter.
- quantify movement rates and residency periods of the PCH during late fall and winter.
- quantify potential effects of exiting linear features on the occurrence and movements of the PCH.

There is a long history of co-management of the PCH among indigenous, state, territorial and federal governments in Canada and the United States. In Canada, management initiatives are led by the Porcupine Caribou Management Board with technical support from the Porcupine Caribou Technical Committee. The Porcupine Caribou Technical Committee leads most monitoring and research work on the PCH, including population and demographic monitoring, seasonal movement monitoring (via GPS telemetry tracking), caribou body condition monitoring, habitat and human disturbance assessments, and annual snow surveys. The portion of the PCH annual range that occurs within Yukon is protected by a network of parks, special management areas, conservation areas, wilderness areas, protected areas, ecological preserves, habitat protection areas, and Integrated Management Area zones within the North Yukon Regional Land Use Plan and the Peel Watershed Regional Land Use Plan. In total, 54% of the annual range of the PCH within Yukon falls within some type of protected area where industrial activity is prohibited, 36% of the annual range occurs within regional land use plan Integrated Management Area zones where development is limited, and 9% of the annual range is not covered by any land management zonation.

Although most barren-ground caribou subpopulations are declining, the PCH numbers have increased over the last two decades. Since the first survey in 1972, the PCH has had two periods of population growth, with an interceding decline. The last successful population survey in 2017 estimated a record high of 218,457 caribou.

Like most barren-ground caribou subpopulations, the PCH has a large annual range and makes long-distance migrations, hundreds or thousands of kilometres, among different seasonal ranges. After calving on the north slope and Arctic coastal plains, the PCH typically splits in two, with portions of the herd moving southwest in Alaska and southeast in Yukon. Animals in the Yukon typically follow a clockwise movement through the seasonal ranges from the calving grounds on the north slope, to the British Mountains in summer, to the Richardson Mountains in late summer, dispersing widely and variably across northern Yukon (as far south as the Ogilvie Mountains) in fall and winter, before returning north to the coastal plains in spring. The PCH has historically overlapped the RSA in the rut/late fall and winter periods. However, the RSA overlaps a small

portion of those ranges — 6.0% of the late fall range and 6.5% of the winter range, and the RSA does not overlap with the most frequently used portions of those ranges.

Habitat selection by the PCH for late fall and winter was estimated using resource selection functions using GPS collar data from 2012 to 2021 for 164 caribou in late fall and 172 caribou in winter. Spatial habitat data included a set of plant functional type layers (light macrolichens, graminoids, forbs, evergreen shrubs, deciduous shrubs, and conifer trees), elevation, aspect, slope, terrain ruggedness, and distance to waterbodies >1 ha. PCH caribou tended to select and avoid similar resources in both late fall and winter. Key covariates in models for both seasons that were statistically significant (i.e., $P < 0.05$) included macrolichen cover (positive coefficient), conifer tree cover (negative coefficient), slope percent (negative coefficient), elevation (variable in fall and winter), and aspect (greater selection for south- and west-facing). Coefficients associated with lichen cover were of the greatest magnitude, suggesting that the selection of lichen is the primary driver of habitat selection in late fall, especially in winter. The resource selection function models were used to derive habitat quality maps with four ratings (Very Low, Low, Moderate, and High), which were determined by assessing selection ratios across resource selection function predictions. The distribution and proportion of selected habitat (Moderate and High) was then examined within the RSA and broader seasonal ranges. The proportion of selected habitat was equivalent between the RSA (0.404) and the broader range during late fall (0.415 ± 0.025) but was less in the RSA (0.265) than the broader range during winter (0.411 ± 0.026). Selected habitat, especially areas of High quality, were mostly dependent on the amount and distribution of macrolichen cover.

The potential for linear features (i.e., the Dempster Highway, winter roads, 2D seismic and 3D seismic) to mediate the base habitat model via avoidance of those features was assessed using a zone of influence (ZOI) framework. Although ZOIs were determined for some features, confidence in the outcomes was low because (i) the magnitude of the ZOI effects were weak (i.e., including the ZOI effects in the habitat models had little effects on the habitat predictions); (ii) the ZOI distance estimates were sensitive to the data and analytical methods used; (iii) the pattern of ZOI effects were not consistent with other studies and basic understanding of the PCH ecology. Developing ZOIs for assessment and management purposes will integrate results from other studies adapted to the Eagle Plains setting and the ecology of the PCH.

To better understand factors affecting PCH caribou movement, two analyses were conducted: (1) a comparison of daily movement rates and residency times of caribou in the Project RSA relative to the broader landscape, and (2) a delineation of movement paths to assess broad-scale movement patterns and the potential for caribou to interact with the Project. The PCH typically exhibits movements of several kilometres per day in late fall and winter. Late fall daily movements (8.7 km/day in the RSA) were substantially greater than during winter (4.4 km/day), and caribou tended to occupy portions of the landscape for shorter periods during late fall than during winter. Caribou residency times in both seasons were two-fold greater in the broader landscape than within the Project RSA, suggesting that, on average, the RSA is used as more of a transitory area than other portions of the seasonal ranges. There were relatively few collared caribou that travelled through the RSA during late fall. However, in the fall of 2015, 14 collared caribou made clear, directed movements along the height of land parallel to the Dempster Highway, from the northeast to the southwest. Most caribou appeared to avoid crossing the Dempster Highway while travelling through the Eagle Plains

region, but all animals eventually crossed the highway farther south, in the Ogilvie Mountains. The movements through Eagle Plains crossed numerous 2D seismic lines, winter roads and a large 3D seismic grid within the RSA.

Photo 5-2. Shrubby riparian area, on the edge of a burn, where willows have been browsed by moose. 81

Photo 5-3. Recent burn in a graminoid structural stage. Generally, regenerating shrubs become available as browse to moose about 10 years after fire disturbance. 83

Photo 5-4. Example of a low shrub 2D seismic line within the RSA. 85

Photo 5-5. Low shrub – shrubby riparian birch – willow habitat (code 20) rated as High winter forage habitat. 100

Photo 5-6. Low shrub – drainage shrubby riparian habitat (code 23) rated as High winter forage habitat. 100

Photo 5-7. Tall shrub – moist birch – willow habitat (code 36) rated as High moose winter forage. 100

Photo 5-8. Low shrub – moist shrub\scrub birch – Labrador tea – willow habitat (code 31) rated as Moderately High moose winter forage. 100

Photo 5-9. Young forest – mesic Alaska paper birch habitat (code 05) rated as Moderately High moose winter forage. 101

Photo 5-10. Mature forest – wet black spruce – carex habitat (code 48) rated as Moderate moose winter forage. 101

Photo 5-11. Shrubby burnt – moist spruce – Labrador tea habitat (code 33) rated as Moderate moose winter forage habitat (note that this is not rated higher than Moderate because much of the shrub cover is less preferred scrub birch). 101

Photo 5-12. Unburnt – moist spruce – Labrador tea habitat (code 33), in Tall Shrub structural stage, was rated as low moose winter forage habitat. 101

Photo 5-13. Tall shrub – wet black spruce – tussock cottongrass – Sphagnum habitat (code 47) rated as low moose winter forage habitat. 102

Photo 5-14. Mature forest – mesic black spruce – Labrador tea habitat (code 06) rated as low moose winter forage 102

Photo 5-15. Low shrub – bog – black spruce – Sphagnum habitat (code B2) rated as very low moose winter forage. 102

Photo 5-16. Low shrub – bog – black spruce – lichen habitat (code B1) rated as very low moose winter forage. 102

Photo 6-1. Mesic, mature forest, with mat-forming terrestrial lichens in the Eagle Plains RSA. 120

Photo 6-2. Lichen communities are often diverse in Eagle Plains. This lichen mat includes *Cladonia spp.* (lighter green) that are preferred forage for caribou, as well as *Stereocaulon spp.* (darker grey) and *Flavocetraria spp.*, which are both also eaten by caribou but less preferred. 121

Photo 6-3. Lichen cover is generally reduced in regenerating burns. However, EDI observed high lichen abundance in some regenerating burns, consistent with previous work by other researchers (Russell et al. 1993). 121

1 INTRODUCTION

Baseline wildlife information and data are required for proposed oil and gas projects submitted to the Yukon Environmental and Socio-economic Assessment Board (YESAB) Executive Committee for screening under the *Yukon Environment and Socio-Economic Assessment Act* (YESAA), as well as applications submitted for an Industrial Licence and Type A Water Licence from the Yukon Water Board, among other permits and licences. To receive authorization for the Eagle Plains Project to proceed, the Project must be evaluated under YESAA. Specific wildlife objectives, as identified in YESAB's Proponent's Guide to Information Requirements for Executive Committee Project Proposal Submissions (2005), are to:

- describe the abundance and distribution characteristics of major wildlife species within the project area and vicinity;
- describe the habitat classifications used in the project area and any implications concerning the distribution and abundance of habitat types that may influence the project;
- provide a map showing the spatial arrangement of habitats of special interest, if applicable;
- identify and describe the transportation corridor and critical, key, and sensitive habitats;
- identify any species listed on the Committee on the Status of Endangered Wildlife in Canada (COSEWIC) and Species at Risk lists;
- describe any special management requirements due to vulnerability, threatened, or endangered status; and,
- identify and describe any ongoing studies and monitoring programs concerning wildlife in the project area and vicinity.

1.1 PROJECT OVERVIEW

The Eagle Plains Project (the Project) encompasses a 2,386 km² area in north-central Yukon, centred approximately 605 km north of Whitehorse and 40 km south and west of Eagle Plains hotel, along the Dempster Highway. The Project occurs within the Eagle Plains sedimentary basin, north of the Ogilvie River and west of the Richardson Mountains. The basin contains proven natural gas and oil reserves (Peel Watershed Planning Commission 2019), including 4.6 billion m³ of gas and 3.2 million m³ of oil (Hannigan 2014).

The Regional Study Area (RSA) has had intermittent periods of oil and gas exploration since the 1950s. That activity has established winter roads, seismic lines, and exploratory well sites across parts of the current RSA. Approximately 40 exploration wells have been drilled in the Eagle Plains sedimentary basin. Eight (8) wells are currently being maintained in suspended status, and the remaining wells have been plugged and abandoned. Seismic exploration has included approximately 10,000 km of two-dimensional (2D) lines (mostly before 1985), and about 325 km² of three-dimensional (3D) seismic was conducted in 2013/2014 (Northern Cross (Yukon) Ltd. 2014).

The current exploration program will build on past exploration to better define the extent, amount and quality of oil and gas deposits in the area. Under the current program, Chance Oil and Gas Ltd. proposes conducting additional 2D and 3D seismic data acquisition programs over large extents of the RSA and drilling up to 30 exploratory wells. Depending on the drilling program results, extended flow testing lasting up to two years may be conducted at wells where crude oil and/or natural gas are discovered to determine the quantity, quality and extent of the oil and gas deposit(s). The existing winter road network will be expanded to support the seismic, drilling, and flow testing programs. Most work is expected to be conducted in the winter (e.g., seismic line clearing and drilling); however, seismic recordings and extended flow testing may also occur during summer or year-round.

1.2 STUDY AREA

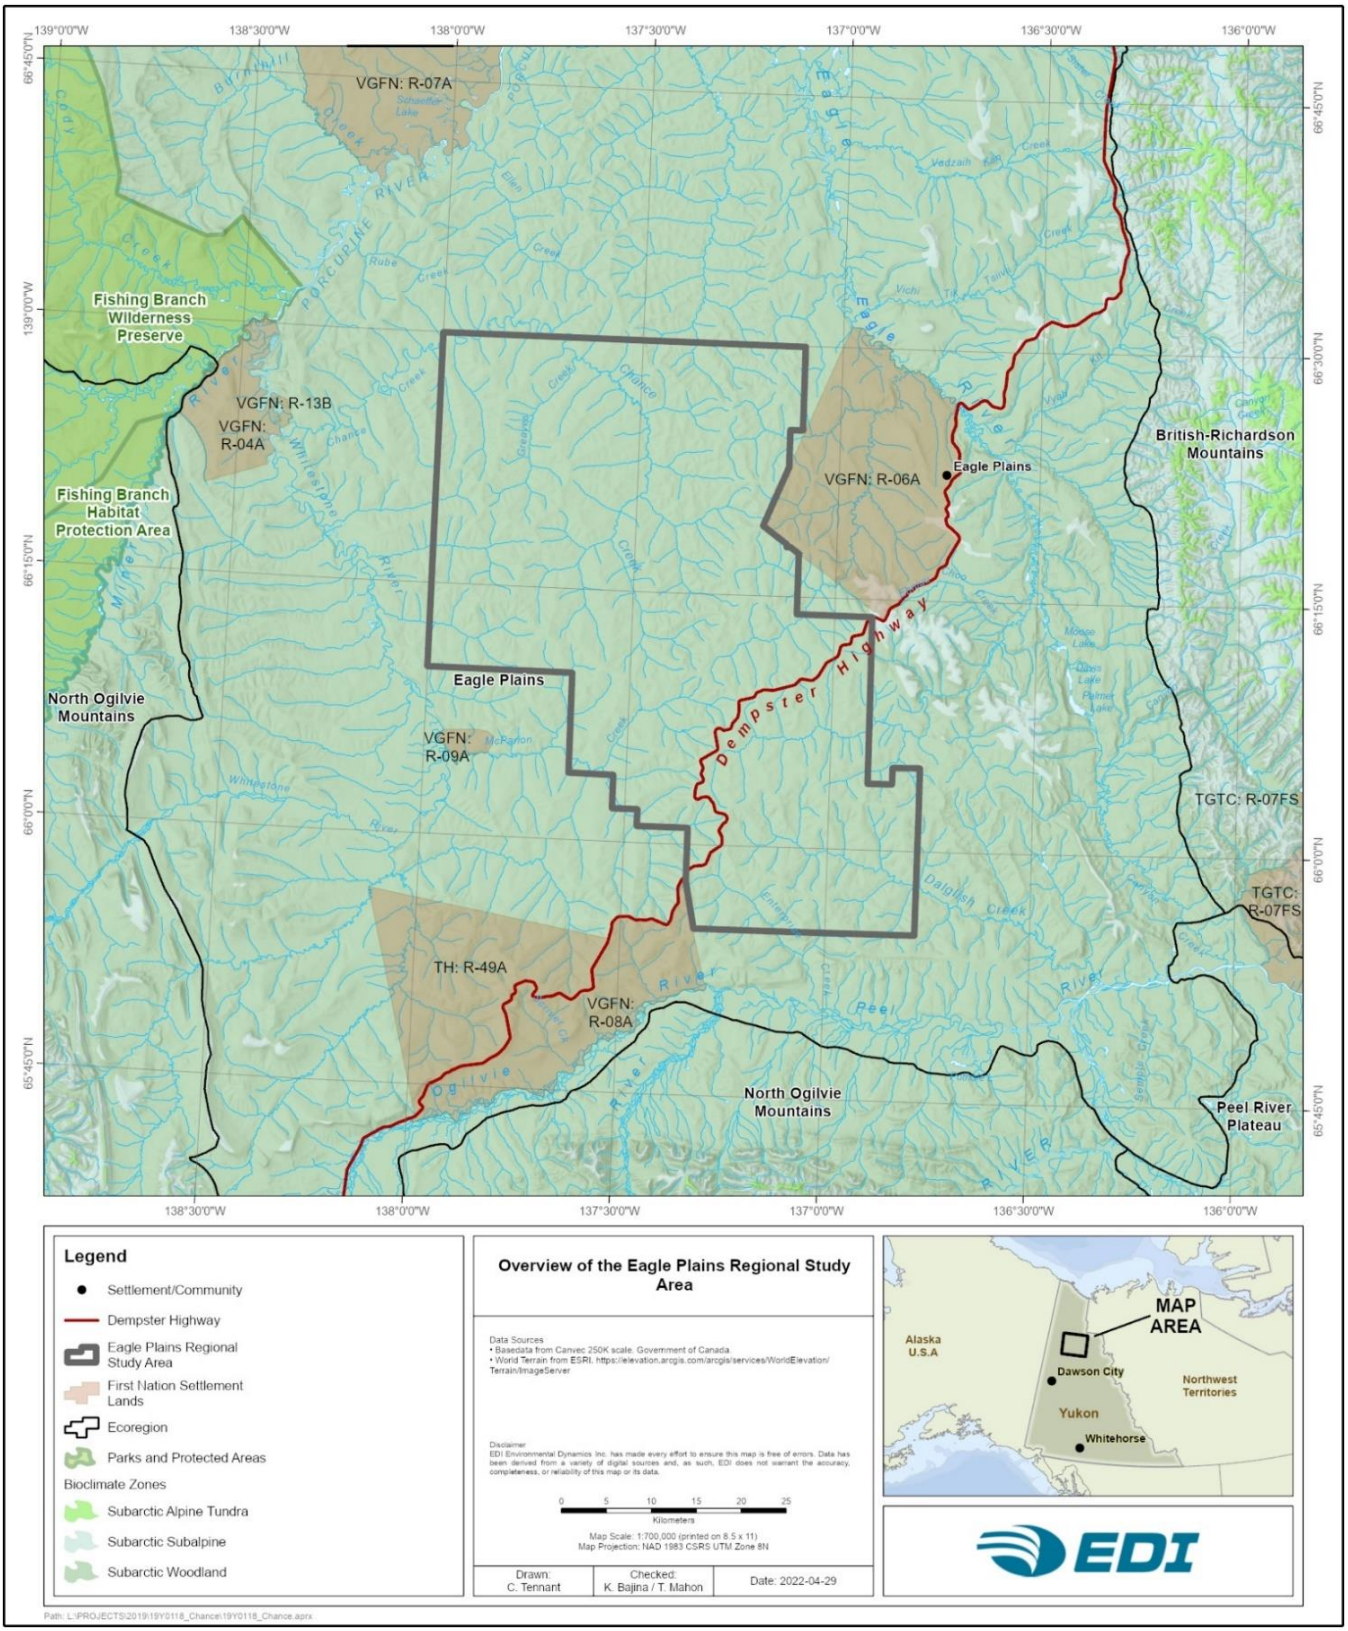
The Eagle Plains Project Regional Study Area (RSA; Map 1-1) is 2,386 km² (238,566 ha), centred in the Eagle Plains Ecoregion in north Yukon. The area consists of subdued topography of rolling hills and sloping plains. The Dempster Highway crosses the RSA along the local height of land. From there, the area drains into the Porcupine River watershed to the north (via Chance Creek) and west (via McParlon Creek and the Whitestone River) and into the Peel River watershed to the southeast (via Dalglish Creek).

The RSA overlaps four First Nation Traditional Territories. Most of the RSA is within the Vuntut Gwitchin First Nation (VGFN) Traditional Territory. The southeastern portion is in an area of overlapping Traditional Territories of VGFN, the Tetlit Gwich'in Council (TGC), the First Nation of Na-cho Nyäk Dun (NND), and Tr'ondëk Hwëchin First Nation (THFN). Although the RSA is outside any First Nation Settlement Lands, it adjoins VGFN Settlement Lands on parts of its east and southwest borders.

Development in the RSA and the surrounding Eagle Plains is low. The Dempster Highway is the main vehicle access corridor, running from approximately Dawson City, Yukon in the southwest to Inuvik, Northwest Territories (NWT) to the northeast and transiting the RSA along the way. Several winter access roads also branch off the Dempster Highway. A network of seismic lines (Photo 1-1) from historical exploration are found in the RSA. The Eagle Plains settlement is located on the Dempster Highway, approximately 30 km east of the RSA boundary and consists of the Eagle Plains Hotel and the Government of Yukon's Highway Maintenance camp.

The Project is within the North Yukon Planning Region and Peel Watershed Planning Region. Therefore, it is subject to the North Yukon Land Use Plan (NYLUP) and Peel Watershed Land Use Plan (PWLUP). The project falls within the Integrated Management Area (IMA) Zone IV of both plans, a zone with lower ecological and cultural values and the highest permissible development of the four IMA zones.

Photo 1-1. Seismic lines from historical exploration activities within the Regional Study Area.



Map 1-1. Overview of the Eagle Plains Regional Study Area.

1.3 ECOLOGICAL OVERVIEW

The Project falls within the Eagle Plains Ecoregion (Map 1-1), a 20,400 km² region in north Yukon between the Richardson and Ogilvie Mountains. The ecoregion consists of low-altitude rolling topography between 300 m and 600 m above sea level (masl), with few scattered peaks above and around 1,000 masl (Ecological Stratification Working Group 1995).

The Eagle Plains Ecoregion experiences moderate precipitation, with annual amounts around 400 mm. Most precipitation falls as rain throughout the summer, averaging 50 to 80 mm per month, from June through August. Precipitation is lighter through September to April and falls as snow, with average winter snowpacks of 80 cm peaking in April. The climate in this region is strongly affected by its latitude, with extended winter conditions that usually last from October through to early May. There is a substantial variation in seasonal temperatures in the Eagle Plains, with cool short summers and long cold winters. Average winter temperatures are between −30°C and −25°C, with extremes as low as −60°C. Average summer temperatures are around 13°C, with extremes as high as 30°C. Due to the northern latitude, this region experiences brief periods of continuous sun above and below the horizon in summer and winter, respectively.

Most of the Ecoregion, including the northeast portion of the RSA, drains north into the Yukon River via the Whitestone, Porcupine and Eagle rivers. That part of the RSA includes the headwaters of the Eagle River and several other tributaries of the Porcupine River, along with the Chance and McParlon Creek subdrainages of the Whitestone River. The southeast corner of the Ecoregion drains east to the Mackenzie River via the Peel, Wind and Ogilvie Rivers. Dalglish and Enterprise creeks flow directly into the Peel River. The few lakes in the Ecoregion are generally oxbow or thermokarst lakes (Yukon Ecoregions Working Group 2004a). Several wetland complexes are found to be associated with larger creeks in the RSA.

The Eagle Plains Ecoregion is dominated by the Crysolic soils that occupy much of the northern third of Canada, characterized by near-surface permafrost. Turbic Cryosols predominate, exhibiting patterned ground formations and hummocks, and are often associated with open stands of black spruce (*Picea mariana*), tamarack (*Larix laricina*) and birch (*Betula* spp.). The active permafrost layer in these ecosystems generally ranges between 20 cm and 90 cm below the surface. The active layer depth is generally deeper under hummocks and shallower under inter-hummock areas (Yukon Ecoregions Working Group 2004a).

The RSA is entirely within the Subarctic Bioclimate Zone (Environment Yukon 2014a). Vegetation in the RSA is characterized by open-canopy, spruce-dominated habitats where permafrost generally limits tree growth and results in stunted, disclimax vegetation communities (Environment Yukon 2016a). Hummocky, black spruce and white spruce (*Picea glauca*) woodlands with well-developed shrub communities are common in upland areas, with white spruce and ground lichens increasing in abundance in well-drained sites. Areas with low slope gradients and fine-textured soils often have ground cover dominated by cottongrass tussocks beneath a shrub layer of birch, black spruce, Labrador tea (*Rhododendron groenlandicum*), and occasionally tamarack (Yukon Ecoregions Working Group 2004a).

Evidence of forest fires can be observed throughout the RSA (Photo 1-2 and Photo 1-3). Alaskan paper-birch (*Betula neoalaskana*) is often the first tree species to colonize burn areas, and the extent of old burns is generally

correlated with young black spruce – Alaskan paper birch woodlands (Yukon Ecoregions Working Group 2004a). Fires increase the depth of the active permafrost layer, causing slope failures and changes in ecosystem moisture regimes.

Photo 1-2. Example of a regenerating moist forest stand after a fire within the RSA.

Photo 1-3. Example of a recently burnt area of the RSA.

2 BIRDS

2.1 PURPOSE AND OBJECTIVES

This section documents the occurrence, relative abundance, and habitat associations of birds occurring or likely occurring in the RSA. It includes a desktop assessment to collect and summarize existing information about birds; and field surveys to document the occurrence, relative abundance, and habitat associations of birds within the RSA. Field surveys were recommended by the regulator responsible for migratory birds (Environment and Climate Change Canada — Canadian Wildlife Service [CWS]) because no systematic bird surveys have been previously conducted in the Project area. Surveys in adjacent areas were limited and mainly were road-based surveys, which had limited or no coverage of particular habitat types. Two field survey types were used to provide representative coverage of broad avian habitat types and associated avian communities: (1) point count surveys and (2) pond and wetland surveys.

2.2 BIRD HABITAT OVERVIEW

The Project falls within Bird Conservation Region 4 (BCR 4), the Northwestern Interior Forest (Environment Canada 2013a). BCR 4 is home to 211 regularly occurring bird species, including 31 waterfowl species, 19 water bird species, 23 shorebird species, and 138 land bird species (Environment Canada 2013a). Most species are breeding season migrants, few are year-round residents. The Project is also within ~30 km of two other bird conservation regions: region 3 (BCR 3), the Arctic Plains and Mountains, and region 6 (BCR 6), the Boreal Taiga Plains. BCR 3 habitats are influenced by a short growing season and continuous permafrost; upland habitats range from heavily vegetated heath communities to sparse cryptobiotic crusts, lichens, and moss; in the southern end, dwarfed spruce trees are often found in restricted patches (Environment Canada 2013b). BCR 6 is primarily characterized by gently rolling or undulating landscapes, vegetation dominated by the boreal forest and interspersed with wetlands and several major river systems (Environment Canada 2013c). In total, BCR 3 has 159 species of birds, while BCR 6 has 288. This current study did not find species uniquely associated with either of these two conservation regions.

The RSA has three predominant bird habitat types: black spruce upland, willow and scrub birch shrubland, and scrub fens and bogs. Upland forests provide potential breeding habitat for resident Northern Goshawk (*Accipiter gentilis*), Spruce Grouse (*Canachites canadensis*), Northern Hawk Owl (*Surnia ulula*), American Three-toed Woodpecker (*Picoides dorsalis*), Canada Jay (*Perisoreus canadensis*), Boreal Chickadee (*Poecile hudsonicus*), White-winged Crossbill (*Loxia leucoptera*), and Common Redpoll (*Acanthis flammea*) (Frisch 1987, YEWG 2004, Environment Canada 2013). Migrants that breed in upland forests include Swainson's Thrush (*Catharus ustulatus*), Gray-cheeked Thrush (*Catharus minimus*), Varied Thrush (*Ixoreus naevius*), Bohemian Waxwing (*Bombycilla garrulus*), Yellow Warbler (*Setophaga petechia*), Yellow-rumped Warbler (*Setophaga coronata*), American Tree Sparrow (*Spizelloides arborea*), and Dark-eyed Junco (*Junco hyemalis*) (Frisch 1987, YEWG 2004). American Kestrel (*Falco sparverius*), Say's Phoebe (*Sayornis saya*), American Robin (*Turdus migratorius*), Orange-crowned Warbler (*Leiothlypis celata*), and Chipping Sparrow (*Spizella passerina*), as well as other species of thrush, warbler,

and sparrow, can be found in more open forests with a well-developed shrub layer, or shrublands with tall shrub and dwarfed spruce (Frisch 1987, YEWG 2004). A frequently occurring species in the Eagle Plains ecoregion, though rare elsewhere in Yukon, is Swainson's Hawk (*Buteo swainsoni*). This species is associated with isolated stands of productive white spruce for nesting habitat, mostly found in narrow riparian strips surrounded by open bogs and shrublands where they regularly forage.

Aquatic habitats for birds consist of open bodies of water (e.g., ponds, lakes), wetlands (mostly bogs and fens) and riparian zones dominated by sedges and shrubs. Open water bodies are limited in the RSA and are thus potentially inhabited by relatively few Tundra Swan (*Cygnus columbianus*), Greater White-fronted Goose (*Anser albifrons*), Canada Goose (*Branta canadensis*), American Wigeon (*Mareca americana*), Green-winged Teal (*Anas crecca*), and Bufflehead (*Bucephala albeola*) (Frisch 1987, YEWG 2004, Environment Canada 2013). Shorebirds such as Lesser Yellowlegs (*Tringa flavipes*), Solitary Sandpiper (*Tringa solitaria*), and Wilson's Snipe (*Gallinago delicata*) remain along the water's edge and in riparian zones consisting of coniferous and deciduous vegetation. Riparian zones also provide potential breeding habitat for Willow Ptarmigan (*Lagopus lagopus*), Alder Flycatcher (*Empidonax alnorum*), Yellow Warbler, Wilson's Warbler (*Cardellina pusilla*), American Tree Sparrow, and Lincoln's Sparrow (*Melospiza lincolnii*) (Frisch 1987, YEWG 2004). Spotted Sandpiper (*Actitis macularius*), Herring and Short-billed Gulls (*Larus argentatus* and *L. brachyrhynchus*), Belted Kingfisher (*Megaceryle alcyon*), Bank Swallows (*Riparia riparia*), and Cliff Swallows (*Petrochelidon pyrrhonota*) can be found along rivers (Frisch 1987, YEWG 2004).

Alpine/subalpine areas are absent from the RSA. Species that inhabit the alpine/subalpine in other parts of the ecoregion include Golden Eagle (*Aquila chrysaetos*), Rock Ptarmigan (*Lagopus muta*), Horned Lark (*Eremophila alpestris*), American Pipit (*Anthus rubescens*), Gray-crowned Rosy Finch (*Leucosticte tephrocotis*), Upland Sandpiper (*Bartramia longicauda*), and Townsend's Solitaire (*Myadestes townsendi*) (Frisch 1987, YEWG 2004).

The Project RSA does not include cliffs or bluffs that could be used by cliff-nesting raptors, such as Golden Eagle, Peregrine Falcon (*Falco peregrinus*) or Gyrfalcon (*Falco rusticolus*). These species' nearest suitable nesting cliffs are along the Porcupine River and Eagle River (Hayes and Mossop 1978).

Data on birds in the Project area are currently limited. The first evaluation of bird occurrences in Eagle Plains was *Birds by the Dempster* (Frisch 1987). Birds of the Yukon Territory (Sinclair et al. 2003) provided a more detailed description of species occurrences, habitat, and relative abundances. More recently, a general account of birds within the region was presented by Environment and Climate Change Canada in their report, *Bird Conservation Strategy for Bird Conservation Region 4 in Canada: Northwestern Interior Forest* (Environment Canada 2013a). The North American Breeding Bird Survey (NABBS) is the best local data source. Two NABBS routes along the Dempster Highway (routes 78 and 79) are close to the Project.

2.3 METHODS

This study consisted of two components: a desktop assessment to collect and summarize existing information about birds relevant to the Project area and field surveys to document the occurrence, relative abundance, and habitat associations of birds across the Project RSA. This approach, field survey design, and methods details

were discussed with CWS representatives during the project planning stage. The methods used considered specific recommendations provided by CWS representatives and a broader set of recommendations in *A Framework for the Scientific Assessment of Potential Project Impacts on Birds* (Hanson et al. 2009). The methods selected and reporting herein also comply with the the ten key considerations identified in the DRAFT updated guidelines *Canadian Wildlife Service Guidance Regarding Information Needed to Support Assessment of Project Effects on Birds* (ECCC-CWS 2022).

2.3.1 DESKTOP ASSESSMENT

A list of bird species that had the potential to occur in the Project RSA was developed from a combination of historical occurrence data in adjacent areas, a territorial field guide, and a national bird conservation assessment.

Historical data were gathered from the NABBS database for two routes (routes 78 and 79) that run along the Dempster Highway in the Eagle Plains region (Pardieck et al. 2019). The NABBS is a long-term, large-scale monitoring program that began in 1966 to track trends in avifauna. It consists of annual (one day a year) standardized roadside surveys, during the peak breeding season, by skilled observers making 50 stops spaced 0.8 km apart, along 39.4 km long routes. Observers record the number of bird species heard from any distance or seen within a 0.4 km radius of each stop during a three-minute observation period. These data are then compiled and made freely available to analyze trends in relative abundance and species composition. From 2014 to 2018, NABBS identified 48 species along Eagle Plains' two routes (above) (Pardieck et al. 2019).

General information about bird species occurrences was obtained from *Birds by the Dempster* (Frisch 1987), *Birds of Yukon* (Sinclair et al. 2003), and the Federal conservation assessment, *Bird Conservation Strategy for Bird Conservation Region 4 in Canada: Northwestern Interior Forest* (Environment Canada 2013a). These sources ranked species as 'Likely' or 'Possible' in the RSA based on habitat requirements, range boundaries, and occurrence information. Likely species were those whose range overlapped with the RSA, and suitable habitat occurred in the RSA. Possible species included (1) those with suitable habitat in the RSA, but whose range was on the edge of the RSA, and (2) those whose range overlapped with the RSA, but for which the availability of suitable habitat was in question.

2.3.1.1 Conservation Status

The conservation status of bird species was identified based on the most recent recommendations by COSEWIC (COSEWIC 2018) and current lists in the *Species at Risk Act* (SARA) registry (i.e., the most recent amendment, Environment and Climate Change Canada 2019) and BCR 4 plan. The SARA registry groups species into one of three schedules:

- Schedule 1 — the official list of species at risk in Canada includes species that are either Extirpated, Endangered, Threatened or of Special Concern;
- Schedule 2 — species designated as Endangered or Threatened, but that have yet to be re-assessed by COSEWIC under the revised criteria; and,

- Schedule 3 — species designated as Special Concern but have yet to be re-assessed by COSEWIC under the revised criteria.

Birds that fall under conservation categories of Special Concern or higher were identified. All bird species of conservation concern, identified through the designation and ranking processes described above, were evaluated against their species conservation status assessment found in the national bird conservation strategy for BCR 4 (Environment Canada 2013a). The BCR 4 strategy outlines conservation planning and priorities to support the implementation of migratory bird conservation programs. The BCR species assessment considered population size, population trend, regional abundances and densities, and species and habitat threats to designate species warranting "Concern and Stewardship at the Regional, National, or Continental level". Stewardship species are based on "having a large proportion of their world population within BCR 4". Species managed by Environment Yukon under the Yukon *Wildlife Act* were also noted.

2.3.2 HABITAT STRATIFICATION

A broad avian habitat classification system was developed to provide representative survey coverage across the RSA. A habitat stratification approach was applied to site selection for all survey sites before field surveys. Avian habitat types were initially developed using Predictive Ecosystem Mapping (PEM), later verified with Ecological and Landscape Classification (ELC) mapping for habitat-related analyses. Two key components of the initial PEM mapping to define avian habitat types were: ecosystem units and structural stage, described below.

2.3.2.1 Ecosystem Units (Ecosites)

The North Yukon PEM was used to classify 16 ecosystem units in the Project RSA. However, the PEM model was unsatisfactory when assessing ecosite predictions in the field because of its low accuracy. The PEM ecosite codes were used to guide each survey location, but adjustments were made to the classifications according to the dominant vegetation. These changes were supplemented with detailed notes and descriptions of plant and tree species (i.e., lichen cover, percent shrubs, tree height and canopy closure), as well as photographs, with the intent of reclassification.

The purpose of reclassifying PEM ecosystem units was to describe site-specific vegetation at a finer resolution and, ultimately, develop more accurate associations between species of birds and habitat in the Project RSA. A detailed review was conducted of all point count and wetland survey forms, including a review of notes on species of vegetation and structural stage (Table 2-1) and analyzing each survey station's photographs. Deciduous and coniferous (i.e., primarily black spruce) vegetation were distinguished based on their relative densities at ecosites previously classified as mixed wood. Patterns of bird occupation were then analyzed to determine whether deciduous and mixed vegetation warranted separate ecosite codes. Shrub-stage and mature-stage spruce stands were differentiated based on tree height and the degree of canopy closure. Separating these two structurally distinct stands yields two ecological communities with different bird assemblages, e.g., species requiring mature trees for nest cavities, such as owls and woodpeckers, are unlikely to be found in shrub-stage forests. These new ecosites were summarized along with their previous PEM codes

and descriptions of key vegetation characteristics. In total, 32 distinct ecosystem units were developed from the PEM model (Table 2-2).

Table 2-1. Structural and successional stages of vegetation associated with ecosystem units in the Eagle Plains Project Regional Study Area.[1]

Code	Structural Stage	Description
1	Non-vegetated	Very recent disturbance and no vegetation (or <5% vegetation).
2a	Sparse	Initial stages of primary and secondary succession with 5–10% vegetation cover maintained by environmental conditions.
2b	Cryptogram (Bryoid-dominated)	Bryophyte-dominated community maintained by environmental conditions.
3a	Herb (Forb-dominated)	Early successional stage of herbaceous communities maintained by environmental conditions or disturbance. Includes non-graminoid herbs and ferns.
3b	Herb (Graminoid-dominated)	Early successional stage of herbaceous communities maintained by environmental conditions or disturbance. Includes grasses, sedges, reeds, and rushes.
3c	Herb (Aquatic)	Early successional stage of herbaceous communities maintained by environmental conditions or disturbance. Dominated by floating or submerged plants.
4a	Tall Shrub	Early successional stage of forest or shrub communities dominated by shrub layer vegetation > 2 m tall.
4b	Low Shrub	Early successional stage of forest or shrub communities dominated by shrub layer vegetation <2 m tall.
5	Pole/Sapling	Trees >2 m tall and typically densely stocked. Vertical structure and layering not yet evident.
6	Young Forest	Forest canopy with distinct layers and somewhat open stand.
7	Mature Forest	Mature trees and well-developed understories at canopy openings.
8	Old Forest	Old and structurally complex stands composed mainly of shade-tolerant and regenerating tree species.

[1] Modified from Environment Yukon 2017.

Table 2-2. Modified predictive ecosystem mapping ecosites relative to original ecosites in the Eagle Plains Project Regional Study Area.

Modified PEM	PEM	*N*[1]	Vegetation Description
211-D	211	7	Wet deciduous shrub; predominantly willow and scrub birch. Structural stage 4b.
211-SB	211, 213	3	Wet black spruce shrub (peat bog). Structural stages 4a–6.
211-SB-ML	211, 213	2	Wet black spruce shrub with moderate lichen cover. Structural stages 4a–6.
213-tp	213	2	Wet black spruce dominant forest; tall and productive stands. Structural stages 6 and 8.
221	221	1	Moist mixed shrub; black spruce and deciduous (scrub birch and willow). Structural stage 4b.

Modified PEM	PEM	*N*[1]	Vegetation Description
221-D	221	12	Moist deciduous shrub; predominantly scrub birch and willow. Structural stages 4a–b.
221-SB	221, 223	18	Moist black spruce shrub. Structural stages 4a-6.
221-SB-LL	221, 223	3	Moist black spruce shrub with low lichen cover. Structural stage 4a.
221-SB-ML	223	2	Moist black spruce shrub with moderate lichen cover. Structural stage 6.
221-SB-HL	221	1	Moist black spruce shrub with high lichen cover. Structural stage 4a.
222	222	6	Moist mixed forest; spruce and deciduous (birch and/or alder). Structural stages 5-8.
222-D	222	1	Moist deciduous forest; birch dominant. Structural stage 6.
223-tp	222, 223	4	Moist black spruce forest; sometimes mixed with white spruce. Structural stages 6-7.
223-LL-tp	223	2	Moist black spruce forest; sometimes mixed with white spruce; low lichen cover. Structural stages 6-7.
230	230	1	Mesic herb with <15% shrub cover. Structural stages 2b and 4b.
231-D	231	4	Mesic deciduous shrub; predominantly willow and scrub birch. Structural stages 4a–b.
231-D-ML	231	1	Mesic deciduous shrub; predominantly willow and scrub birch; moderate lichen cover. Structural stage 4a.
231-SB	231, 233	7	Mesic black spruce shrub. Structural stages 4a–6.
231-SB-HL	233	3	Mesic black spruce shrub with high lichen cover. Structural stages 4a–6.
232	232	3	Mesic mixed forest; black spruce and deciduous (paper birch and/or trembling aspen). Structural stages 5–6.
232-D	232	3	Mesic deciduous forest; predominantly paper birch and willow. Structural stages 5–6.
233-tp	233	5	Mesic black spruce forest sometimes mixed with white spruce; tall and productive stands. Structural stages 6-7.
233-LL-tp	233	1	Mesic black spruce forest with some black spruce shrubs; low lichen cover; tall and productive stands. Structural stages 4b, 6–7.
233-HL-tp	233	1	Mesic black spruce forest; high lichen cover; tall and productive stands. Structural stage 6.
310	310	4	Riparian herb with little to no shrub cover. Structural stages 3b–c.
311-D	311	22	Riparian deciduous shrub; predominantly scrub birch and willow. Structural stages 4a-b.
311-SB	311, 313	4	Riparian black spruce shrub. Structural stages 4a–6.
311-SB-T	311	4	Riparian black spruce and tamarack shrub. Structural stages 4a–6.
313	313	11	Riparian spruce forest; mix of black and white spruce, as well as hybrids. Structural stages 6–8.
400	400	4	Wetland herb. Structural stage 3b.
401-D	401	1	Wetland deciduous shrub; predominantly scrub birch and willow. Structural stage 4b.
500	500	17	Open water.

[1] Sample size, the number of survey stations (point count or pond) within each modified PEM ecosite.

2.3.2.2 Bird Habitat Types

Once ecosystem units were reclassified, they were grouped according to vegetation and structural stage similarities. Mixed and deciduous vegetation, while ecologically distinct, did not differ in their use by birds; therefore, they were grouped in a single category. Ultimately, 32 ecosystem units were consolidated into ten broad avian habitat types: Herb, Deciduous/Mixed Shrub, Tall Shrub – Black Spruce, Deciduous/Mixed Forest, Spruce Forest, Riparian/Wetland Deciduous Shrub, Riparian Coniferous Shrub, Riparian Spruce Forest, Open Water, and a classification ('Unknown') for distant (>100 m) or flyover observations that prevented associating birds with habitat (Table 2-3). As a post hoc exercise, ELC ecosite types were assigned to broad habitat types based on the spatial overlap with survey sites with the ELC map and verified using field-based habitat descriptions (Table 2-3). For a complete list of ELC codes, names, and descriptions, see Attachment Table 1 in Section 2.6.1 (Attachment 2-A).

Table 2-3. Avian habitat types developed by grouping modified Predictive Ecosystem Mapping ecosites, based on their similarities in vegetation and structural stages, in the Eagle Plains Project Regional Study Area. *A posteriori* classified ELC ecosites are provided for each habitat type.

Avian Habitat Type	Modified PEM Ecosite	ELC Ecosite[1]	Structural Stages	*N*[2]	Vegetation Description
Herb	230, 310, 400	31, 33, 42, B2	2b, 3b, 3c, 4b	9	Herb dominant sites found along crests and upper slopes, riparian zones, and wetlands; <20% shrub cover.
Deciduous and Mixed Shrub	211-D, 221, 221-D, 231-D, 231-D-ML	06, 22, 23, 31, 33, 34, 35, 42, B2	4a-b	24	Predominantly scrub birch and/or willow vegetation, sometimes with a mix of black spruce; lichen cover possible.
Tall Shrub – Black Spruce	211-SB, 211-SB-ML, 221-SB, 221-SB-LL, 221-SB-ML, 221-SB-HL, 231-SB, 231-SB-HL	05, 06, 14, 20, 23, 33, 34, 42	2b, 4a-b, 6	35	Tall shrub/dwarfed black spruce dominated area often with low to high lichen cover.
Deciduous and Mixed Forest	222, 222-D, 232, 232-D	04, 05, 06, 33, 34	5, 6, 7, 8	13	Birch dominant forest or mix of spruce and deciduous (e.g., birch, aspen, and alder) stands.
Spruce Forest	213-tp, 223-tp, 223-LL-tp, 233-tp, 233-LL-tp, 233-HL-tp	05, 33, 42, B1	6, 7, 8	14	Black spruce dominant forest, sometimes mixed with white spruce, and often with low to high lichen cover. Ranges from intermediate height stands with open canopy to tall and closed canopy forest.
Riparian/Wetland Deciduous Shrub	311-D, 401-D	20, 23, 31, 33, 35, 42, 43, 44	2b, 3b, 4a-b	23	Predominantly scrub birch and willow shrub along riparian zones and wetlands.
Riparian Coniferous Shrub	311-SB, 311-SB-T	22, 33, 35, 42, 43, B1	2b, 4a-b, 6	8	Black spruce and tamarack dominant riparian shrub.
Riparian Spruce Forest	313	22, 23, 31, 35, 42, 43, B2	6, 7, 8	11	Dominated by mix of black and white spruce, as well as spruce hybrids.
Open Water	500	LA, PD	1	17	Non-vegetated open water.
Unknown	UNK	UNK	UNK	74	Unknown habitat due to distant observations (>100 m) or flyovers.

[1] Broad ELC polygons within which survey stations were located.

[2] Sample size, the number of survey stations (point count or pond) within each habitat group.

2.3.3 OCCURRENCE AND DISTRIBUTION SURVEYS

Two experienced bird biologists conducted field surveys in the Project RSA between June 25 to 30, 2019. Each biologist had more than 15 years of experience conducting point count surveys and could reliably identify all bird species by sight and vocalizations that had the potential to occur. All surveys employed a targeted, stratified habitat design to provide sampling across all broad avian habitat types.

2.3.3.1 Breeding Bird Point Count Surveys

'Point count' surveys were conducted in terrestrial habitats following standardized survey methods (Ralph et al. 1995, Resources Inventory Committee 1999a, Matsuoka et al. 2014). Point count stations were visited along walking transects to facilitate efficient survey productivity (i.e., versus individual point counts spaced more widely, which would have resulted in longer travel time and a lower number of survey stations). Point count survey stations were established within a Geographic Information System (GIS) using guided site selection to provide coverage across all avian habitat types and broad spatial coverage across the RSA (Map 2-1). Random site selection approaches were explored but ultimately not used because of challenges associated with safety (steep terrain), logistics (access), and reduced sample sizes (i.e., randomization resulted in much smaller sample sizes due to greater travel times to transect starting stations and between stations). Site selection targeted a minimum of four stations in each habitat type. The location of existing and proposed development features was also considered to ensure the surveys covered those areas. Stations were spaced approximately 500 m apart, with a minimum spacing of 400 m, to avoid counting the same birds from multiple stations. Point count locations were chosen in two ways to associate bird occurrences with habitat types: (1) locating stations within one PEM polygon, at least 100 m from the polygon edge; and (2) locating the station on the boundary between two PEM polygons where the location of birds in different habitat types could be reliably determined (e.g., on the transition between shrubland and forest type). Each point count station was surveyed once to maximize the number of sampled sites.

Survey methods followed standard point count survey methodologies (Ralph et al. 1995, Resources Inventory Committee 1999a, Matsuoka et al. 2014). Surveys used a 10-minute detection period and an unlimited recording distance. Biologists conducted surveys during the dawn chorus (i.e., a half-hour before dawn to ~8:30) when territorial singing rates are highest. Upon arriving at the predetermined survey station location, surveyors evaluated the station location and, where appropriate, revised the location by up to 50 m to aid in accurately plotting bird locations in their associated habitat types. Once on station, surveyors waited two minutes to allow any birds disturbed by the surveyor's arrival to settle and resume their activities. Once the official observation period began, surveyors recorded all birds detected (visual or auditory) during the 10-minute detection period by plotting their locations on a point count map form and recording the standardized four-letter species name abbreviation, time of detection, sex, age, number, behaviour, and the habitat type in which they occurred (i.e., ecosystem unit and structural stage). Surveyors assigned birds estimated to be >100 m distant at a distance of 101 m due to the high uncertainty of estimates at those distances. Following the surveys, a bearing and distance were measured on the point count map from the

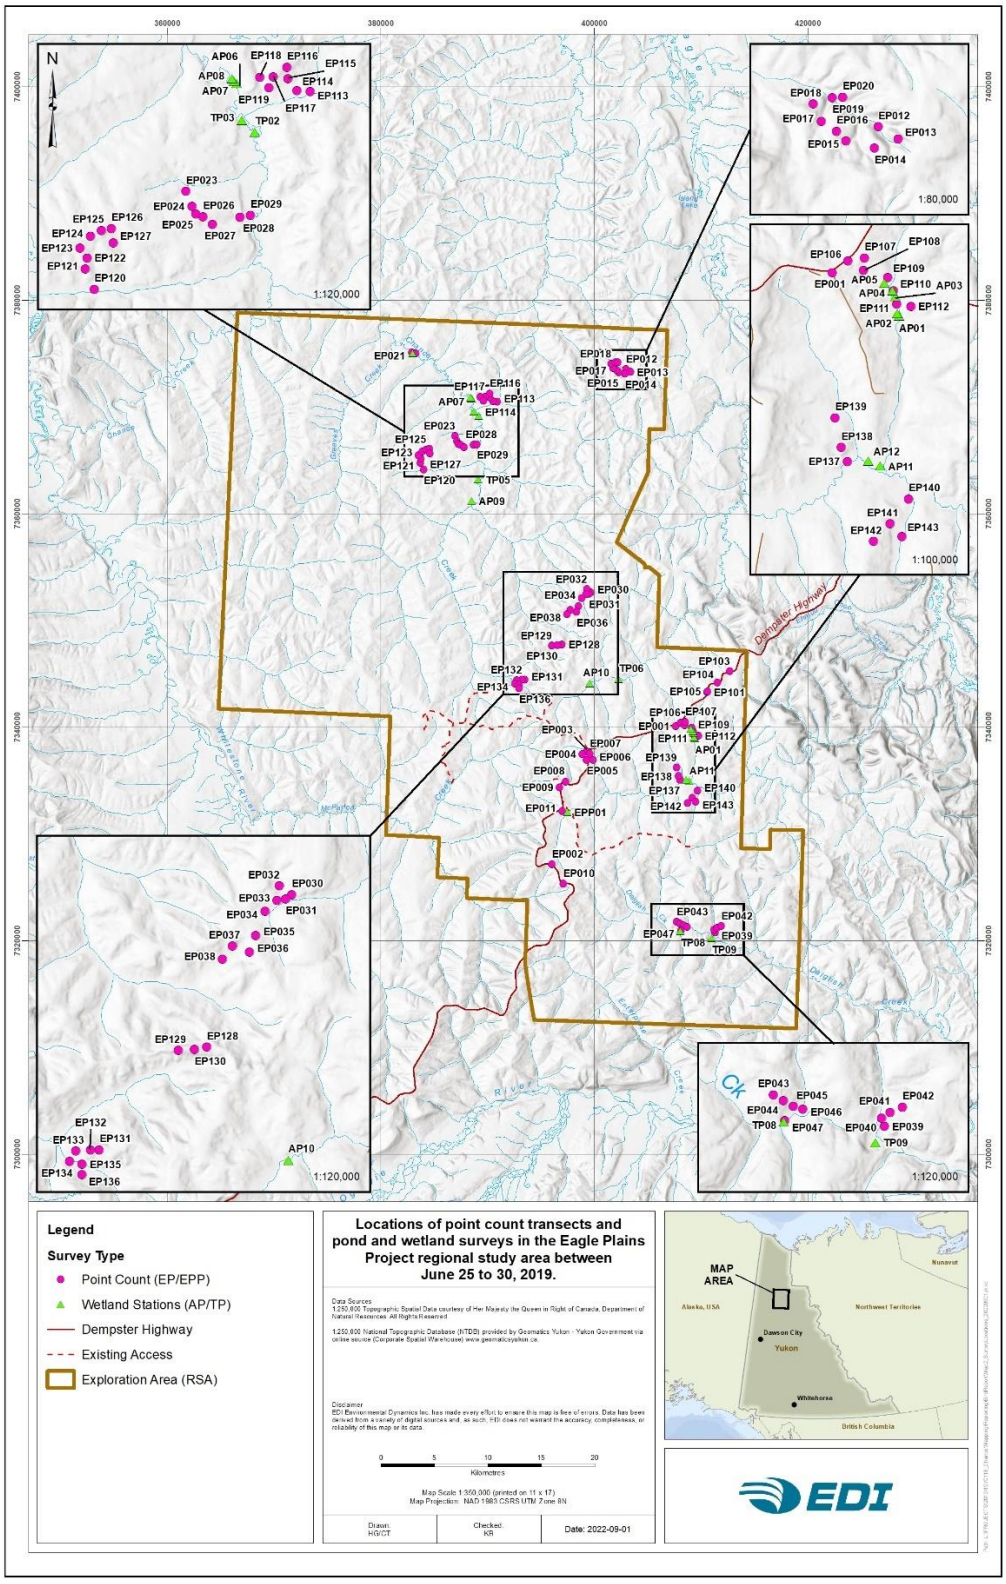
station location for each bird observation (<100 m) used to calculate coordinates for each observation. A total of 91 point count stations were surveyed over six days.

2.3.3.2 Pond and Wetland Surveys

For wetland surveys, protocols were adapted from the BC RISC Standards *Inventory Methods for Waterfowl and Allied Species* (Resources Inventory Committee 1999b). Before surveys, ponds and open water wetlands within 3 km of existing or proposed project development were identified using the PEM map. Shoreline surveys were conducted at 19 unique ponds, and observations were made from stations along the shoreline using binoculars and scopes. The number of stations varied from one to five, depending on the size and shape of the ponds. Approximately half of a pond's total perimeter was traversed along a section of shoreline parallel to the longest axis of the feature to provide complete visual coverage of the waterbody. Surveyors approached waterbodies covertly and began surveys behind screening vegetation to avoid flushing birds from the ponds before they were tallied. Ground-based surveys were thought to provide a census of birds present at each pond. However, a few birds obscured by shoreline vegetation may not have been counted. Biologists recorded the following information for each pond for all detected birds: species, sex, age, number, and habitat associations.

2.3.3.3 Cliff-nesting Raptors Habitat Assessment

Cliff-nesting raptors, including Peregrine Falcon, Gyrfalcon, and Golden Eagle, are relatively common in parts of North Yukon with suitable cliffs, such as the Ogilvie Mountains, south of Eagle Plains. Nesting occurrences of these species are not known in the Eagle Plains area. Due to the subdued topography of the Eagle Plains area, suitable nesting cliffs are likely to be uncommon or non-existent. We systematically assessed the potential for suitable nesting cliffs across the study area by mapping areas with a slope >30 degrees (the lowest gradient in which EDI Environmental Dynamics Inc. (EDI) staff have found cliff nests in other parts of the Yukon). This mapping exercise did not identify any suitable cliffs in the area. Therefore, targeted field surveys for this species group were not conducted.



Map 2-1. Locations of point count transects and pond and wetland surveys in the Eagle Plains Project Regional Study Area between June 25 to 30, 2019.

2.4 RESULTS AND DISCUSSION

2.4.1 DESKTOP ASSESSMENT

Based on range and habitat requirements, 128 species can occur in the Eagle Plains Project RSA. This includes 99 'Likely' species (52 confirmed by surveys and incidental observations presented in this report) and 29 'Possible' species. These 'Possible' species included Common Nighthawk (*Chordeiles minor*) observed once in the RSA during these surveys. Despite the confirmed occurrence, the species is still considered 'Possible' because it is outside its regular range, and none were observed during NABBS between 2014 and 2018 (i.e., the single observation during these surveys could have been an extralimital record). A summary of these potential species and conservation statuses, ordered by species groups, is provided in Table 2-4. A more detailed discussion of the species identified within the Project RSA is provided in Section 2.4.2. For an exhaustive list of all potential bird species, see Attachment Table 2 in Section 2.6.2 (Attachment 2-B).

The NABBS database is a valuable information source for the occurrence and distribution of bird species in the region because they are a recent and systematic survey. Of the two survey routes near the Project area (i.e., routes 78 and 79), route 79 was surveyed annually between 2014 and 2018, and route 78 was surveyed in each of those years except 2016. In total, observers who participated in these surveys identified 1,945 birds from 48 species (Table 2-4). Though these data are useful in identifying species common to the region, road-side surveys introduce bias in estimating species occurrences and relative abundances, especially when extrapolating to off-road areas (Sólymos et al. 2020). This may explain why 'Possible' species (e.g., Harlequin Duck [*Histrionicus histrionicus*], Surfbird [*Calidris virgata*], and Golden-crowned Sparrow [*Zonotrichia atricapilla*]) were recorded on the NABBS routes but not within the RSA, and why 18 species confirmed during surveys within the RSA (e.g., Red-necked Phalarope [*Phalaropus lobatus*], Great Gray Owl [*Strix nebulosa*], and American Three-toed Woodpecker), were not detected over five years of road-side surveys.

Overall, species occurrence and relative abundance patterns differed among years in both NABBS routes. The total number of detections decreased from 2014 to 2018, and this pattern was consistent for most bird species. This may partly correspond to the survey effort. The number of species identified and the number of birds detected were similar between route 78 (920 counts from 34 species) and route 79 (1,025 counts from 39 species) during the five-year period. No species-specific trends were evident in the data.

The NABBS data also included three species (six detections) federally designated as Special Concern: Short-eared Owl (*Asio flammeus*; one occurrence in both 2015 and 2016, and two occurrences in 2018), Rusty Blackbird (*Euphagus carolinus*; one occurrence in 2015), and Olive-sided Flycatcher (*Contopus cooperi*; one occurrence in 2018).

Table 2-4. Total number of potential (likely and possible) bird species in the Eagle Plains Project Regional Study Area, June 2019, grouped by higher-order classification. North American Breeding Bird Survey (2014–2018) confirmed species and counts are provided.

Order	Likely	Possible	Likely + Possible (Total)	NABBS Confirmed (2014–2018)[1]
Grebes – Podicipediformes	2	0	2	0

[1] Count of individual bird observations for each group in brackets.

2.4.2 OCCURRENCE AND RELATIVE ABUNDANCE

A total of 974 birds from 52 species were detected during the breeding bird surveys (i.e., point count transects and wetland/pond surveys). One raptor species not included in these counts—Swainson's Hawk—was identified, incidentally, on four separate occasions between June and August 2019, totalling five individuals. These additional observations bring the number of total detections to 979 birds from 53 species.

Songbirds (*Passeriformes*) were the most diverse and abundant group of birds, while falcons (*Falconiformes*), owls (*Strigiformes*), and nightjars (*Caprimulgiformes*) were the least diverse and abundant (Table 2-5). Proportionally, more waterfowl and shorebirds were identified during wetland/pond surveys, and more songbirds and raptors were identified during point count transects. More birds were counted during point count transects (743 versus 231), but a similar number of species were identified during point counts transects and wetland/pond surveys (42 in point counts and 37 in wetlands; Table 2-5).

Table 2-5. Total counts and species of birds observed during point count transects and wetland/pond surveys in the Eagle Plains Project Regional Study Area, June 2019, grouped by higher-order classification.

Order	Point Count Transects		Wetland/Pond Surveys		Combined	
	Count	No. Species	Count	No. Species	Count	No. Species
Waterfowl – Anseriformes	3	2	99	7*	102	7
Shorebirds – Charadriiformes	18	4	38	7*	56	7

2.4.3 SPECIES AND HABITAT ASSOCIATIONS

Analyses of the association between bird species and habitat type controlled for survey effort (i.e., average counts per point count station). The average number of birds (i.e., relative abundance) and the average number of species varied considerably among survey stations and the different avian habitat types (Figure 2-1; Table 2-6). The average relative abundance was greatest in Open Water, Deciduous and Mixed Shrub, Riparian/Wetland Deciduous Shrub, and Spruce Forest habitats; it was lowest in Riparian Spruce Forest, Herb, and Tall Shrub – Black Spruce habitats. Among habitat types, the proportion of (average) detections to the (average) number of species was consistent, with a higher relative abundance being associated with a greater number of species. In general, this pattern was related to the structural complexity and productivity of the various habitat types. For example, Herb habitat is less structurally complex and consists exclusively of graminoid ground cover; it had the fewest species (but had a relatively high number of unique species; see Figure 2-2). In contrast, Spruce Forest habitat can be structurally complex due to variations in canopy cover, understory, and ground cover, and older stands may contain a variety of forest structures that provide habitat for a variety of bird species and life requisites including nesting (e.g., Yellow-rumped Warbler), perching (e.g., Olive-sided Flycatcher), and insect foraging (either on the ground [e.g., Gray-cheeked Thrush] or on live/dead trees [e.g., American Three-toed Woodpecker]). Consequently, Spruce Forest had the greatest species richness of all avian habitat types. The exception to the general association between relative abundance and species richness was Open Water habitat, which had the highest relative abundance but one of the lowest average number of species.

The number of species (i.e., species richness) and the number of unique species (i.e., species exclusive to a habitat type) were summarized for each avian habitat type. Unequal survey effort across habitat types could bias such comparisons of species totals across habitat types; however, it does provide a useful approach to examine general patterns of bird occurrence and assemblages within and across habitat types. Spruce Forest, Riparian/Wetland Deciduous Shrub, and Deciduous and Mixed Shrub habitat types had the greatest species richness, while Herb and Open Water habitat types had the least species richness (Figure 2-2). Patterns of species richness may, in part, be due to the distribution of survey stations in each habitat type, especially in Herb habitat (only nine stations). The Open Water habitat also had low species richness despite surveys at 17 survey stations. This may reflect the limited availability of waterbodies and wetlands in the broader region (i.e., relatively few water-associated bird species occur because the habitat is so limited and dispersed).

No clear association was found between species richness and the number of unique species. For example, Open Water was one of the least species-rich habitat types but had the most unique species. This is not surprising because Open Water is a unique habitat compared to the other terrestrial habitats, and a different complement of bird species occurs there. Other habitat types with many species (e.g., 21 species in Deciduous and Mixed Shrub) had no species unique to those habitats. Likely, riparian habitat types did not have unique species because species that occupy riparian habitat often have broad, rather than specific, requirements. For example, Rusty Blackbird and Lesser Yellowlegs were found in Riparian Coniferous Shrub, Riparian/Wetland Deciduous Shrub, and Herb habitat types.

Patterns of bird occurrences were analyzed in terms of species-specific detection rates (Table 2-6). Songbird species had the highest detection rates overall because these species consistently occupied several different habitat types. Only 15 species occupied a single habitat, and the remaining 47 species occupied multiple habitats (most frequently two or three habitats; Figure 2-3). Species that occupied four or more habitat types were exclusively songbirds and had the highest detection rates. This included species groups such as thrushes, sparrows, and their respective allies. Only 10 species occurred in six or more habitats: Canada Jay, American Robin, Gray-cheeked Thrush, Swainson's Thrush, Common Redpoll, Fox Sparrow (*Passerella iliaca*), White-crowned Sparrow (*Zonotrichia leucophrys*), American Tree Sparrow, Lincoln's Sparrow, and Yellow Warbler. Overall, species with high detection rates included a combination of habitat specialists and habitat generalists. Waterfowl and obligatory wetland species (e.g., Red-necked Phalarope), which were restricted to Open Water habitat, had high detection rates in that habitat (Table 2-6).

In contrast, thrushes (e.g., Gray-cheeked Thrush) and warblers (e.g., Yellow Warbler), which occupied several different habitat types, had high detection rates in many of the habitats they occupied (Table 2-6). The five species with the highest overall (average) detection rates (i.e., across all 110 survey stations in the RSA) were Canada Jay, Swainson's Thrush, Lincoln's Sparrow, White-crowned Sparrow and Yellow-rumped Warbler. For a general overview of bird species assemblages within each habitat type, ordered by highest to lowest detection rates, see Table 2-7. General patterns of frequency and use of habitat types by species in the RSA are consistent with expectations and correspond to patterns reported in other studies (Schieck and Song 2006, Mahon et al. 2016).

[2] Values in the column headings indicate the number of samples per habitat type.

2.4.4 SPECIES OF CONSERVATION CONCERN

Four species observed in the Project RSA (Red-necked Phalarope, Common Nighthawk, Olive-sided Flycatcher, and Rusty Blackbird) were federally listed as either Special Concern or Threatened (Table 2-8). These species are either of regional, national, or continental concern, and two are designated with regional stewardship in BCR 4. The conservation statuses of all potential bird species in the Project area are listed in Attachment Table 2 in Section 2.6.2 (Attachment 2-B). Of those species, three additional species of Conservation Concern are likely to occur in the Project RSA, including Horned Grebe (*Podiceps auritus)*, Short-eared Owl, and Bank Swallow (Table 2-8). Two cliff-nesting raptors listed as 'specially protected' species under the Yukon *Wildlife Act*, Peregrine Falcon and Gyrfalcon, can occur in the broader region but are unlikely to occur in the Project RSA because of a lack of appropriate cliffs. Another 'specially protected' species, Trumpeter Swan (*Cygnus buccinator*; not listed below), is exclusive to southern Yukon and Alaska during the breeding season and, thus, is unlikely to occur in the Project RSA.

Table 2-8. The conservation status and counts of bird species in the Eagle Plains Project RSA.

Species Common Name	COSEWIC[4]	SARA[5]	BCR 4 Priority[6]	Yukon *Wildlife Act*	RSA Count	NABBS Count (2014–2018)
Horned Grebe[1]	SC (Apr 2009)	1 – SC	R – stewardship N/C – concern	No	0	0
Red-necked Phalarope	SC (Nov 2014)	1 – SC	N/C – concern	No	15	0
Peregrine Falcon[2]	NAR (Nov 2017)	–	R – stewardship N/C – concern	Yes	0	0
Gyrfalcon[2]	NAR (Apr 1987)	–	–	Yes	0	0

			Totals		**41**	**6**

[1] Species that are 'Likely' to occur in the Eagle Plains Project RSA.

[2] Cliff-nesting raptors that are 'Likely' to occur in the broader region, but do not have suitable habitat in the Eagle Plains Project RSA.

[3] A species that is 'Possible' in the Eagle Plains Project RSA because of its range limits. One occurrence was observed but status remains uncertain.

[4] Most recent COSEWIC assessments; E = Endangered, NAR = Not at Risk, SC = Special Concern, T = Threatened.

[5] SARA statuses from the latest amended list in May 2023 (Legislative Services Branch 2023); Schedule 1 codes equivalent to COSEWIC.

[6] Priorities, concerns, and stewardships from BCR 4 2013 report; C = Continental, N = National, R = Regional.

2.4.5 ADEQUACY OF ONE YEAR OF SURVEYS

The official guidance provided by the Canadian Wildlife Service for avian baseline studies usually is to conduct at least two years of field surveys (Hanson et al. 2009), and the DRAFT 2022 guidelines emphasize a statistical review of the power to detect changes (ECCC-CWS 2022). Repeat surveys account for annual variation in patterns of bird occurrences and distribution and imperfect detectability associated with bird survey methods. During our initial consultation with CWS we proposed conducting a single year of surveys, dependent on the outcome of the surveys. CWS indicated that they always prefer to see multiple years of data collected. However, they may not raise objections to the Project Proposal if significant avian conservation concerns or information uncertainties do not occur. In our opinion, the one year of multi-species field surveys that we conducted, in combination with the desktop assessment, provides sufficient baseline information about bird species to proceed with the Project Proposal.

2.5 SUMMARY

The purpose of this study was to document the potential occurrence, relative abundance, and habitat associations of birds across the Project's RSA. This study consisted of a combination of a desktop assessment and field surveys. The information presented in this report was collected by Professional Biologists and qualified environmental practitioners, following generally accepted scientific survey designs and methods. The field survey design used a targeted, stratified habitat design to provide a representative sample across the RSA.

Based on range and habitat, 128 species potentially occur in or adjacent to the RSA. Forty-eight (48) were recorded from the North American Breeding Bird Survey data in adjacent areas. Possible species include eight listed under the SARA or identified in the Yukon *Wildlife Act*, and 67 are considered a priority and management concern under the federal Bird Conservation Region 4 Plan. Birds listed under the SARA observed during surveys included Red-necked Phalarope, Common Nighthawk, Olive-sided Flycatcher, and Rusty Blackbird.

Field surveys observed 53 species in the RSA. Point counts identified 42 species, and wetland surveys identified 37 species. Swainson's Hawk was identified via incidental sightings and is an interesting species. It has a disjunct breeding range in North Yukon separated by several hundred kilometres from their primary range to the south. Patterns of species relative abundance and richness (number of species) varied among the different habitat types. Average relative abundance and species richness were the greatest in Spruce Forest, Deciduous and Mixed Shrub, Riparian/Wetland Deciduous Shrub habitats, and lowest in Herb and Tall Shrub – Black Spruce habitats. These patterns were generally related to the structural complexity and productivity of these different habitat types. However, the number of unique species in each habitat did not depend on structural complexity. Many unique species were found in the Herb and Open Water habitats. General patterns of bird occurrence and habitat associations in the RSA are consistent with expectations and correspond with the limited existing information about birds in the area.

2.6 BIRD SECTION ATTACHMENTS

2.6.1 ATTACHMENT 2–A — ECOLOGICAL AND LANDSCAPE CLASSIFICATION ECOSYSTEM UNITS

Ecological and Landscape Classification (ELC) Ecosystem Units (Ecosites)

Codes, names, and descriptions of ecosites assigned *a posteriori* to habitat groups in the Project RSA are listed below.

Attachment Table 1. Ecological Landscape Classification ecosystem units developed for the Eagle Plains Project Regional Study Area.

Code	Name	Description and typical situation
10	Sparsely Vegetated	Vegetative cover <10%.
11	Dry Herb	Area dominated with herbaceous vegetation with very low shrub cover (<5%).
12	Dry Lichen	*Cladonia* sp. (i.e., caribou forage species) dominated areas with very low shrub cover (<5%) typically on south facing slopes.
13	Dry Mix Shrub	Dry shrub dominated areas with very low *Cladonia* sp. (i.e., caribou forage species) cover (<10%); disclimax community.
14	Dry Shrub/ Spruce – Lichen	Dry areas with spruce cover >5% and *Cladonia* sp. (i.e., caribou forage species) cover >10%.
15	Dry Shrub/ Aspen – Lichen	Dry areas with aspen cover >5% and *Cladonia* sp. (i.e., caribou forage species) cover >10%.
16	Dry Spruce – Birch – Lichen	Dry areas with either white spruce, black spruce, and/or Alaskan paper birch cover; spruce, scrub birch, and *Cladonia* sp. (i.e., caribou forage species) cover >10%.
17	Dry Aspen	Dry areas with aspen dominant canopy and very low *Cladonia* (i.e., caribou forage species) cover (<5%).
01	Mesic Herb	Area dominated by herbaceous vegetation with very low shrub cover (<5%); neither disclimax nor successional pathway known. No distinct mottles or seepage present; some sites may have permafrost (frozen layer contains no ice crystals or ice layers).
02	Mesic Birch – Willow	Area has a history of anthropogenic disturbance; regeneration is dominated by either Alaskan paper birch and/or willow species. No distinct mottles or seepage present, some sites may have permafrost (frozen layer contains no ice crystals or ice layers).
03	Mesic White Spruce – Alaskan Paper Birch – Alder	Area dominated by Alaskan paper birch with mixed-wood understory (i.e., white spruce and alder). Usually found along upper slope to crest positions on gentle to moderate slopes. No distinct mottles or seepage present, some sites may have permafrost (frozen layer contains no ice crystals or ice layers).
04	Mesic Black Spruce – Alaskan Paper Birch	Area dominated by black spruce and Alaskan paper birch with >30% shrub cover; mid-slope position. No distinct mottles or seepage present, some sites may have permafrost (frozen layer contains no ice crystals or ice layers).
05	Mesic Alaskan Paper Birch	Area dominated by Alaskan paper birch stands with > 30% shrub cover; mid- to upper-slope position. No distinct mottles or seepage present, some sites may have permafrost (frozen layer contains no ice crystals or ice layers).
06	Mesic Black Spruce – Labrador Tea	Area dominated by black spruce with Labrador tea shrub layer; level or mid- to upper-slope position on gentle slopes. No distinct mottles or seepage present, some sites may have permafrost (frozen layer contains no ice crystals or ice layers).

Code	Name	Description and typical situation
20	Shrubby Riparian Birch – Willow	Shrubby riparian area dominated by scrub birch, tea-leaved willow, or diamond leaved willow and bog cranberry; disclimax community.
21	Riparian White Spruce – Prickly Rose	Treed riparian zone dominated by white spruce with a mixture of shrub species; rose usually present.
22	Riparian Spruce – Birch – Willow	Treed riparian zone dominated by white and black spruce, possibly some Alaskan paper birch, and a mixture of shrub species such as scrub birch and willow.
30	Moist Herb	Area dominated with herbaceous vegetation with very low shrub cover (<5%) on gentle to moderate slopes. Faint to distinct mottles can be observed; no seepage or slight seepage present. Permafrost is present but at variable depths; some ice crystals can be observed in frozen layer.
31	Moist Shrub/ Scrub Birch – Labrador Tea – Willow	Area dominated by scrub birch and Labrador tea with <10% spruce cover; shrub layer has tea-leaved willow. Typically found at level or mid- to upper-slope position on gentle slopes. Successional pathway unknown but considered a shrub disclimax site. Faint to distinct mottles can be observed; no seepage or slight seepage present. Permafrost is present; some ice crystals can be observed in frozen layer.
32	Moist Shrub/ Spruce – Scrub Birch – Labrador Tea	Area dominated by >10% spruce cover, <5% willow cover, and >15% lowbush cranberry. Typically found at mid to upper slope position on gentle slopes; disclimax community. Faint to distinct mottles can be observed; no seepage or slight seepage present. Permafrost is present but at variable depths; some ice crystals can be observed in frozen layer.
33	Moist Spruce – Labrador Tea	Area dominated by >15% spruce tree cover. Presence of *Cladonia* sp. (i.e., caribou forage species). Typically found at level or upper-slope position on gentle slopes. Faint to distinct mottles can be observed; no seepage or slight seepage present. Permafrost is present but at variable depths due to frost boils; some ice crystals can be observed in frozen layer.
34	Moist Spruce – Alder – Labrador Tea	Area dominated by >15% spruce tree cover; alder and *Cladonia* sp. (i.e., caribou forage species) present. Typically found at mid-slope position on gentle slopes. Faint to distinct mottles can be observed; no seepage or slight seepage present. Permafrost is present but at variable depths due to frost boils; some ice crystals can be observed in frozen layer.
35	Moist Spruce – Scrub Birch – Labrador Tea	Area dominated by <15% spruce tree cover with *Cladonia* sp. (i.e., caribou forage species) present. Typically found at level or gentle slopes. Faint to distinct mottles can be observed; no seepage or slight seepage present. Permafrost is present but at variable depths due to frost boils; some ice crystals can be observed in frozen layer.
36	Moist Birch – Willow	Area dominated by willow and birch trees, often associated with old anthropogenic disturbances; successional pathway unknown. Faint to distinct mottles can be observed; no seepage or slight seepage present. Permafrost is present but at variable depths due to frost boils; some ice crystals can be observed in frozen layer.
40	Wet Herb	Area dominated with herbaceous vegetation with very low shrub cover (<5%) on level to lower-slope positions. Distinct to prominent mottles; seepage present; permafrost near surface. Ice layer present within or above frozen soil or frozen organic layer.
41	Wet Shrub – Tamarack	Area with >5% tamarack; low presence of *Cladonia* sp. (i.e., caribou forage species) and high presence of *Sphagnum* sp. or glow moss. Scrub birch and Labrador tea present. Distinct to prominent mottles; seepage present; permafrost near surface. Ice layer present within or above frozen soil or frozen organic layer.
42	Wet Shrub – Black Spruce – Tussock Cottongrass	Area dominated by >5% black spruce and >10% tussock cottongrass. Labrador tea, scrub birch, *Sphagnum* sp. and *Cladonia* sp. (i.e., caribou forage species) present. Typically found on level ground but also from toe to mid-slope positions; disclimax community. Distinct to prominent mottles; seepage present; permafrost near surface. Ice layer present within or above frozen soil or frozen organic layer.

Code	Name	Description and typical situation
43	Wet Shrub – Black Spruce – Sphagnum	Area dominated by >5% black spruce, <10% tussock cottongrass, and >25% *Sphagnum* sp.; disclimax community. Distinct to prominent mottles; seepage present; permafrost near surface. Ice layer present within or above frozen soil or frozen organic layer.
44	Wet Shrub – Scrub Birch – Tussock Cottongrass	Area dominated by <5% black spruce, >10% scrub birch, and >30% tussock cottongrass; disclimax community. Distinct to prominent mottles; seepage present; permafrost near surface. Ice layer present within or above frozen soil or frozen organic layer.
45	Wet Shrub – Scrub Birch – Graminoid	Burned area composed of <5% black spruce; dominant shrub is scrub birch, while dominant graminoid is either spruce muskeg sedge or bluejoint reedgrass; disclimax community. Distinct to prominent mottles; seepage present; permafrost near surface. Ice layer present within or above frozen soil or frozen organic layer.
46	Wet Black Spruce – Labrador Tea – Cladonia	Area with >15% black spruce, >20% *Cladonia* sp. (i.e., caribou forage species), and <5% tussock cottongrass. Distinct to prominent mottles; seepage present; permafrost near surface. Ice layer present within or above frozen soil or frozen organic layer.
47	Wet Black Spruce – Tussock Cottongrass – Sphagnum	Area with >15% Labrador tea and <10% *Cladonia* sp. (i.e., caribou forage species). Distinct to prominent mottles; seepage present; permafrost near surface. Ice layer present within or above frozen soil or frozen organic layer.
48	Wet Black Spruce – Carex	Area dominated by either a spruce muskeg sedge or bluejoint reedgrass herbaceous layer; shrub layer is a mixture of Labrador tea, scrub birch, and willow species with >30% cover. Distinct to prominent mottles; seepage present; permafrost near surface. Ice layer present within or above frozen soil or frozen organic layer.
B1	Bog – Black Spruce – Lichen	Treed or shrubby peatland ecosystem unit with poor nutrient regime within the rooting zone. Stunted black spruce with <50% *Sphagnum* sp. and >10% *Cladonia* sp. (i.e., caribou forage species) ground cover.
B2	Bog – Black Spruce – Sphagnum	Treed or shrubby peatland ecosystem unit with poor nutrient regime within the rooting zone. Stunted black spruce with >50% *Sphagnum* sp. ground cover.
F	Fen	Treed, shrubby, or graminoid peatland ecosystem unit where groundwater inflow maintains relatively high mineral content within the rooting zone. Graminoid fen has >20% *Sphagnum* sp. or moss cover.
M	Marsh	Shallowly flooded mineral wetland ecosystem dominated by emergent vegetation. Area dominated by graminoids and has less than 10% Sphagnum or moss cover.
S	Swamp	Treed or shrubby mineral wetland ecosystem unit with a flowing or fluctuating, semi-permanent, near-surface water table.
W	Shallow Water	Shallow water ecological communities dominated by rooted, water submerged, and floating aquatic plants.
AN	Anthropogenic	An area of anthropogenic disturbance not included in other definitions (e.g., areas cleared for camps).
ES	Exposed Soil	Any area of exposed soil not included in other definitions. Includes areas of recent disturbance (e.g., terrain slides) and human-made disturbances where vegetation cover is <5%.
Fa	Flood Active Channel	Ecological communities scoured by river floodwaters for prolonged periods. Usually dominated by annuals or herbs that can re-sprout from underground structures.
LA	Lake	A body of water >2 m deep or large enough to be classified as a lake (>8 ha).
PD	Pond	A small body of water greater than 2 m deep, but not large enough to be classified as a lake (<8 ha).

Code	Name	Description and typical situation
Rc	Rock Cliff	Ecological communities of vertical rocky sites commonly with some bryophyte cover (rock crusts); small pockets of soils may support vascular vegetation. Also used to map non-vegetated cliffs.
RI	River	A watercourse formed when water flows between continuous, definable banks. The flow may be intermittent or perennial.
Ro	Rock Outcrop	Bluffs and knobs of solid rock with limited soil development and high cover of exposed rock; drought tolerant cryptogams often prominent.
Rt	Rock Talus	Active and inactive talus (i.e., large rocks) and scree (i.e., smaller rocks and more soil); small pockets of soils may support some vascular plants.
RZ	Road	An area cleared and compacted for the purpose of transporting goods and services by vehicle.

2.6.2 ATTACHMENT 2–B — LIST OF ALL POTENTIAL BIRD SPECIES AND THEIR CONSERVATION STATUSES

All bird species with the potential to occur in the Project area:

Names, federal conservation statuses (SARA, COSEWIC), BCR 4 priority, territorial status (i.e., species highlighted by Environment Yukon and those considered of conservation concern in the Yukon Conservation Data Centre track list), and indication of occurrence in the Project RSA for all 128 bird species, are listed below:

Attachment Table 2. List of species with the potential to occur in the Eagle Plains Project Regional Study Area.

Species Common Name[1]	Documented in RSA[2]	COSEWIC[3]	SARA[4]	Environment Yukon (YCDC Track List)[5]	BCR 4 Priority Species[6]
Horned Grebe [L]		SC (Apr 2009)	1 – SC	*	R – stewardship N/C – concern

3 MARTEN

3.1 PURPOSE AND OBJECTIVES

American marten (*Martes americana*; hereafter marten) were selected as a Valued Component (VC) for the Project due to their value as a furbearer, as well as their relevance as an indicator species for mature and old forest values (Buskirk and Ruggiero 1994, Suffice et al. 2017). The VGFN have a community trapline within the RSA and value marten as a furbearer for its economic value, social values associated with trapping, and environmental values as a component of the regional wildlife community.

This section provides a summary of marten ecology in the subarctic taiga. That information is used to develop a habitat model to quantify the quality, amount, and distribution of potential marten habitat across the RSA. A Habitat Suitability Index (HSI) model was developed using relevant environmental data in a GIS to quantify the amount of marten habitat into relative quality categories (i.e., High, Moderate, Low, and Nil/Very Low).

3.2 TRAPPING

According to trapping records, marten were the most heavily trapped species in the two group trapping concessions that overlap the RSA between 2012 and 2018 (Figure 3-1,). Between 2012 and 2018, 715 marten were reported from the two concessions (i.e., 401, 402) overlapping the RSA. The number of marten reported varied widely among the trapping seasons: the greatest harvest was 240 marten reported in 2015 compared to the lowest harvest of 0 marten the following year. Unfortunately, trapping records from 2019 onwards were unavailable for those concessions.

Trapping mortality in marten is biased towards males and juveniles, and harvests that include a high proportion of adult females indicate potential overharvesting (Strickland and Douglas 1987, Hodgman et al. 1994, Fortin and Cantin 2005). Exhaustive trapping removes resident adult marten from the population and allows juveniles to establish home ranges in vacant areas, thus lowering the overall age of the population. Juveniles have lower reproductive output relative to adults; therefore, this change in age structure can lower population fecundity and growth rates (Archibald and Jessup 1984, Fortin and Cantin 2005). Without knowledge of the age and sex structure of harvested marten, it is not possible to assess the sustainability of trapping in the RSA.

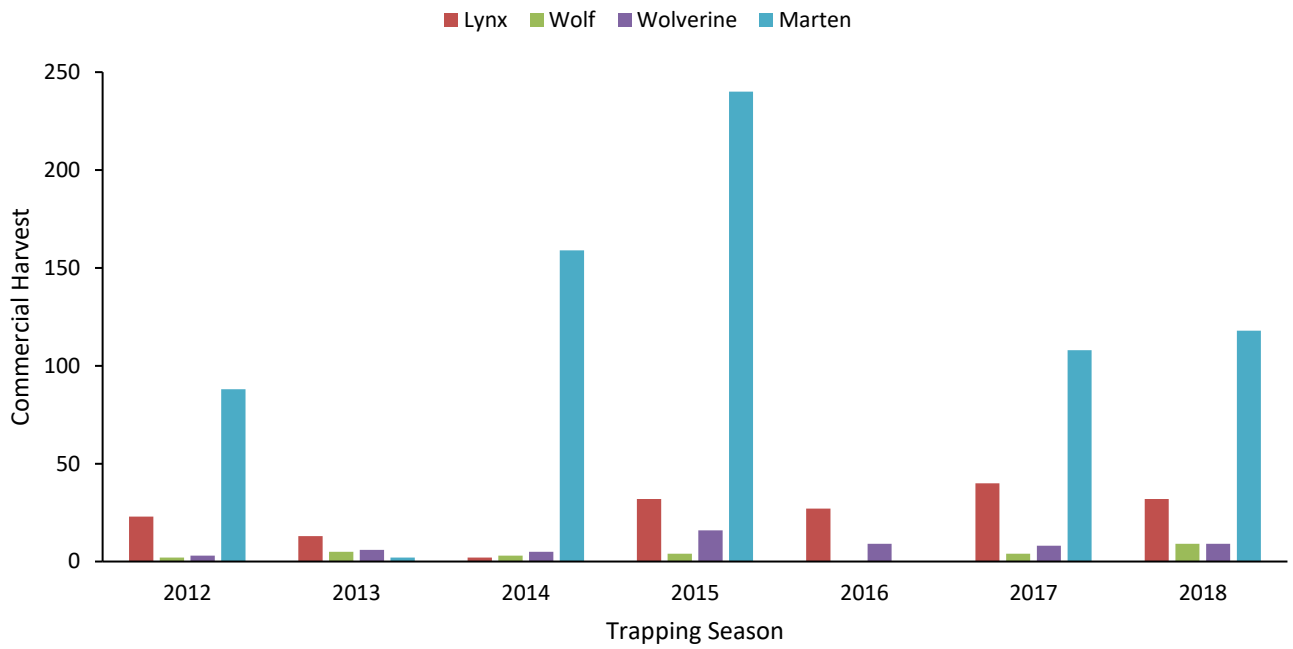

Figure 3-1. Commercial harvest returns for group trapping concessions overlapping the RSA for which records were available.

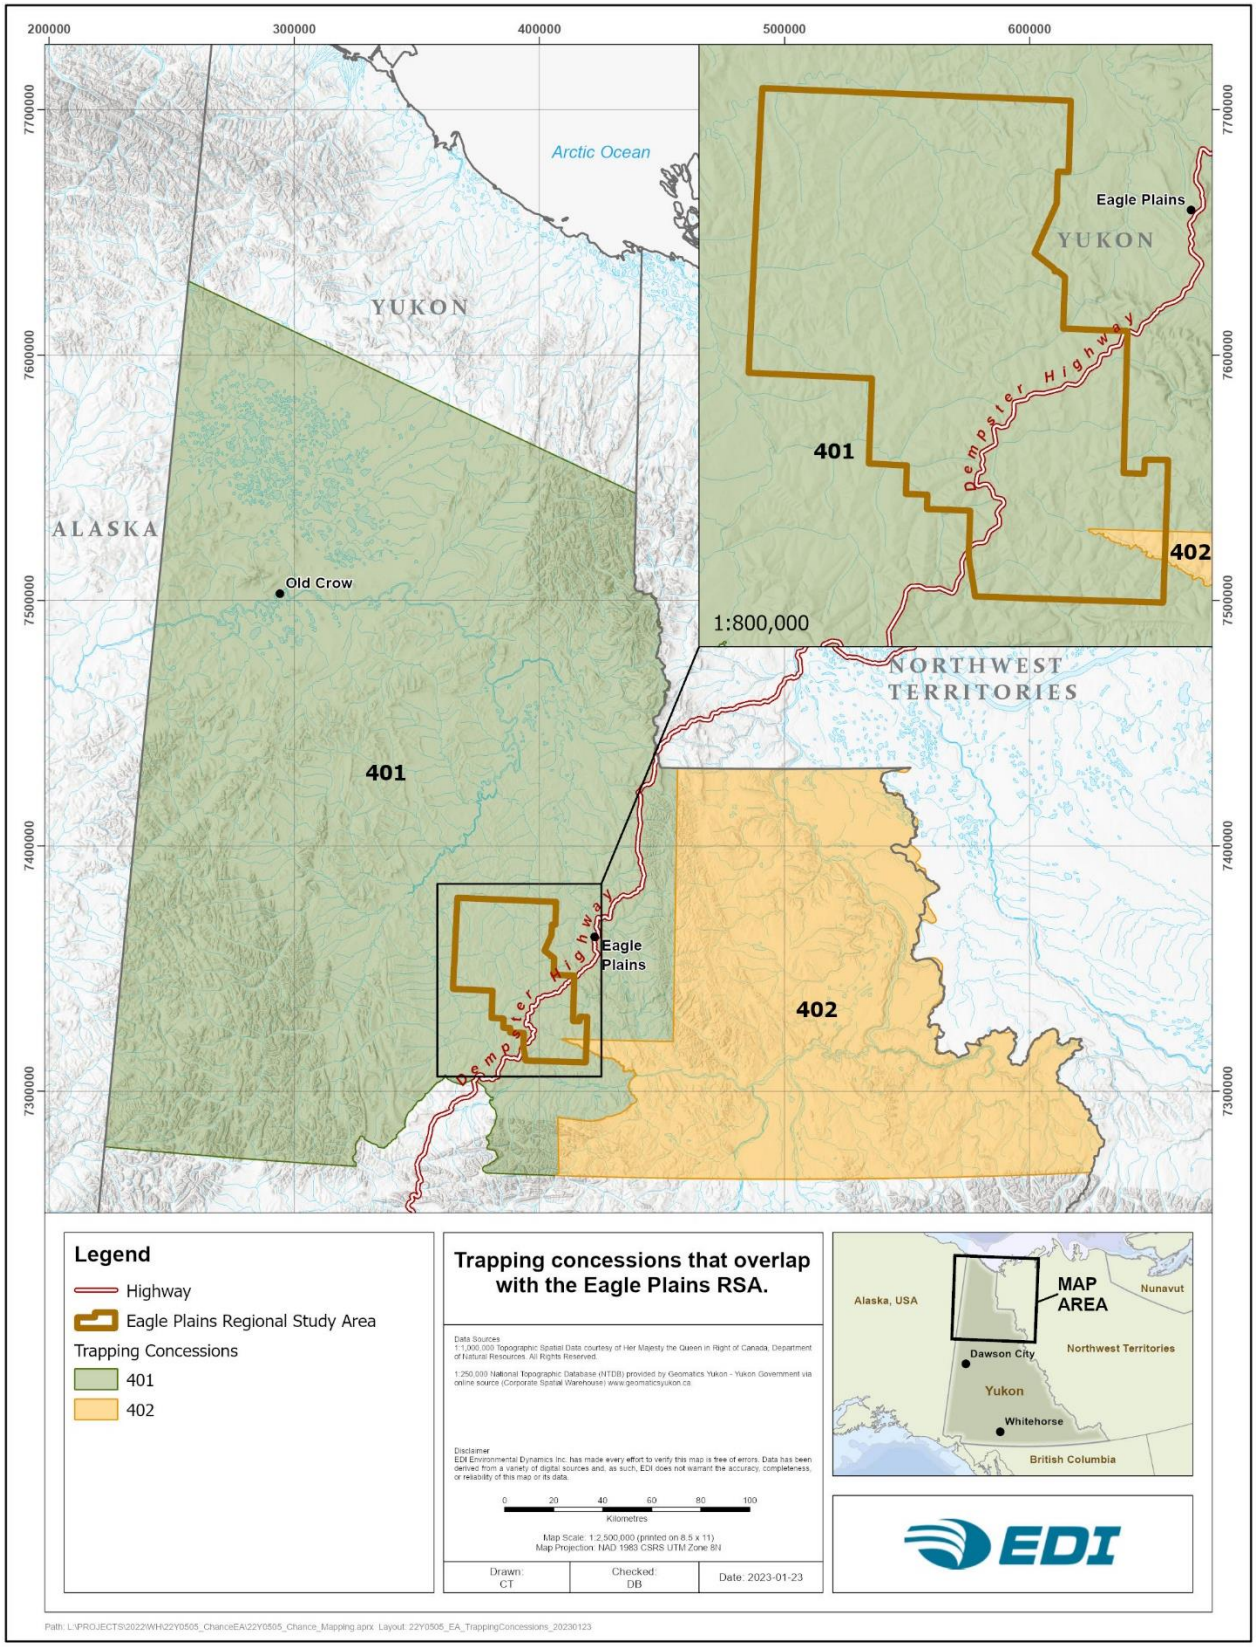

Map 3-1. Trapping concessions that overlap with the Eagle Plains RSA.

3.3 GENERAL HABITAT ECOLOGY OF MARTEN

The RSA occurs in the boreal taiga, at the northern limit of marten range (Buskirk and Ruggiero 1994, Yukon Ecoregions Working Group 2004a). While marten occur over a contiguous range across northern North America from Labrador to Alaska (Snyder and Bissonette 1987, Buskirk and Ruggiero 1994, Drew 1995, Paragi et al. 1996), little is known about their basic ecology in northern boreal forest and taiga ecosystems (Latour et al. 1994). In more productive forests to the south, marten are often associated with mature forest structures, such as large trees, snags, and coarse woody debris (CWD; Buskirk and Ruggiero 1994, Thompson et al. 2012). However, there is some evidence that in northern boreal forests, marten exploit structural stages with short, stunted trees that are sparsely distributed (Latour et al. 1994, Paragi et al. 1996). Marten in the Alaskan taiga selected habitat types with the greatest amount of CWD and the greatest abundance of vole, rather than canopy cover (Paragi et al. 1996). Across the Yukon forest-to-tundra ecotone, marten preferred open taiga areas rather than boreal forest, and were positively associated with small mammal (i.e., taiga vole [*Microtus xanthognatus*], and red-backed vole [*Myodes* spp.]) biomass (Pretzlaw 2006). Therefore, occurrence and habitat selection patterns for marten in northern boreal and taiga ecosystems can differ from those described elsewhere in North America (Pretzlaw 2006).

During 2015 and 2016, EDI performed snow tracking surveys to quantify the presence and distribution of furbearers and ungulates south of Dawson, Yukon (EDI Environmental Dynamics Inc. 2017). Snow tracking transects covered various habitat types, including 49% shrub, 13% coniferous, 10% herbs, 8% exposed land, 7% frozen rivers, and 13% other classes (i.e., broadleaf, mixedwood, rock/rubble, wetland). Marten tracks occurred in shrubland 51% of the time, coniferous forest 15% of the time, and herb sites 10% of the time. These results indicate that marten occurred across all major vegetated habitat types approximately in proportion to their availability on the landscape (EDI Environmental Dynamics Inc. 2017).

Home ranges of marten in the taiga are larger than in other regions of North America (Latour et al. 1994). In the Mackenzie Valley, NWT, mean home range sizes of adult males were 1,420 ha, and those of adult females were 680 ha. Overall, mean home range size of adult marten was 1,110 ha (Latour et al. 1994). In contrast, the average size of a marten home range in British Columbia (BC) is 525 ha for males and 316 ha for females, and in Ontario, the size of a typical marten home range is between 390 and 660 ha (Lofroth 1993, Manlick et al. 2017a). Marten density in the taiga (the carrying capacity) is likely limited by the availability of arboreal cavities for natal denning, subnivean CWD sites and underground shelters, small mammal abundance, predation, and intraguild competition (Brainerd et al. 1995). The estimated minimum density of marten was 0.0016/ha in the Mackenzie Valley, NWT (Latour et al. 1994), and 0.0025/ha in the Alaskan taiga (Paragi et al. 1996). The estimated fall density of resident adults in the northern boreal region of the Yukon was 0.006/ha (Archibald and Jessup 1984).

3.3.1 FORAGING

Marten habitat selection in the Eagle Plains Ecoregion may depend largely on prey distribution and availability (Paragi et al. 1996). Taiga vole are the prey most selected by marten in the Alaskan taiga, likely due to their larger size (mean weight = 54 g) relative to red-backed vole (mean weight = 20 g; Paragi et al. 1996). Potential

and confirmed mammalian prey in the taiga includes snowshoe hare (*Lepus americanus*), red squirrel (*Tamiasciurus hudsonicus*), red-backed vole, taiga vole, lemmings (*Lemmus* spp., *Dicrostonyx* spp.), and to a lesser extent, deer mice (*Peromyscus maniculatus*) (Paragi et al. 1996). Non-migratory grouse, including willow ptarmigan and spruce grouse, are available year-round and are likely prey for marten in the taiga (Paragi et al. 1996). However, marten are dietary generalists and their diet fluctuates seasonally with the breeding cycles of small mammal prey, bird migration and nesting periods, and fruiting periods of understory plants (Ben-David et al. 1997, Carlson et al. 2014, Twining et al. 2019).

In northern latitudes, marten foraging and population dynamics are influenced by fluctuations in the abundance of small mammal prey (Zielinski 2000). Multiple scat analyses in the NWT and Alaska found that small rodents, including vole and lemming, were the most important diet item for marten (Buskirk and Ruggiero 1994). Small rodents in northern regions undergo relatively large periodic fluctuations in population size (Krebs 1996). Marten populations are likely tightly coupled with these small mammal population cycles due to the relatively low diversity of mammalian prey species in the Eagle Plains Ecoregion (Yukon Ecoregions Working Group 2004a, Roth et al. 2007). Marten abundance and fecundity are correlated with temporal variability in the abundance of preferred prey, likely due to nutritionally demanding processes associated with reproduction and juvenile recruitment (Carlson et al. 2014, Flynn and Schumacher 2016).

Previous research has shown berries to be most important for marten diet during the summer and fall (July–November) when fruit availability is greatest (Baker 1992, Schaumann and Heinken 2002, Twining et al. 2019). Further, there is recent evidence that *Vaccinium* fruit are also an important winter food item for marten in coastal areas where they remain accessible year-round (Banner et al. 2014, Eriksson et al. 2019). Similarly, common juniper (*Juniperus communis*) berries are an important winter food item for marten in other regions (Hargis and McCullough 1984). Therefore, marten in the RSA likely consume fruit from several species of shrub depending on habitat and season, including blueberry and lowbush cranberry in upland woodlands, and crowberry (*Empetrum nigrum*), lingonberry, cloudberry (*Rubus chamaemorus*), and bog cranberry (*Vaccinium oxycoccos*) in lowland black spruce-shrub sites (Yukon Ecoregions Working Group 2004a).

The diet of marten in interior regions of North America is typically dominated by species of voles associated with structurally complex forests (Thompson and Colgan 1994, Poole et al. 2004, Eriksson et al. 2019). Habitat structures normally associated with old forests, including stumps, snags, and large pieces of downed wood, provide subnivean access to small mammal prey in areas with deep snow (Zielinski et al. 1983, Baker 1992, Delheimer et al. 2019). However, within the Yukon, red-backed voles are present across all vegetation types and appear to be more abundant in subalpine shrub habitats than lower elevation boreal forests (Pretzlaw 2006, EDI Environmental Dynamics Inc. 2017). Taiga vole are restricted to the taiga and avoid forest cover (Pretzlaw 2006). Taiga vole in Alaska appear to select post-fire structural stages and are found in black spruce forests, birch forests, forest-grassland edge, and grasslands (Wolff and Lidicker Jr. 1980). Provided there is sufficient understory shrub cover, habitat used for foraging is probably directly associated with increased prey availability regardless of forest age or structural stage (Keim et al. 2011, Vigeant-Langlois and Desrochers 2011).

3.3.2 COVER

Across much of their distribution, marten select home ranges with old or late-mature forests and avoid recently cut forests (Chapin et al. 1998, Bridger et al. 2017, Suffice et al. 2017). Older forests contain complex woody structures, including mature trees, stumps, snags, and large pieces of CWD that marten require to meet many life history requirements, including thermal cover and escape cover from predators (Zielinski et al. 1983, Mowat 2006a, Andruskiw et al. 2008). Shrub cover can also be an important factor influencing marten habitat quality, as marten use understory shrubs as cover from aerial predators such as Northern Goshawk (*Accipiter gentilis*; Poole et al. 2004, Zielinski et al. 2005, Slauson et al. 2007).

Important habitat features typically associated with old forests, including stumps, snags, and large pieces of downed wood, provide subnivean access to winter denning in areas with deep snow (Zielinski et al. 1983, Baker 1992, Delheimer et al. 2019). A winter den is a structure that may be used repeatedly for resting for prolonged periods (Birks et al. 2005). Natal dens are used for parturition and kit rearing during the breeding season, and may be used as resting sites in other seasons (Birks et al. 2005). A scarcity of tree cavities leads marten to use denning sites that provide suboptimal thermal cover and escape from predators (Birks et al. 2005). Marten dens may be found in tree branches, bird nests, rock crevices, underground burrows, occupied houses, nest boxes, or barns (Birks et al. 2005). Therefore, marten may use a range of below or above-ground structures for winter denning in the RSA, regardless of forest age or structural stage.

3.3.2.1 Thermal Cover

In winter, marten possess limited energy reserves and must reduce energetic costs by seeking insulated resting sites (Spencer 1987, Buskirk et al. 1989, Brainerd et al. 1995). Marten are shown to be more dependent on subnivean resting sites at more northern latitudes (Brainerd et al. 1995). Marten's choice of resting above or below snow cover depends on the ambient air temperature relative to the temperature in a microenvironment; in other words, marten are more likely to rest wherever is warmest (Buskirk et al. 1989). In Scandinavia, marten seek underground or subnivean resting sites instead of arboreal sites when the ambient air temperature is very low (Brainerd et al. 1995). Any subnivean spaces not entirely surrounded by snow are suitable; however, CWD is best in terms of thermal properties (Buskirk et al. 1989). Therefore, thermal cover generally increases with increased coniferous cover and associated CWD. Rock provides some protection from digging predators; however, rock provides poor insulation than wood, and rock dens may contain organic bedding for insulation (Buskirk et al. 1989, Birks et al. 2005).

3.3.2.2 Escape Cover

As a mesocarnivore, pressure from competition and predation can play an important role in the population dynamics of marten populations (Kiseleva 2012, Manlick et al. 2017b). Aside from marten, wolf (*Canis lupus*), red fox (*Vulpes vulpes*), lynx (*Lynx canadensis*), and wolverine (*Gulo gulo*) are the primary mammalian predators in the Eagle Plains Ecoregion. Marten likely select habitat with sufficient escape cover (e.g., medium-sized coniferous trees and CWD) to avoid risk of intraguild predation by these species (Slauson et al. 2007, Eriksson

et al. 2019). Furthermore, marten within the Eagle Plains Ecoregion compete with least weasel (*Mustela nivalis*), lynx, and red fox for shared small mammal prey (Slough and Jung 2007).

Marten in North America select home ranges that contain vertical forest or understory shrub cover where they perceive lower risk of predation from aerial predators as well as larger carnivores that, depending on the system they occupy, includes mustelid, canid, and felid species (Slauson et al., 2007; Eriksson et al., 2019). Red fox are the most generalist and widespread carnivore in the northern boreal-tundra ecotone, and may limit marten populations through intraguild predation (Lindström et al. 1995, Birks et al. 2005, Pretzlaw 2006). Therefore, fox predation may force marten to remain arboreal and den above ground (Birks et al. 2005). Aerial predators include Northern Goshawk and Great Horned Owl (*Bubo virginianus*), both of which are predators of marten in other regions and occur year-round in forests in the Yukon (Bull and Heater 2001, Doyle and Smith 2001, Sinclair et al. 2003). Golden Eagle also occur in northern Yukon during the breeding season and may be predators of marten. However, marten may perceive a lower risk of predation in open woodlands and shrublands of the Eagle Plains due to the absence of several predators of marten in more southern biomes, including bobcat (*Lynx rufus*) and coyote (*Canis latrans*; Thompson and Colgan 1994, Bull and Heater 2000, Moriarty et al. 2016).

3.3.3 REPRODUCTION

Natal dens are used for the parturition and rearing of neonates and are critical for recruitment and population viability (Buskirk and Ruggiero 1994). Across North America, most natal dens are found in structurally complex sites (Buskirk and Ruggiero 1994). Marten prefer arboreal cavities for parturition and rearing neonates due to the shelter they provide from terrestrial predators, including red fox (Spencer 1987, Brainerd et al. 1995). Marten kits are very vulnerable to fox predation when kits move out of arboreal dens (Brainerd et al. 1995). However, scarcity of arboreal cavities may force marten to use alternative structures for natal denning (Birks et al. 2005). For example, arboreal cavities are rarely used as resting sites in Finland and northern Russia (Brainerd et al. 1995). In the NWT, an adult female marten denned and produced young within a 21-year-old burn (Latour et al. 1994). Therefore, a better understanding of habitat selection by adult female marten in the taiga is needed (Paragi et al. 1996).

3.3.4 DISPERSAL

North American marten are sensitive to forest fragmentation and are found across landscapes with greater amounts of contiguous forest (Thompson et al. 2012). Previous studies show that 5 km of nonforested habitat between forest patches is an effective barrier to dispersal for marten (Buskirk and Ruggiero 1994). Timber harvesting and extensive road networks increase the density of forest edges and generally reduce habitat connectivity for species such as marten adapted to forest interiors (Robitaille and Aubry 2000, Mowat 2006b). However, marten use narrow strips of forest and abandoned roads as movement corridors between more suitable patches of mature forest (Potvin and Bertrand 2004, Breault et al. 2021).

Furthermore, there is evidence that in regions with sparse forest cover, marten may be adapted to meet certain resource requirements in nonforested habitats. For example, in Scotland, forest habitat is limited and pine

marten (*Martes martes*) consistently use matrix habitats, including scrub and tussock grassland, to meet life history requirements (Caryl et al. 2012). Intensively managed forests in Scotland lack resources such as den sites and important prey (e.g., short-tailed field vole [*Microtus agrestis*]), abundant in grasslands long thought to be impermeable to marten movement or at best suboptimal marten habitat (Caryl et al. 2012).

Cold temperatures and high seasonality result in different patterns of habitat use among marten in North America (Zielinski et al. 1983). Marten habitat selection was investigated in the Alaskan taiga in a landscape composed of mature coniferous forests of black spruce and larch (*Larix laricina*) from 5–20 cm diameter at breast height (DBH) 100–115 years post-fire, as well as dense, young forests 30 years post-fire, and tall shrub and pole sapling forests with some moss and herb structural stages 10 years post-fire (Paragi et al. 1996). Marten abundance, hunting intensity (based on snow-tracking), and CWD density were the greatest in 10-year burns relative to 30-year burns and mature forests (Paragi et al. 1996).

However, this study found that juveniles were more common in recent burns than in mature stands, and recent burns were likely used only by nonbreeding marten (Paragi et al. 1996). Non-transient marten used coniferous forest more often than transient adult and juvenile marten, which were more likely to use scrub habitat (Paragi et al. 1996). For natal denning, resources are limited in herb and shrub structural stages and prey populations are unpredictable relative to mature forests (Paragi et al. 1996). Therefore, post-fire clearings may be only suitable for dispersing juveniles and transient adult marten (Paragi et al. 1996). Herb and shrub structural stages may function as population sinks for immature and transient marten dispersing from contiguous mature forest (Paragi et al. 1996). Previous HSI models for marten in the taiga have ranked nonforested habitats, including post-fire clearing and shrubland as low-suitability habitat (EDI Environmental Dynamics Inc. 2018). However, habitat requirements of breeding marten in the taiga are not well-understood (Paragi et al. 1996).

3.3.5 DISTURBANCE

3.3.5.1 Fire

Marten are dietary generalists and are not limited to prey associated with mature/old forest structural stages (Baker 1992, Paragi et al. 1996, Poole et al. 2004). Marten in the Alaskan taiga use snags and windthrown trees as winter cover in recent burns before coniferous regeneration occurs (Paragi et al. 1996). Trappers in Alaska view fire as beneficial to furbearer populations. Rodent prey, including red-backed vole, tundra vole (*Microtus oeconomus*), meadow vole (*Microtus drummondii*), and taiga vole, are abundant in dense herbaceous vegetation growth following recent fires (Stephenson 1984). Extensive use of post-fire clearings occurred by marten 1– 3 years post-fire. High population abundance occurs within 3–10 years post-burn, with activity centred in unburned inclusions and burn edges (Stephenson 1984).

In the Alaskan taiga, marten abundance, frequency of investigations, hunting intensity, and CWD density were greatest in 10-year burns relative to older burns and mature forest (Paragi et al. 1996). Subnivean access based on tracks was greatest in 10-year burns relative to mature forests and 30-year burns (Paragi et al. 1996). Small mammal biomass and diversity were greatest in the 10-year burn. This structural stage provided a more stable

prey base due to greater diversity of rodents and more stable populations of red-backed vole (Paragi et al. 1996). Young forests 30 years post-fire had the least stable small mammal populations and lacked taiga voles, the prey most selected by marten in this study (Paragi et al. 1996). The suitability of post-fire clearings for marten may be low at first and increase 6–10 years post-fire as ground cover recovers and small mammals occupy the habitat (Paragi et al. 1996). Suitability begins to decrease 15–20 years post-fire and reaches minimum suitability 25–30 years post-fire when CWD has fully decayed and young forests establish. These forests lack near-ground structures for subnivean foraging, escape cover, denning, and resting sites (Paragi et al. 1996).

Adult marten in the NWT were more likely to have home ranges in unburned stands than burned stands (Latour et al. 1994). Unburned forests were open, 90-year-old black spruce-herb, or black spruce-bog forests with average tree height from 5–10 m, and average DBH from 4–14 cm (Latour et al. 1994). Burned stands were characterized by regeneration of open to sparse deciduous vegetation (40% bare ground), a primarily willow shrub layer, and a birch/balsam fir canopy (Latour et al. 1994). Wet areas were characterized by moss, lichen, and Labrador-tea in the understory with sparse, stunted black spruce in the tree layer (Latour et al. 1994). Long-term use by adult marten within home ranges indicated greater use of unburned forests relative to burned forests (Latour et al. 1994). In burns, most snags remained standing and deadfall lay directly on the ground; therefore, burns did not provide access to subnivean spaces, and hunting was mostly on the surface of snow with little protection from predation (Latour et al. 1994). However, an adult female marten with a home range partially within a burn, denned and produced young within the 21-year-old burn (Latour et al. 1994). Furthermore, home ranges of 1 adult and 1 juvenile tracked for 14 and 15 months were entirely within the burns (Latour et al. 1994). Using post-fire structural stages by breeding marten in the taiga is not well understood and should be explored in future studies (Paragi et al. 1996).

3.3.5.2 Roads

The Dempster Highway runs roughly southwest to northeast through the southern half of the RSA. The RSA includes numerous winter roads (15 m average width) from previous exploration activities dating back to the 1960s. Project activities will be accessed via existing and new winter roads. Generally, marten avoid open areas and areas of high human disturbance, including roads (Hargis et al. 1999, Potvin et al. 2000). Marten in North America generally avoid roads due to increased predation risk and lower availability of preferred prey; however, predation risk is assumed to be low in the RSA because primary predators of adult marten are absent or at low density in the Eagle Plains Ecoregion (Yukon Ecoregions Working Group 2004a, Moriarty et al. 2011, 2015, Joyce 2018). Therefore, marten may perceive a lower risk of predation along roads within the RSA due to the absence of several predators of marten in more southern biomes (Bull and Heater 2001, Mowat 2006a, Thompson et al. 2012). Further, abandoned roads (5 m average width) may provide easier pathways for marten movement than undisturbed forest and greater cover from aerial predators than openings (Breault et al. 2021). However, extensive road networks may fragment woodland and shrubland, reducing habitat connectivity and limiting marten dispersal (Caryl et al. 2012).

3.3.5.3 Seismic Lines

The RSA contains numerous 2D seismic lines (range = 5–8 m wide, mean = 5.4 m wide) from previous exploration activities dating back to the 1960s. Most 2D exploration occurred between 1961 and 1984, with new 2D exploration in 2001 incorporating Low Impact Seismic (LIS) techniques(Access Consulting Group and EBA Engineering Consultants Ltd. 2001, GEOTIR 2014). Approximately 2,200 km of new 3D LIS exploration (1.5–3 m wide) was conducted in a 32,500 ha area between November 2013 and April 2014 (GEOTIR 2014). This new 3D exploration is located near the RSA's centre, north and south of the Dempster Highway. The entire RSA, including legacy and contemporary seismic lines, was assessed as a linear feature study. There were signs of normal and magnified succession on 2D and 3D seismic lines. Among 2D lines, 89% had growth >1.5 m height and were considered fully recovered, and 22% of 2D lines made in the 1950s and 1960s showed magnified succession. All 3D lines were made in 2014 and showed normal succession.

In the northern boreal forest (i.e., southwest NWT, northeast BC, and northwest Alberta), marten use of seismic lines is strongly influenced by line width and state of regeneration (Tigner et al. 2015). In this study, forests were open black spruce bogs in lowlands, and upland white spruce-aspen with dense shrubs. Remote wildlife cameras were used to quantify marten use of seismic lines relative to adjacent interior forests. Marten were detected in open lines >3 m wide up to 90% less than forest interiors, but were detected in open lines <2 m wide or lines >6 m with at least partially recovery roughly equally to forest interiors (Tigner et al. 2015). Use of seismic lines is thought to be driven by the perceived risk of predation; marten avoid open habitats but use disturbed habitats following sufficient recovery of overhead and lateral cover (Tigner et al. 2015).

3.3.6 HABITAT SUMMARY

In more productive forests to the south, marten are often associated with mature forest structures, such as large trees, snags, and CWD (Buskirk and Ruggiero 1994, Thompson et al. 2012). Marten select habitats with structural complexity which provides subnivean access to small mammal prey, thermal cover, escape cover from predators, as well as natal denning sites (Spencer et al. 1983, Buskirk and Ruggiero 1994, Latour et al. 1994, Paragi et al. 1996). Within the Subarctic Bioclimate Region, characterized by stunted, open canopy spruce-dominated habitats, tree growth is often limited by the presence of permafrost resulting in disclimax vegetation communities with tall and low shrub structural stages. Therefore, patterns of habitat selection of marten in the RSA may differ from those in southern biomes (Pretzlaw 2006).

Habitat quality in the RSA should be evaluated within the context of reduced availability of old forest structures and lack of contiguous, coniferous forests in the Eagle Plains Ecoregion. Marten select habitat types with the most large pieces of downed wood and the largest standing live and dead trees available at the landscape scale (Zielinski et al. 1983, Baker 1992, Delheimer et al. 2019). Trees, snags, and CWD >30 cm in diameter are associated with older structural stages within the RSA. These structures would be considered too small to provide thermal cover and support natal denning requirements for marten elsewhere in North America (Buskirk et al. 1989, Delheimer et al. 2019). However, these structures are likely large enough to provide thermal cover and support natal denning requirements for marten in the northern context of the RSA (Spencer 1987, Brainerd et al. 1995).

3.4 METHODS

An HSI model was used to estimate habitat quality across the RSA (U.S. Fish and Wildlife Service 1980). An HSI model, also referred to as a knowledge-based habitat suitability model (Clarke 2012), is a common method for assessing habitat quality for wildlife species, and a method adapted for use in environmental impact assessments (U.S. Fish and Wildlife Service 1980). Habitat is defined as the particular place occupied by a specific population within a community and usually characterized by the dominant plant form or physical characteristics (U.S. Fish and Wildlife Service 1980). Each species requires habitat to supply space, food, cover, water, and other requirements for survival (U.S. Fish and Wildlife Service 1980). Suitability is defined as the habitat's ability, in its current structural stage, to provide the life requisites of the species (Resources Inventory Committee 1999c).

3.4.1 HABITAT SUITABILITY MODELLING

HSI modelling uses spatial datasets such as land cover, disturbance history, and topography. It ranks available habitats according to their ability to support a selected species. The habitat rankings can be based on various sources, including ecological survey data, local knowledge, expert knowledge, and traditional knowledge. HSI models can be based on suitability ratings for one habitat variable or the combination of ratings for multiple variables to quantify the quality, amount and distribution of potential habitat for the species (Dijak and Rittenhouse 2009).

3.4.1.1 Rating Scheme

Habitat ranking schemes reflect knowledge of the species' habitat use and ecology (Resources Inventory Committee 1999). A 4-class system was chosen to rank habitat suitability in this study because there is an intermediate level of knowledge of habitat quality for marten in the taiga (Resources Inventory Committee 1999, EDI Environmental Dynamics Inc. 2018). Thus, habitat was assigned a suitability ranking of High (H), Moderate (M), Low (L), or Nil/Very Low (N/VL) relative to the range of habitat quality across the RSA. Using a mathematical equation, the HSI score was produced by combining suitability ratings for several specific habitat variables (e.g., vegetation community type) into one final HSI score.

The developed habitat model produced HSI scores ranging from 0 to 1. Scores were used rather than classes to combine scores and adjustments from multiple variables into a final HSI score. Scores were categorized into four qualitative categories: High (>0.75 to 1.0), Moderate (>0.50 to 0.75), Low (>0.25 to 0.50), Nil/Very Low (>0.0 to 0.25; Resources Inventory Committee 1999). The rating categories correspond to qualitative predictions of the relative suitability of the habitat for supporting five life requisites of marten: reproduction, thermal cover, escape cover, foraging, and dispersal. High-quality habitat supports all five life requisites. Moderate-quality habitat supports escape cover, foraging, and dispersal. Low-quality habitat only supports limited foraging and dispersal. Nil/Very Low-quality habitat does not contribute significantly to any life requisites; however, herb and shrub structural stages and stunted disclimax forest areas likely function as permeable barriers and allow intra-territorial movements within marten home ranges (Caryl et al. 2012). Habitat conditions and suitability interpretations for each rating class are provided in Table 3-1.

Table 3-1. Description of habitat rating classes used in the marten HSI model.

HSI Score	Habitat Rating	Description
>0.75 to 1.0	High	Suitable (optimal). Provides conditions for natal denning (large live conifer trees, large snags, large CWD), thermal cover (medium/large-sized elevated CWD subnivean), escape cover, foraging, and dispersal.
>0.50 to 0.75	Moderate	Suitable (suboptimal). Provides conditions for escape cover (small/medium-sized live or dead conifer trees, and/or small CWD, and/or dense shrub cover), foraging, and dispersal.
>0.25 to 0.50	Low	Limited Suitability. Provides conditions for foraging (i.e., any size or species of tree that would support prey species and CWD large enough for subnivean access; grass and/or horsetails for hare, voles, birds, and/or berries for prey or marten), and dispersal (i.e., some herb or sparse deciduous/shrub cover).
>0.0 to 0.25	Nil/Very Low	Unsuitable. Non-vegetated areas, such as alpine, water, or highways, that do not provide conditions to support any life requisites for marten. Non-vegetated areas may be used for intra-territorial movements.

3.4.1.2 Habitat Variables

Habitat variables were identified as potentially important for describing marten habitat (Table 3-2). Variables were evaluated for inclusion based on the strength of relationships found in other studies, the ecological relevance to marten in the Eagle Plains Ecoregion, and the availability of the variable in GIS databases for the RSA. Based on these criteria, ELC and Linear Feature (LF) data were included in marten habitat modelling.

Distance to riparian areas was considered for inclusion in the model. Riparian areas are important foraging habitat for marten in North America (Spencer et al. 1983, Ben-David et al. 1997), and elder members of the VGFN observed good marten habitat in the area where the Blackstone and Peel rivers meet (Sherry and Vuntut Gwitchin First Nation 1999, p. 140). Riparian areas generally have greater prey availability relative to the surrounding landscape due to higher densities of prey and greater volumes of CWD, which increase access to subnivean spaces (Buskirk et al. 1989). ELC data accurately represent increased habitat quality in mature/old riparian forests found as narrow strips along most major watercourses in the RSA, including Chance Creek in the northwest and Dalglish Creek in the southeast. Therefore, a variable for distance to riparian was redundant with the ELC mapping and was not included in the model.

The history of fire disturbance has influenced marten distribution and was considered for inclusion in the model. However, the nature of the relationship between fire history and patterns of use by marten is unclear for the taiga biome. Recent burns and post-fire clearings are generally considered suboptimal habitat. They are used mainly by nonbreeding and dispersing juvenile marten (Paragi et al. 1996). In the NWT, adult martens were likelier to locate home ranges in unburned stands than burned ones (Latour et al. 1994). However, recent burns may provide foraging opportunities not present in older burns or mature forests (Paragi et al. 1996). Furthermore, fire history was explicitly accounted for in the structural stage of the ELC mapping. Therefore,

a separate variable for fire history was determined to be redundant with ELC mapping and was not included in the model.

Elevation was considered as a variable for inclusion in the model. Marten generally occur at higher elevations than similarly-sized mesocarnivores, due to adaptations for travelling over snowpack and hunting in subnivean spaces (Grinnell et al. 1937, Zielinski et al. 2005, 2017). However, elevation within the rolling topography of the RSA does not vary substantially (range = 343–752 m asl) and was likely not a significant driver of marten distribution. Therefore, elevation was not included as a variable in the model.

Table 3-2. Summary of habitat variables commonly associated with marten habitat quality from published literature relevant to the Regional Study Area.

Variable	Included in model?	Rationale
Ecosite (ELC)	Yes	Marten select conifer-dominated stands with dense shrub cover.
Structural Stage (ELC)	Yes	Marten select mature/old forests with complex structure.
Distance to Riparian	No	Most ecosites defined by permafrost rather than riparian. ELC data more accurately represent increased habitat quality in mature/old riparian forests than distance to riparian.
Linear Features	Yes	Generally, marten avoid linear features due to increased predation risk. It is included as a habitat modifier/downgrade to adjacent habitat.
Fire History	No	Different patterns of use by marten depending on study. Fire may affect habitat quality positively or negatively, dependent on ecosite and time since disturbance. Fire history was explicitly accounted for in the structural stage of the ELC mapping. Therefore, it would be redundant to include it in the model.
Elevation	No	Range in elevation within RSA (343–752 m asl) is not enough to affect marten distribution.

Ecological and Landscape Classification

ELC mapping refers to an integrated approach to mapping and classifying land units according to their ecological similarity (Environment Yukon 2016a). As part of another study in the RSA (EDI Environmental Dynamics Inc 2021), field plots were used to establish preliminary classification units and site/soil conditions across various ecological communities. The vegetation association organization and ecosite and coding system follows the Yukon ELC Mapping Guidelines (Environment Yukon 2016a). Non-forested and sparsely/non-vegetated ecosystem were assigned to group/realm following *Biogeoclimatic Ecosystem Classification of Non-forested Ecosystems in British Columbia* (BC MFLNRORD and BC MOE 2010, Mackenzie 2012), and anthropogenic units were classified following *Standards for Terrestrial Ecosystem Mapping in British Columbia* (Resources Inventory Committee 1998a). Wetland sites were classified according to the Canadian Wetland Classification System for class, form, subform, type and subtype.

The remaining ecosites were coded with a two-digit number that indicates, by its number series, a certain range of soil moisture conditions: 10s are dry sites, 00s are mesic sites, 20s are riparian sites, 30s are moist

sites, and 40s are wet sites. Ecosite names reflect plant species that are important indicators of the vegetation found within the ecosite (e.g., 33 – Moist Spruce – Labrador Tea).

Biologists delineated ELC polygons in a GIS based on discernible differences among vegetation, topography, terrain, soils, gradients, and patterns (relationship patterns between ecosystem units, polygon shape and orientation). Three or fewer ecosystem units (i.e., ecosites) were entered per polygon. Each ecosite had an associated structural stage modifier (e.g., pole sapling) and decile, representing the percent area of the polygon in each ecosite (i.e., all deciles sum to 100%).

A subsample (n = 97) of ELC field plots were used to describe habitat suitability rankings for marten within the context of the Eagle Plains Ecoregion. Field plots were identified as High (n = 10), Moderate/high (n = 21), Moderate (n = 20), Moderate/low (n = 44), and Low (n = 2). No field plots were in Nil/Very Low habitat suitability. ELC ecosites and structural stages were used to generalize habitat rankings from field plots to ELC GIS data (Table 3-3).

Every combination of ecosite and structural stage was assigned an initial HSI score of High (HSI >0.67 to 1.0), Moderate (HSI >0.33 to 0.67), Low (HSI >0 to 0.33), or Nil/Very Low (HSI = 0). Only ecosites and structural stages represented in the RSA were included in habitat modelling. All non-vegetated ecosites (AN, ES, Fa, LA, PD, RI, RZ) were ranked as Nil/Very Low (0.0). Vegetated ecosites in the non-vegetated structural stage (1) were ranked as Nil/Very Low (0.0). Ecosite 10 (sparsely vegetated) was ranked as Nil/Very Low (0.0) regardless of structural stage. All other vegetated ecosites with Sparse/cryptogram (2/2a) or Herb/graminoid-dominated (3/3b) structural stage were all ranked as Low quality (0.1). Vegetated ecosites in Low shrub (4b) structural stage were ranked as Low quality (0.33) and ranks increased with structural stage to a maximum of 1.0 (High quality) for conifer/mixedwood ecosites, and a maximum of 0.67 (Moderate quality) for deciduous/shrub ecosites, and 0.33 (Low quality) for wetland (bog, marsh, fen) ecosites.

Linear Features

Linear features (LF) were surveyed in the RSA as a companion study for the exploration project proposal (EDI Environmental Dynamics Inc., unpublished study). LFs were classified as 2D, 3D, winter roads (any trails or limited use roads with an obviously curving path), and the Dempster Highway. A subsample (n = 64) of field plots from the LF surveys were used to investigate habitat suitability for marten on-line and off-line. Determining the relative level of impact of various types of LFs established empirical evidence for modelling.

No linear features contained high suitability habitat; the average difference between off-line and on-line habitat suitability rankings across all types of LFs was 0.81 (SD = 0.79, range = 0–3, n = 64). All 2D lines (average width = 5.4 m, n = 27) were moderate-low habitat suitability on-line, and when compared to off-line habitat, the average difference in suitability ranking was 0.85 (off – on), (SD = 0.82, range = 0–2). 3D lines (width range = 1.75–5 m, n = 27) were mostly moderate-low habitat suitability (n = 24), and the average difference between off-line and on-line suitability was 0.63 (SD = 0.69, range = 0–2). The average difference among winter roads (average width = 5 m, n = 8) was 0.88 (SD = 0.64, range = 0–2). Along the Dempster Highway (average width = 15 m, n = 2), the average difference was 2.5 (SD = 0.71, range = 2–3). The average difference in HSI between off-line and on-line field plots was scaled to a score from 0–1 for downgrading:

- Dempster Hwy (30.0 m wide) = (2.5*0.25) = 0.625
- Winter Roads and 2D lines (10.0 m wide) = (0.87*0.25) = 0.218
- 3D lines (10.0 m wide) = (0.63*0.25) = 0.158

2D and 3D lines were mapped using a 10 m width due to limitations of the spatial scale of modelling (10 m raster). The 2D lines are wider than 3D lines and thus have a greater local effect on marten habitat suitability. The difference in effect between 2D and 3D lines on marten habitat was accounted for by applying a greater value for downgrading 2D lines (–0.218) compared to 3D lines (–0.158).

Table 3-3. HSI ratings for marten habitat quality in the Eagle Plains RSA based on an assessment of ELC field plots.

Ecosite Name	Ecosite Code	Structural Stage											
		Non-vegetated	Sparse / cryptogram	Sparse (5–10% cover)	Herb	Graminoid dominated	Low shrub	Shrub	Tall shrub	Pole sapling	Young Forest	Mature Forest	Old Forest
		1	2	2a	3	3b	4b	4	4a	5	6	7	8
Mesic Birch - Willow	2	0.00	0.10	0.10	0.10	0.10	0.35	0.40	0.45	0.50	0.60	0.60	0.60

3.4.1.3 Model Structure

Each ELC polygon contains up to three ecosites with deciles indicating percent cover relative to the total area of the polygon. A weighted average HSI score was calculated for each polygon using the following equation:

$$ELC_r = \frac{\sum_{i=1}^{n} d_i h_i}{\sum_{i=1}^{n} d_i}$$

where ELC_r is the initial weighted average, d_i is the decile value, and h_i is the HSI score for each ecosite. HSI polygons were converted to a 10x10 m resolution raster, and linear feature adjustments were applied to the initial HSI scores for each cell:

$$HSI = ELC_r - LF_r$$

where LF_r is the LF adjustment.

3.5 RESULTS AND DISCUSSION

The model indicated a patchwork of High, Moderate, and Low-quality marten habitat, across the RSA (Table 3-4; Map 3-1). High-quality marten habitat is associated with mesic, spruce-dominant ecosites in mature to late structural stages. It includes some of the most common ecosystem units in the RSA, including Moist Spruce – Labrador Tea (33), Moist Spruce – Alder – Labrador Tea (34), and Mesic Black Spruce – Alaska Paper Birch (04; Figure 3-1). Concentrations of High-quality habitat include Enterprise and Dalglish Creeks watersheds in the south, a band running east-west north of the Dempster Highway, and the western part of the northern half of the RSA. Moderate-quality habitat is associated with wetter or younger ecosystem units than High-quality habitat and is widespread across the RSA. High and Moderate-quality habitat is also concentrated in narrow strips of mature/old riparian forests along some of the major watercourses in the RSA, including Chance and Greaves Creeks in the northwest and McParlon Creek west of the Dempster Highway.

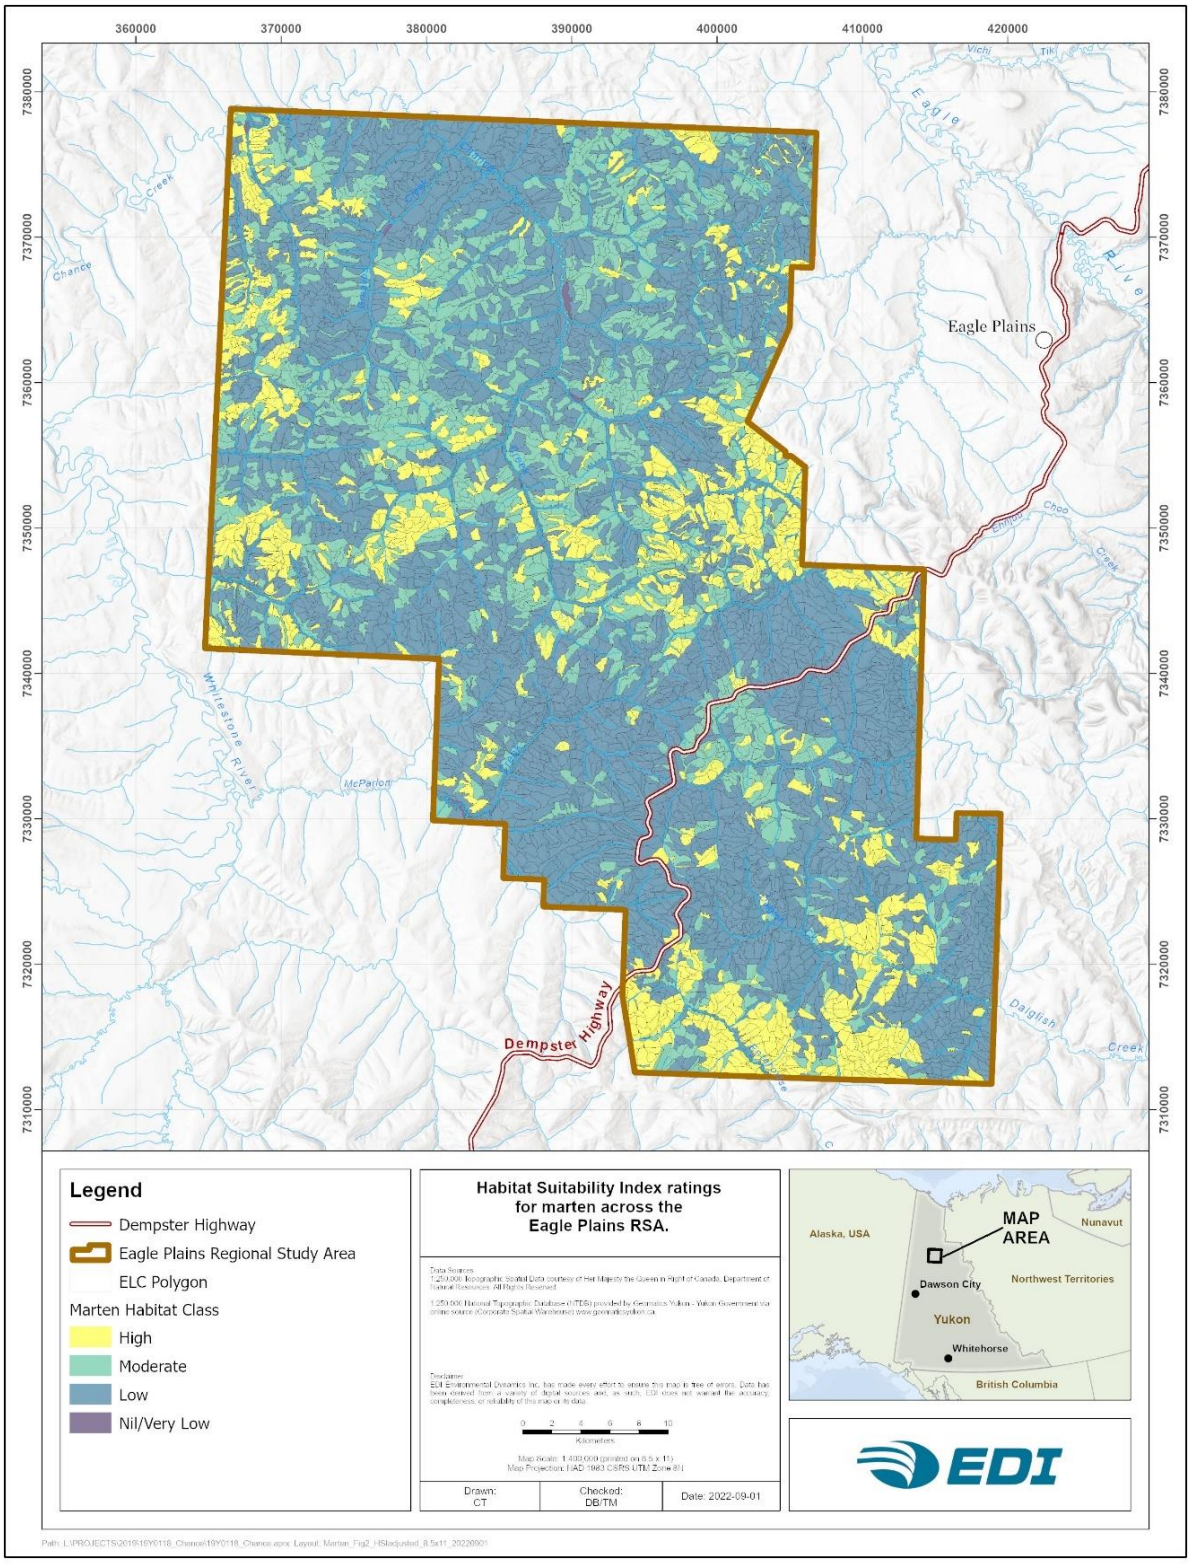
There is extensive Low-quality habitat, represented by vegetation communities in tall and low shrub structural stages found throughout the RSA (Figure 3-1). These habitats generally lack mature forest structures, such as large trees, snags, and CWD, which marten require for subnivean foraging, escape/thermal cover, and denning (Buskirk and Ruggiero 1994, Thompson et al. 2012). Low-quality habitat was associated with shrubby wetlands and stunted black spruce sites in low valley bottoms in the Chance watershed in the northwestern portion of the RSA and regenerating fire-disturbed areas on both sides of the Dempster Highway in the southern part. Completely non-vegetated areas are rare in the RSA; thus, there is almost no Nil/Very Low-quality habitat (Table 3-4; Map 3-1).

Linear features had a relatively minor effect on the overall quality, amount, and distribution of potential habitat for marten. The effect of linear features on habitat suitability for marten is mainly limited to site-level effects (Map 3-2). This effect was due to the narrow width of linear features (Moriarty et al. 2016, 2017) and their small extent relative to the overall RSA. Though existing linear features reduce habitat quality at the site level,

their effects are negligible to habitat supply at the home range scale for marten (Table 3-4). The Dempster Highway was likely the only linear feature in the RSA that could limit the movement of marten. Marten avoid crossing open areas due to increased predation risk relative to areas that provide escape cover (Slauson et al. 2017). However, the highway likely functions as a barrier, not an obstacle or constraint to their movement (Beyer et al. 2016). Therefore, it is likely that marten can and will cross the highway, so the potential barrier limits to their movement likely do not affect habitat availability at the home range scale.

Table 3-4. Relative availability of marten habitat in the Eagle Plains RSA.

Habitat Rating	HSI Scores	Area (ha)	Area (%)
High	>0.75 to 1.0	38,049.63	15.94
Moderate	>0.50 to 0.75	55,202.05	23.12
Low	>0.25 to 0.50	142,484.78	59.68
Nil/Very Low	>0.0 to 0.25	3,015.79	1.26
Total		238,752.25	100



Map 3-2. Habitat Suitability Index model ratings for marten across the Eagle Plains RSA.

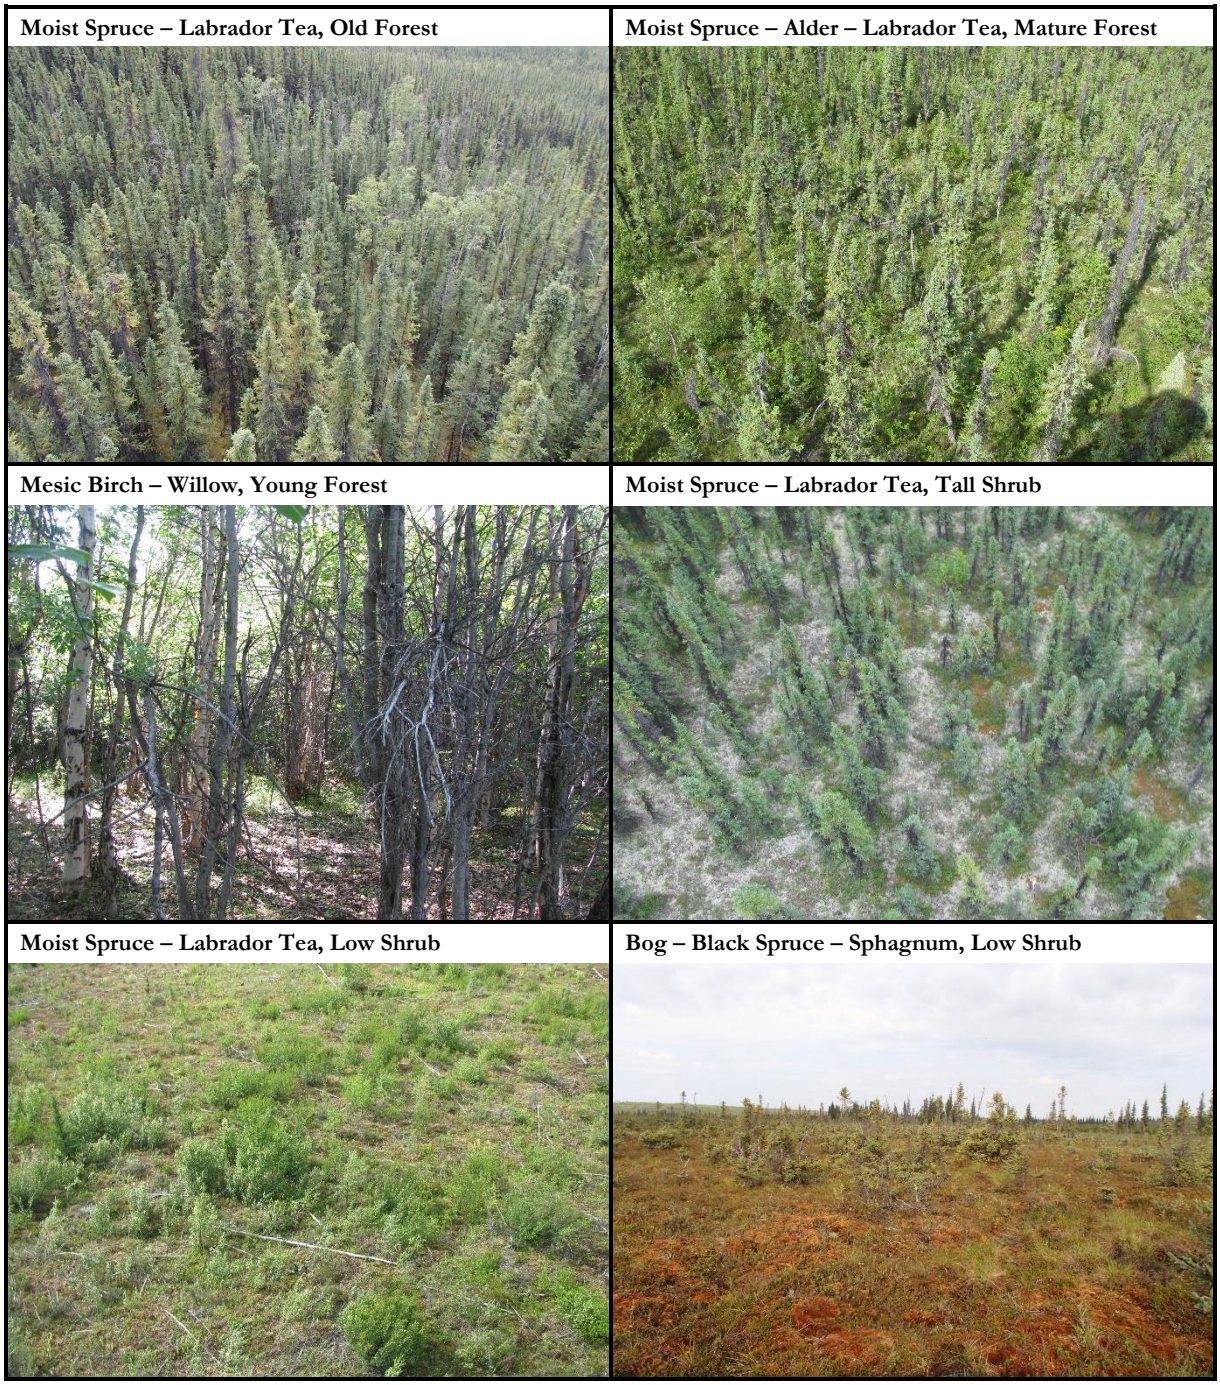


Figure 3-2. Examples of High (top row), Moderate (middle row), and Low (bottom row) quality marten habitat in the Eagle Plains RSA.

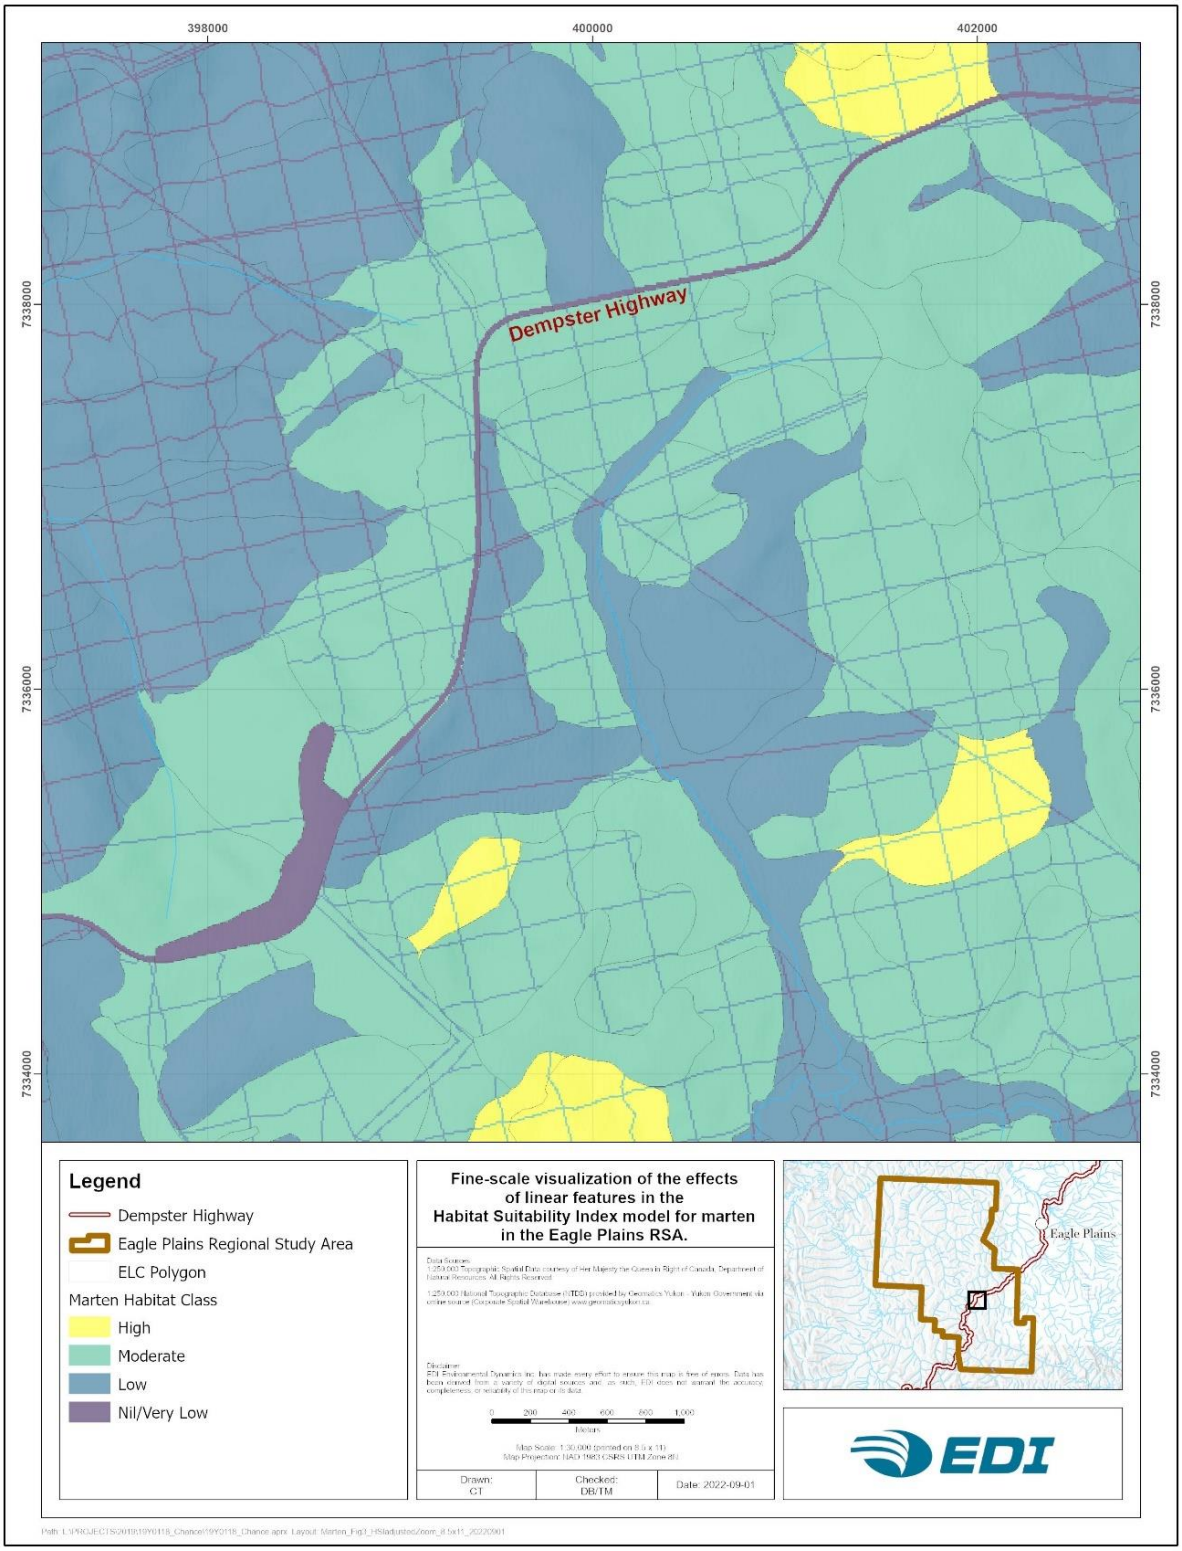


Map 3-3. Fine-scale visualization of the effects of linear features in the Habitat Suitability Index model for marten in the Eagle Plains RSA.

3.5.1 MODEL VERIFICATION AND CONFIDENCE

The frequency of use of habitat by marten in the RSA is expected to correlate to the ordinal habitat classes used in the model. However, independent marten occurrence data were not available to test that expectation. The overall confidence in the model is moderate based on moderate knowledge of marten in northern ecosystems and the lack of local field verification.

3.6 SUMMARY

The quality, amount, and distribution of potential habitat for marten were quantified across the RSA using a Habitat Suitability Index model. Ecosite and vegetation structural stages were used to assign areas an initial HSI score, which was then modified based on the presumed adverse effects of linear features on marten habitat. The HSI model indicates a patchwork of High (16%), Moderate (23%), and Low (60%) quality marten habitat across the RSA. High-quality marten habitat occurred in relatively large areas of contiguous mature/old spruce forests and narrow strips of mature/old riparian forests along major watercourses. The RSA contains extensive Low-quality habitat, associated with vegetation communities in tall and low shrub structural stages, including regenerating burns and open, stunted black spruce forest. Non-vegetated areas that constitute Nil/Very Low habitat are a minor component of the RSA. Linear features reduce habitat quality at the site level, but their effects on habitat supply at the scale of a marten's home range are limited.

4 GRIZZLY BEAR

4.1 PURPOSE AND OBJECTIVES

Grizzly bears (*Ursus arctos horribilis*) were selected as a VC for the Project due to their conservation status and social, cultural, and economic value. Grizzly bear have been assessed as a species of Special Concern in Canada, indicating their populations are at risk of becoming threatened if not adequately managed (COSEWIC 2007). Grizzly bears have cultural significance for Indigenous people of Yukon, some of which have traditional uses for their fur, fat, and meat (Benson 2014, Yukon Grizzly Bear Conservation and Management Plan Working Group 2019a). In addition, grizzly bears are managed as a Big Game species in Yukon (Government of Yukon 2002) and harvested by Yukon residents and non-residents (i.e., outfitting operations) throughout much of the territory. Grizzly bear are considered an iconic Yukon species and the opportunity to view grizzly bears attracts tourists from around the world (Yukon Grizzly Bear Conservation and Management Plan Working Group 2019a).

This section summarizes the current state of knowledge about grizzly bear ecology in the Project and broader areas, including population trends, distribution, habitat selection, diet, and sources of mortality. This report emphasizes grizzly bear ecology specific to the Taiga Cordillera Ecozone where the Project is located. The behavioural ecology and population characteristics of grizzly bears in the taiga are likely distinct from bears inhabiting coastal, boreal, and arctic barren-ground ecosystems, given substantial variation in habitat and food availability across these regions (Mowat and Heard 2006, Mowat et al. 2013). This report draws from multiple sources, including published and unpublished literature, personal communications with biologists, and traditional knowledge where available. Few studies on grizzly bears have been conducted in the region and the broader Taiga Cordillera. Thus, literature from surrounding regions was consulted when local information was unavailable.

4.2 POPULATION STATUS AND DISTRIBUTION

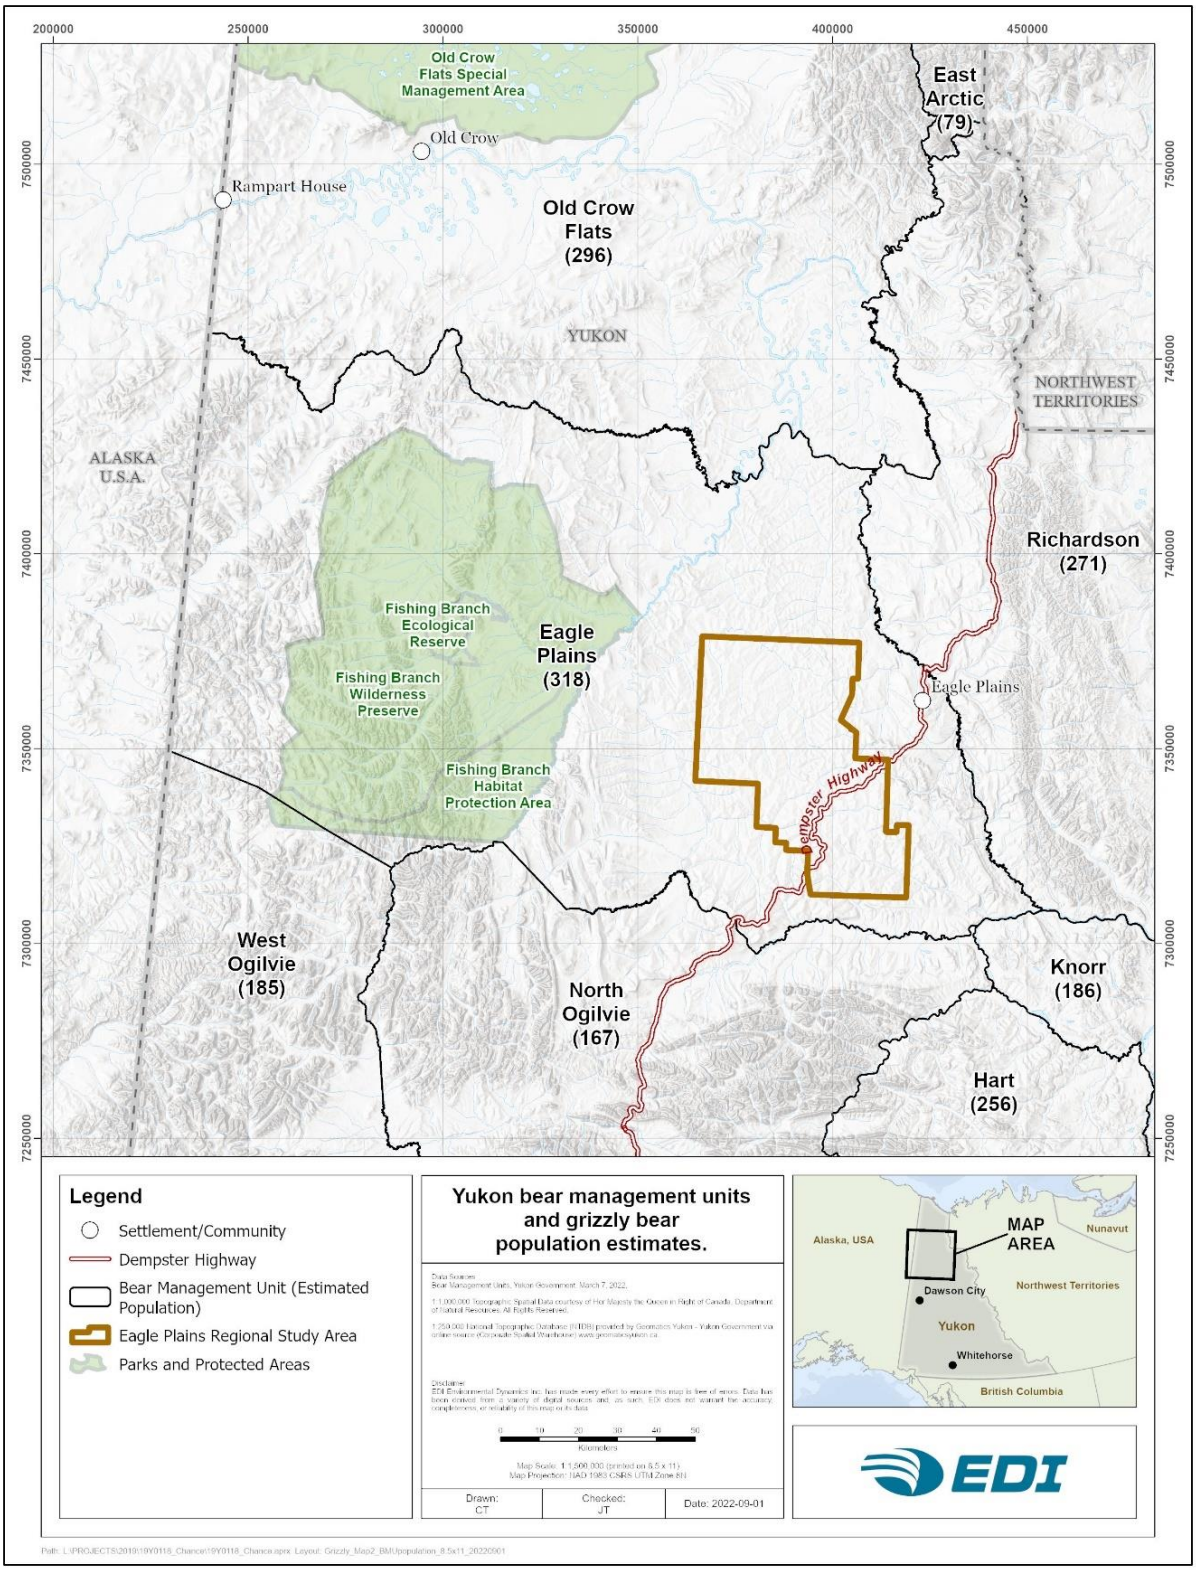
4.2.1 POPULATION

Yukon's grizzly bear population is estimated at 6,000 to 7,000 individuals, comprising approximately 25% of Canada's total grizzly bear population (COSEWIC 2007). The Yukon population estimate was derived from expert-opinion-based estimates of grizzly bear densities in each Yukon Ecoregion, using habitat information and local knowledge collected in the 1980s (Smith and Osmond-Jones 1990, Yukon Grizzly Bear Conservation and Management Plan Working Group 2019b). The exceptions are the Southern Lakes Region and Yukon North Slope, where more recent estimates are available from population assessments using genetic mark-recapture methods (Yukon Fish and Wildlife Branch 2016, 2017). The RSA is located within the Eagle Plains Ecoregion, which has a grizzly bear population estimate of 184 individuals (Yukon Grizzly Bear Conservation and Management Plan Working Group 2019b).

Yukon's grizzly bear populations are managed within bear management units (BMU), generally delineated by outfitting concession boundaries. The Inuvialuit Settlement Region is an exception, where grizzly bears are managed under a separate co-management agreement (WMAC [NS] and WMAC [NWT] 1998). Population estimates for each BMU were derived from the original expert-based Ecoregion estimates (except the Southern Lakes Region and North Slope). Population estimates for BMUs range from 43 to 503 bears; with variation attributed to differences in habitat quality and the sizes of BMUs.

The Eagle Plains BMU, which encompasses the RSA, has a population estimate of 318 bears (Map 4-1). However, the population estimate for the Eagle Plains BMU includes Ni'iinli Njik (Fishing Branch) Territorial Park, which likely has much higher grizzly bear densities than the RSA due to abundant salmon and winter denning habitat (Vuntut Gwitchin Government and Environment Yukon 2010). Grizzly bear densities are considered low throughout the RSA, although limited information is available (Pongracz and Suitor, pers. comm., 2022). Population densities for the adjacent Richardson Mountains are estimated at approximately 23 bears per 1,000 km^2 (Clarkson et al. 1993), but grizzly bears are more abundant in the mountains than the taiga plains that characterize the RSA (Benson 2014).

Grizzly bear population trends in Yukon are primarily tracked through harvest monitoring. The Yukon population is stable (Yukon Grizzly Bear Conservation and Management Plan Working Group 2019a). There is minimal data on population trends within the Eagle Plains BMU, given low grizzly bear harvest rates (refer to Section 3.1), but traditional knowledge provides some insight. Gwich'in knowledge holders suggest that grizzly bears in the Gwitch'in Settlement Area have a generally stable population (Benson 2014). However, elders noted that grizzly bears have declined in some areas from 1940 to the early 2000s due to increased hunting pressure, the opening of the Dempster Highway, increased use of snow machines, and a general northward range shift towards the Inuvialuit Settlement Region.



Map 4-1. Yukon bear management units and grizzly bear population estimates.

4.2.2 DISTRIBUTION

Grizzly bears occur throughout the Yukon, ranging from the BC/Yukon border to the Arctic coast. They are generalist omnivores that may live in various habitat types (Mowat et al. 2013), and they occur in all Ecoregions within Yukon.

In northern Yukon, seasonal grizzly bear distribution generally tracks the availability of key food resources such as berries, fish, ungulate calves, and ground squirrels (MacHutchon and Wellwood 2003). Very little information exists about grizzly bear distribution within the RSA. The Whitestone River adjacent to the RSA (Map 1-1) is an area of higher grizzly bear concentration in the region (Pongracz and Suitor, pers. comm., 2022). During the fall, grizzly bears congregate in Ni'iinli Njik (Fishing Branch) Territorial Park, approximately 20 km west of the RSA, to feed on spawning salmon in the Fishing Branch River (Vuntut Gwitchin Government and Environment Yukon 2010).

In and adjacent to the Gwitch'in Settlement Region, grizzly bears are more common in the Richardson Mountains, the Ogilvie Mountains, and the barren arctic coast than in the flat, low-elevation taiga that overlaps the RSA (Benson 2014). These distributional patterns are attributed to a lack of ground squirrels and other key food sources in the moist, hummocky spruce forest that characterizes much of the RSA.

4.2.3 CONSERVATION STATUS AND THREATS

COSEWIC has assessed grizzly bears as a species of Special Concern (COSEWIC 2007). The Western Canadian grizzly bear population is listed under Schedule 1 of the SARA, which requires measures to prevent grizzly bears from becoming Threatened or Endangered. Within Yukon, grizzly bears are not currently considered a species of conservation concern (Yukon Conservation Data Centre 2019), although a conservation plan was developed for grizzly bears in 2019 to promote healthy and viable grizzly bear populations into the future (Yukon Grizzly Bear Conservation and Management Plan Working Group 2019a).

The greatest threats to the Canadian grizzly bear population are considered to be 1) human-caused mortality, including illegal and legal hunting, conflict kills, and railway or road mortalities, and 2) habitat loss and fragmentation (COSEWIC 2007). Members of the VGFN had observed in the late 1990s that Grizzly bears did not come near to the Dempster highway but were concerned with the old garbage dump areas along the highway possibly attracting bears (Sherry and Vuntut Gwitchin First Nation 1999, p. 286, 289). Key threats to grizzly bear populations in the Yukon are human-wildlife conflict and harvest mortality, although habitat loss and climate-related changes to food availability may also be significant (Yukon Grizzly Bear Conservation and Management Plan Working Group 2019a). Northern grizzly bear populations cannot sustain high mortality rates due to their low reproductive rates and low densities (Nagy et al. 1983). Sources of mortality in the RSA and surrounding region are discussed in detail in Section 4.4.

4.3 MORTALITY AND HARVEST

Grizzly bears are managed as a big game species in Yukon (Government of Yukon 2002), and harvest is permitted in most parts of the territory outside of National Parks, including resident, non-resident, and subsistence harvest. The overall mortality management system is based on estimated total sustainable mortality rates of ≤ 2% of the female population, ≤ 6% of the male population, and ≤ 4% of the total population (Yukon Grizzly Bear Conservation and Management Plan Working Group 2019a). Total allowable mortality rates account for mortality from harvest, and other sources, including vehicle collisions and defence of life and property (DLP) kills (i.e., conflict kills).

Yukon grizzly bear harvest is managed within BMUs, although harvest rates are often reported at the scale of Game Management Subzones (GMS) or broader Game Management Zones (GMZ). The bag limit is one grizzly bear every three years in open subzones, and hunters must report all bear kills (Government of Yukon 2021). The RSA is located within GMZ 1, with the lowest licenced grizzly bear harvest rates in the Yukon. Between 1980 and 2014, the annual grizzly bear harvest in GMZ 1 varied from zero to three bears (Milligan 2018). More specifically, within the Eagle Plains BMU (Map 4-1), only two grizzly bears were harvested from 1995 to the present (Pongracz and Suitor, pers. comm., 2022). The Eagle Plains BMU does not overlap any outfitter concessions (i.e., no non-resident harvest), so reported harvest rates are attributed to licenced resident harvest.

Other sources of grizzly bear mortality include DLP kills, collisions with vehicles, and predation from other bears or large carnivores. Grizzly bear mortality rates in the Eagle Plains BMU are low relative to other BMUs in the territory, with an annual average mortality density of < 0.1 bears per 1,000 km², based on records from 2005 to 2016 (Yukon Grizzly Bear Conservation and Management Plan Working Group 2019b). Mortality rates tend to be higher in southern Yukon, where both the human population and road densities are comparatively high, with mortality densities up to 0.6 bears per 1,000 km² in some BMUs (Yukon Grizzly Bear Conservation and Management Plan Working Group 2019b). However, these rates do not account for unreported human-caused mortality (e.g., unreported DLP kills) or natural sources of mortality. Reported DLP kills accounted for an average of 11 grizzly bear mortalities per year in Yukon from 1980 to 2016. DLP mortality rates are very low within the Eagle Plains BMU; from 1995 to 2021, only one grizzly bear DLP kill was reported (Pongracz and Suitor, pers. comm., 2022).

The correlation between road density and grizzly bear mortality has been well documented in other parts of western North America (McLellan 1990, Mace et al. 1996, Boulanger and Stenhouse 2014, Proctor et al. 2019). Most historical grizzly bear mortalities in central BC and Alberta were related to human activity and occurred within 500 m of a road (Ciarniello et al. 2004, Boulanger and Stenhouse 2014). In BC, grizzly bear mortality rates are known to increase in areas where road densities exceed 0.6 km/km² (Lamb et al. 2018). Mortalities were caused by higher rates of legal harvest, poaching, and conflict kills near roads, in addition to direct mortalities from road collisions. Roadside hunting of grizzly bears is currently permitted in Yukon, although this is under review in some local areas (Yukon Grizzly Bear Conservation and Management Plan Working Group 2019a).

Grizzly bear mortalities from vehicle collisions are rare in Yukon. Fifteen grizzly bear mortalities resulted from collisions with vehicles from 2003 to 2014 on all Yukon Highways (EDI Environmental Dynamics Inc. 2015). Collisions tended to occur in spring and summer when grizzly bears were foraging on roadside vegetation. Most collisions occurred on the Alaska Highway (60%), which has higher traffic volumes than other roads in the territory. The only major road in the RSA is the Dempster Highway, which has comparatively low traffic volumes and is unpaved. From 2003 to 2014, only one bear collision was reported on the Dempster Highway near Dawson City. The bear species was unidentified.

Predation is a source of mortality for grizzly bears, but predation rates are generally unknown in the Yukon. Male grizzly bears occasionally prey on females and cubs on the North Slope (Clarkson and Liepins 1994). Wolves in packs have also been known to kill grizzly bears in northern Yukon (Benson 2014).

4.4 REGIONAL HABITAT ECOLOGY AND DIET

The distribution of available forage strongly influences habitat selection by grizzly bears during spring, summer, and fall seasons (Nielsen et al. 2010, Milakovic et al. 2012) and the supply of suitable den sites in winter (Smereka et al. 2017). Security and thermal cover are also important (McLellan 1990). However, they are generally selected with nearby foraging habitats (Milakovic et al. 2012).

Much of the available information on seasonal grizzly bear habitat selection and diet comes from the interior mountains and coastal regions of western North America (e.g., Hamilton 1978, McCormick 1999, McLellan and Hovey 2001, Ciarniello et al. 2007, Maraj 2007, Nielsen et al. 2010, Milakovic et al. 2012, McClelland et al. 2020). However, the ecological characteristics of these populations may differ substantially from that of grizzly bears in northern Yukon. At a finer spatial scale, grizzly bear ecology within the RSA differs from grizzly bears elsewhere in northern Yukon, such as the Yukon North Slope or the nearby Ogilvie and Richardson Mountains (Pongracz and Suitor, pers. comm., 2022), but very little information exists about grizzly bears within the RSA. Literature and traditional knowledge from similar ecosystems in northern Yukon have been summarized to the extent possible, including the Taiga Cordillera and adjacent Taiga Plains Ecozones. When information specific to the region was unavailable, literature from other parts of the Yukon or western North America was consulted.

4.4.1 SEASONAL DIET

Grizzly bears have broad omnivorous diets, including plants, fish, terrestrial wildlife, and insects (MacHutchon and Wellwood 2003, Ciarniello and River 2018). Grizzly bear diets differ among regions due to variations in food availability across local climates (Mowat and Heard 2006, McLellan 2011, Coogan et al. 2014). Individual grizzly bear diets are also highly variable and dependent on seasonal and annual availability of food items within their home ranges (MacHutchon and Wellwood 2003, McClelland et al. 2020).

Seasonal grizzly bear diets generally reflect the phenological progression of key food resources such as herbaceous plants, ungulate calves, berries, and fish (Hamer and Herrero 1987, MacHutchon and Wellwood 2003, McClelland et al. 2020). Vegetation is a major component of grizzly bear diet in northern Yukon; for

example, vegetation comprised more than 30% of grizzly bear diet in the Richardson Mountains (Koizumi 2012). During spring, important plant foods for grizzly bears in the Taiga Cordillera include the roots of alpine hedysarum (*Hedysarum alpinum*), sedges (*Carex* spp.), grasses, horsetail (*Equisetum spp.),* and berries leftover from winter such as kinnikinnik (*Arctostaphalos uva-ursi*), bearberry (*Arctostaphalos rubra* or *A. alpina*), and crowberry (MacHutchon 2000, MacHutchon and Wellwood 2003). In summer and early fall, grizzly bear diet in northern Yukon includes a variety of berries such as blueberry (*Vaccinium uliginosum*), soapberry (*Shepherdia canadensis*), crowberry, bearberry, kinnikinnik, cranberry (*Vaccinium vitis-idaea*), and cloudberry (MacHutchon 2000, MacHutchon and Wellwood 2003). When berries are unavailable, grizzly bears may forage on herbaceous vegetation such as sedges, grasses, and horsetails. As berry availability declines in late fall, grizzly bears may dig for alpine hedysarum more frequently (MacHutchon and Wellwood 2003).

In northern Yukon, grizzly bear diets incorporate a relatively high proportion of terrestrial wildlife, comprising up to 70% of their diet (Mowat and Heard 2006, Koizumi 2012). Mammals are likely an important food source throughout the spring, summer, and fall whenever they are available, including caribou (*Rangifer tarandus*), moose (*Alces alces*), arctic ground squirrels (*Spermophilus parryii*), and small rodents (MacHutchon 2000, MacHutchon and Wellwood 2003, Koizumi 2012). Arctic ground squirrels are an important food source, and grizzly bears may spend increasing effort pursuing them as berry availability declines in late fall (MacHutchon and Wellwood 2003). Arctic ground squirrels tend to select slopes with well-drained soils and avoid wet, flat, or hummocky terrain (Barker and Derocher 2010), which characterizes much of the RSA. Thus, grizzly bears with home ranges that overlap the RSA may rely heavily on other food sources (e.g., alpine hedysarum or ungulates). Traditional knowledge suggests that bears may travel to the nearby Richardson Mountains to forage on ground squirrels in fall (Benson 2014).

Ungulates may be a particularly important food source in spring, when grizzly bears in northern Yukon and Alaska prey on caribou and moose calves (Boertje et al. 1988, MacHutchon 2000, MacHutchon and Wellwood 2003). Barren-ground caribou (*Rangifer tarandus groenlandicus*) are a focal food source for grizzly bears in northern Yukon during caribou calving and seasonal migration periods (MacHutchon and Wellwood 2003). Grizzly bears may follow caribou as they migrate to and from their calving grounds (Reynolds and Garner 1987, Benson 2014), targeting calves or opportunistically preying on adults (MacHutchon and Wellwood 2003). Northern grizzly bear populations that prey on caribou during calving or migration have higher reproductive rates and population densities than those that do not overlap caribou range (Reynolds and Garner 1987). Grizzly bear diet has not been studied within the RSA, and there is no scientific data on the relative importance of caribou as a food source. However, the Porcupine caribou herd migrates through the RSA en route to calving grounds on the arctic coastal plain and again during their return to winter range in the Richardson and Ogilvie mountains (Russell et al. 1993, Ryder et al. 2007). Grizzly bears within the RSA likely use caribou during spring and fall migration.

Salmon, trout, and char are important seasonal foods for grizzly bears (Mowat and Heard 2006, Adams et al. 2017). During fall, grizzly bears congregate at the Fishing Branch River in Ni'iinlii Njik Territorial Park to feed on chum salmon (*Oncorhynchus keta*) (Vuntut Gwitchin Government and Environment Yukon 2010). Grizzly bears on the north slope are also known to feed on Dolly Varden trout (*Salvelinus malma*) (MacHutchon and Wellwood 2003). Baseline fish inventories for the Project found that salmon and trout were absent within the

RSA (EDI Environmental Dynamics Inc. 2022a). Arctic grayling (*Thymallus arcticus*) were the most common fish species, although longnose sucker (*Catostomus catostomus*) and round whitefish (*Prosopium cylindraceum*) were also present. Grizzly bear in the Richardson Mountains have been observed feeding on arctic grayling (Benson 2014), and whitefish and sucker are known food sources in the central Canadian arctic (Gau et al. 2002, Barker 2011).

4.4.2 FORAGING HABITAT

The availability, abundance, and distribution of important grizzly bear forage directly influence grizzly bear abundance and distribution during the growing season (McLoughlin et al. 2002a, Nielsen et al. 2017, McClelland et al. 2020). Grizzly bear populations in the subarctic and arctic are generally considered limited by food (McLoughlin et al. 2002a). Grizzly bears may balance the selection of high-quality food patches with avoidance of landscape features associated with high mortality risk, such as areas with dense human developments and roads (Nielsen et al. 2010, Proctor et al. 2017). However, given the relatively low harvest rates and low levels of human development in the RSA, it is likely that grizzly bear habitat selection is driven by food availability.

The literature on grizzly bear foraging habitat selection in the mountains, boreal forest, and coastal regions of western North America is extensive (e.g., Hamilton 1978, McCormick 1999, McLellan and Hovey 2001, Ciarniello et al. 2007, Maraj 2007, Nielsen et al. 2010, Milakovic et al. 2012, McClelland et al. 2020), but far less is known about habitat use in northern ecosystems. Studies in northern Yukon, Alaska, and NWT have focused mainly on arctic barren-ground grizzly bears (Phillips 1987, MacHutchon 1996, Gau 1998, McLoughlin et al. 2002a, Barker 2011), leaving a substantial knowledge gap about grizzly bear ecology in the Taiga Cordillera (particularly non-mountainous areas such as the Eagle Plains Ecoregion).

Grizzly bear distribution was clumped in the Richardson Mountains rather than uniform; bear densities were comparatively high in habitats with abundant food such as riparian valleys and low in flat tundra plains (Clarkson et al. 1993). Local traditional knowledge suggests that mountains are better grizzly bear habitat than taiga or barren-ground plains due to the abundance of berries and ground squirrels, and the earlier snowmelt on windblown and south-facing slopes in spring (Benson 2014). Grizzly bears in northern Yukon have large home range sizes (up to 1,250 km^2) and travel long distances to reach suitable foraging habitat (MacHutchon 2000). Thus, grizzly bears in the RSA may travel to the Richardson or Ogilvie Mountains for seasonal forage. This is consistent with the knowledge that grizzly bears have low densities in the RSA, and their behaviour is characterized by seasonal movements through the area (Pongracz and Suitor, pers. comm., 2022).

In the central Canadian arctic, barren-ground grizzly bears selected eskers, shrubby riparian zones, and tussock tundra throughout the spring, summer, and fall, corresponding with the spatial and temporal availability of food (Phillips 1987, McLoughlin et al. 2002a). Esker slopes support a relatively high abundance of berry-producing shrubs and arctic ground squirrels (Gau 1998, Barker and Derocher 2010, Barker 2011), whereas riparian zones and tussock tundra may provide herbaceous forage such as horsetails, sedges, and cotton grasses (*Eriophorum* spp.) (Gau 1998, Gau et al. 2002). Barren-ground grizzly bears also selected habitat with abundant lichen, which may attract caribou (McLoughlin et al. 2002a). During the Porcupine caribou

migration on the Yukon north slope, grizzly bears travelled along river channels or selected hillsides with long sight-lines, presumably to increase their chances of detecting caribou (MacHutchon 2001).

4.4.3 COVER (SECURITY AND THERMAL HABITAT)

Security habitat includes areas of dense vegetation that provide visual screening from other grizzly bears or humans (Mace and Waller 1997). Security cover may be particularly important for sub-adult male bears and sows with cubs to avoid adult males defending their territories or killing cubs to bring females into estrus (LeFranc et al. 1987, McLellan 2005). Female grizzly bears may select lower-quality foraging habitat if it provides high security values or spatial separation from potentially aggressive male bears (Pearson 1975, McLellan and Shackleton 1988). For example, female grizzly bears in the arctic are thought to occupy the Mackenzie Delta to avoid male bears in adjacent mountain ranges (Benson 2014).

Thermal cover includes habitat that provides relief from the elements, such as solar exposure or extreme weather. Cover from heat and solar exposure is provided by various habitats such as open water (e.g., rivers, streams, lakes), permanent snow patches, steep north aspects, and mature forest patches with high canopy closure (Pearson 1975, LeFranc et al. 1987). Grizzly bears may also select forests with high canopy closure for day beds to seek shelter from heavy rains (Pearson 1975, Munro et al. 2006). The importance of thermal cover for grizzly bears in the Taiga Cordillera has not been studied.

4.4.4 WINTER DENNING HABITAT

Grizzly bears in northern Yukon hibernate in winter from approximately October to May (Nagy et al. 1983, MacHutchon 2000), although the timing for den entry and emergence depends on annual weather patterns. Grizzly bears will enter their dens as late as mid-November and emerge as early as March if the weather is warm (Benson 2014).

No records exist of grizzly bears dens within the RSA, although grizzly bears are known to den in the mountains of Ni'iinli Njik (Fishing Branch) Territorial Park, approximately 20 km west of the RSA (Pongracz and Suitor, pers. comm., 2022). Grizzly bears in the arctic and subarctic typically excavate their dens in locations with suitable soil, such as sand, gravel, or glacier-deposited rock (MacHutchon 2000, Smereka et al. 2017). Grizzly bears in Vuntut National Park in northern Yukon preferentially select den sites in the mountainous regions of the park and avoid denning in Old Crow Flats, which is characterized by flat topography, large wetland complexes, and spruce forests (MacHutchon 2000). Denning within Old Crow Flats is likely limited to dry, steep riverbank slopes (MacHutchon 2000). Grizzly bears throughout the Gwitch'in Settlement Area are known to prefer denning in the mountains; however, in areas with flat topography (such as the RSA), grizzly bears will select small topographical features such as hills, steep riparian banks, or lakesides to excavate their dens (Benson 2014). Grizzly bears in northern Yukon have large home ranges (Section 4.5.5) and may travel long distances to reach winter den sites (up to 65 km; Craighead 1976). Thus, some grizzly bears with home ranges overlapping the RSA may travel to nearby mountain ranges (Richardson Mountains, Ogilvie Mountains, or Ni'iinli Njik Territorial Park) to hibernate.

In arctic barren-ground ecosystems, grizzly bears select river banks, lakesides, or eskers with silty or sandy soil for denning (Harding 1976, Mueller 1995) and avoid open spruce forest (Smereka et al. 2017). Grizzly bears prefer to excavate their dens on steep south-facing slopes with abundant shrub cover in the arctic (Mueller 1995, McLoughlin et al. 2002b) and the boreal forest of southern Yukon (Libal et al. 2012). The root structures of tall shrubs such as willow (*Salix* spp) and dwarf birch (*Betula glandulosa*) may provide support to the ceilings of excavated grizzly bear dens (McLoughlin et al. 2002b).

4.4.5 HOME RANGE AND SEASONAL MOVEMENTS

Grizzly bear home range sizes are variable and have an inverse relationship with food availability (Nagy and Haroldson 1990, McLoughlin et al. 2000). Thus, grizzly bear home ranges in productive coastal or interior mountain habitats of BC are typically smaller and have greater overlap than those in less productive boreal, taiga, or arctic barren-ground ecosystems (McLoughlin et al. 2000, Edwards et al. 2009, Hamilton et al. 2018). Additionally, the size of individual home ranges may vary annually in response to fluctuations in the quality and abundance of food (McLoughlin et al. 2000). The largest recorded grizzly bear home range sizes in North America were in the central Canadian Arctic, where mean home range sizes for female and male bears were 2,100 km² and 7,245 km², respectively (McLoughlin et al. 2003).

No data on grizzly bear home range sizes within the RSA are available, but studies conducted in other parts of the Taiga Cordillera provide some insight. Grizzly bear home range sizes in the Old Crow flats of Vuntut National Park were estimated at 650 – 750 km² for females and 1,150 – 1,250 km² for males (MacHutchon 2000). In the Richardson Mountains north of the RSA, female grizzly bears had mean annual home ranges of 442 km² and males had home ranges of 760 km² (Koizumi 2012). The smaller home ranges in the Richardson Mountains may be attributed to more food resources, such as berries and ground squirrels relative to the taiga plains (Benson 2014).

Grizzly bears have low fidelity to home ranges in unproductive arctic ecosystems, where food distribution is spatially and temporally heterogenous, and grizzly bear population densities are low (Edwards et al. 2009). Under these conditions, it is beneficial for grizzly bears to adjust the size and location of their home ranges to maximize forage availability. For example, in northern Yukon and Alaska, grizzly bears may travel long distances to follow the seasonal migration of barren-ground caribou (Reynolds and Garner 1987, MacHutchon 2001). Grizzly bears in northern Yukon are also thought to travel long distances to find suitable winter denning habitat in the mountains (Benson 2014).

4.5 SUMMARY

Available data suggest that a low density of grizzly bears are distributed throughout the RSA. Rates of recorded harvest mortality are low within the Eagle Plains BMU, but other sources of mortality are largely unknown and unrecorded. Grizzly bear diet in the RSA and surrounding region predominantly consists of vegetation (berries, roots, and herbaceous plants) and terrestrial wildlife, including caribou, moose, and arctic ground squirrels. Grizzly bears may rely heavily on caribou (particularly calves) during the seasonal migration of the Porcupine caribou herd through the region. Habitat quality in the RSA is generally poor compared to the adjacent mountain ranges, where berries and ground squirrels are more abundant. Lastly, grizzly bears in the RSA may excavate their winter dens in riverbanks, lakesides, and hills where suitable soil can be found, or they may travel to nearby mountain ranges to den on steep south-facing slopes. Most of the information presented in this review was based on scientific studies.

5 MOOSE

5.1 PURPOSE AND OBJECTIVES

Moose (*Alces alces*) were selected as a VC for the Project due to their importance as a managed game species, and their cultural values to First Nations living in the Yukon. Winter, and especially the late winter season, is often a difficult time for moose due to the limited availability of forage and increased energetic demands to move through crusted or deep snow. A winter habitat suitability map was developed for moose in the RSA to identify high-suitability winter forage habitat areas. The map quantifies the winter forage habitat in each habitat class (high, moderate, low/nil/very low) within the RSA.

This section summarizes information and data on moose use and ecology in the subarctic taiga that was used to develop habitat suitability mapping to quantify the suitability, amount, and distribution of potential habitat for moose in the RSA.

5.2 GENERAL HABITAT ECOLOGY OF MOOSE

5.2.1 EXISTING INFORMATION

There is limited knowledge of moose within the RSA. In 2001, Anderson Resources Ltd submitted a project application and a mitigation plan for an Eagle Plains 2001–2003 Seismic Survey Program (Access Consulting Group and EBA Engineering Consultants Ltd. 2001). This report describes moose knowledge of the area as being limited and incidental. The authors reviewed the existing data and had discussions with local wildlife biologists and other resource users about winter usage patterns by moose in the general vicinity of the Eagle Plains project area. At that time, moose were only superficially studied in the Eagle Plains Area (Access Consulting Group and EBA Engineering Consultants Ltd. 2001).

The 2001 project application report stated that an approximate moose density of about 0.05 moose/km² was estimated for the project area based on general habitat assessment. The application also provided the following information:

> "*Within the project area, moose are not commercially exploited and there are no outfitting concessions. There is limited off-road access and the moose population density within the project area is known to be low, hence the subsistence harvest is minor. YTG Renewable Resources harvest data show that, in the last twenty years, only 13 moose have been harvested in the Dempster Corridor subzones (Game Management Zone 1-55 and 1-56).*
>
> *Anderson conducted a post-rut moose survey in early November of 2000, to augment the currently very limited knowledge regarding moose populations in the project area. The survey was conducted to provide baseline information on the level of range usage by moose within the project area. During the course of the 2-day survey, 30 moose were observed and an additional 64 sets of tracks were encountered. In general, moose were more frequently associated with the higher elevations (between 400 m and 700 m above sea level), but were widely dispersed throughout all of project*

area's drainages. From the survey results, an overall population of approximately 60-90 moose was estimated (Access Consulting Group and EBA Engineering Consultants Ltd. 2001)."

These observations of greater moose abundance at higher elevations are consistent with observations from VGFN elders around the same time (Sherry and Vuntut Gwitchin First Nation 1999, p. 7). They discussed that Eagle Plains was an important moose range, but that some animal populations had changed their land use after the Dempster highway was built and there was low density near the highway (Sherry and Vuntut Gwitchin First Nation 1999, p. 287, 299).

In 2001, an aerial survey was completed from June 18–22 within the 2001 project area. During that survey, 19 moose were incidentally observed, with most observations noted in the South Eagle River and Dalglish Creek area. A general point of interest was that moose calving was expected in several drainages, but was particularly noteworthy in the South Eagle River (Access Consulting Group and EBA Engineering Consultants Ltd. 2001).

In 2013 Environment Yukon conducted an 'Eagle Plains Mammal Occupancy Aerial Survey' from March 19 to March 24, 2013 (Environment Yukon, unpublished data). The survey aimed to assess the occurrence and distribution of large mammals within the broader Eagle Plains Ecoregion. Over the 6 survey days, 64 moose were observed, including cow and calf observations. The data indicated that moose were widely distributed within the Eagle Plains area, but the area was not comprehensively surveyed, and formal analyses/reporting were not included with the data.

From October 2014 through August 2016, Yukon Environment deployed 37 (2014) to 48 (2015) pairs of remote cameras in the Eagle Plains area (Burden 2016). The objective was to assess the use of linear features by medium to large mammals (wolves, caribou, and moose) by comparing the use of wildlife on and off seismic lines by placing cameras at random locations on seismic lines, and camera locations off seismic lines. The report is a data summary with no statistical analysis, and the results are non-standardized (e.g., lacking a catch per unit effort reporting metric). Regardless, there was some information collected for moose relevant to this study. Over the two years of study, moose encounters were infrequent and varied slightly among years (0.33 moose/100 camera days in 2014–2015, 0.43 moose/100 camera days in 2015–2016). Moose were found in the study area throughout the year but were observed more often from May through November (spring through fall). No statistical analyses or apparent trends were used to determine moose associations with linear disturbances.

EDI did not complete other population or distribution surveys for moose as part of the current baseline studies. Efforts focused on developing a winter habitat model to quantify habitat suitability, amount, and distribution across the RSA.

5.2.2 HABITAT ECOLOGY OF MOOSE

Moose are one of the most widely distributed ungulates and range from the Arctic coasts of North America, Europe, and Asia down to the southern limits of the boreal forest and farther south where suitable montane biomes are located exist. In the Yukon, moose densities generally range between 100 and 250 moose for every 1,000 km^2 of suitable moose habitat (Environment Yukon 2016b). The Regional Biologist has indicated that,

based on his observations, moose densities in Eagle Plains are relatively low compared to some parts of the southern Yukon, but that moose densities in Eagle Plains are high compared to other parts of North Yukon (Mike Suitor, pers comm).

Moose make seasonal movements to various habitats such as calving, summer, rutting, and winter habitats. These seasonal movements may range from a few to many kilometres (Clarke et al. 2017, Government of Yukon 2022). Changing environmental conditions can affect the quality, quantity, distribution, and accessibility of cover and forage over a landscape. Key habitat requirements are rarely distributed evenly over space or time, so moose move to access various resources as availability changes. Periodic disturbances, such as wildfire and vegetation clearing change the abundance and availability of moose cover and forage. Moose are generally not evenly distributed across the landscape; they concentrate in particular habitats offering higher forage opportunities(Government of Yukon 2022). Moose with access to large quantities of forage are known to travel less than those in areas where forage is less abundant (McCulley et al. 2017). There is a wide variation in home range sizes for moose across the boreal forest and between seasons (Phillips et al. 1973, Addison et al. 1980, Clarke et al. 2017, McCulley et al. 2017). Moose that frequent the Old Crow Flats wetland complexes in northern Yukon are known to spend summer months within this area and then migrate 250 km to spend the winter within the Alaska Arctic National Wildlife Refuge (McCulley et al. 2017).

Moose habitat selection patterns vary among populations, individuals, seasons, and sexes (Clarke et al. 2017, McLeod and Clarke 2017). Furthermore, habitat use by moose can differ depending on the type of land cover and the availability of resources in a particular area. In northern Yukon, moose appear to frequent narrow strips of forest along the rivers (Photo 5-1), and VGFN elders have observed good moose habitat just south of the RSA along the Blackstone and Ogilvie rivers and the wetlands of the Blackstone Uplands (Sherry and Vuntut Gwitchin First Nation 1999, p. 303). In the south, moose frequent the treeline in the subalpine shrub zone. Moose in the Yukon also tend to concentrate in recent burns and along waterways with interconnecting ponds, marshes and meandering streams (Government of Yukon 2022).

Moose inhabit numerous stand-cover types and structural stages. Conifer stands are generally used primarily as cover to moderate extremes of cold, wind, heat, deep snow, and security from predators (Timmermann and McNicol 1988, McCulley et al. 2017). Early seral areas are usually shrub-dominated and used by moose because shrub species comprise more than 60% of a moose's annual diet (Renecker and Schwartz 2007). During the spring and summer, moose forage primarily on the leaves of woody plants, aquatic plants, and forbs. During winter, the diet shifts to highly lignified woody stems, resulting in higher ruminating times (Renecker and Hudson 1986). Plant form and twig diameter have also been shown to affect digestion rates, influencing moose winter foraging (Vivas et al. 1991). Some preferred moose forage species include:

- Willows (*Salix* spp.)
- Red-osier dogwood (*Cornus sericea*)
- Saskatoon serviceberry (*Amelanchier alnifolia*)
- Highbush cranberry (*Viburnum edule*)
- Mountain ash (*Sorbus sitchensis*)
- Scrub birch (*Betula glandulosa / nana*)

- Trembling aspen (*Populus tremuloides*)
- Lodgepole pine (*Pinus contorta*)
- Paper birch (*Betula papyrifera*)

These browse species may be used preferentially due to their height and growth form (Baker 1990, Van Ballenberghe et al. 1989). The palatability of shrub species can also vary from region to region. Soopolallie (*Shepherdia canadensis*) was recorded as an important forage species for moose on the Kenai Peninsula, Alaska (Edwards 1940) but appears to be unpalatable in other parts of the boreal forest (Rolley and Keith 1980). In northeast Alberta, the preferred browse species was Saskatoon serviceberry; even in areas where it was uncommon, the species was still heavily used when it was present (Nowlin 1978). In the Peace-Athabasca Delta, moose feed primarily on willow, red-osier dogwood, paper birch and balsam poplar. In one study done in the taiga region ranging from northwestern Manitoba to Great Slave Lake NWT, winter moose diet was mainly composed of *Betula papyrifera* bark (Thomas 1990). Risenhoover (1989) found that willows accounted for more than 94% of the winter moose diet in Denali National Park and Preserve.

Within the RSA, willows and scrub birch are the dominant browse species available for moose. Willows often form the predominant diet in other northern areas. Willows are well adapted to wetter soils and are commonly found in wetland and riparian habitats (Photo 5-2). Willows are also an early successional species and are often abundant in early seral habitats resulting from forest fires and human-disturbed areas (e.g., seismic lines, cutblocks, and road rights-of-way). Moose have been reported selecting previously burned habitats and areas within 100 m of streams and waterbodies, presumably due to the abundant forage (Wasser et al. 2011). In habitats with low availability of twigs and leaves, moose sometimes use a foraging technique called 'bark-stripping' where long, linear strips of bark are peeled from certain trees, such as aspen (LeResche and Davis 1973, Miquelle and Van Ballenberghe 1989). However, the bark is usually a relatively small component of moose diets (Miquelle and Van Ballenberghe 1989). It is unlikely to be a significant food source in Eagle Plains due to the dominance of spruce, whose bark is non-palatable.

Across Canada, heavily used areas by moose include wetlands, floodplains of major rivers, riparian areas, regenerating cut blocks and burns, and avalanche chutes. Their preferred habitat types include recent burns, logged areas, lake and river shores, willow and alder swamps and other wetland areas MacCracken et al. 1997). Food (including forage quality) and climate are considered important aspects of habitat for moose (Franzmann 1981). Analyses of moose range commonly stress the abundance, production, and use of woody shrubs as important characteristics when describing moose habitat requirements (LeResche and Davis 1973; Jung et al. 2009).

In Labrador, moose can be observed more often in riparian areas and hardwood stands and less often in string bogs, open conifer-lichen stands, barren hilltops than expected based on the availability of those habitat types during the winter (Jung et al. 2009). Riparian areas are often high suitability habitats for moose in winter due to the availability of high-quality forage species such as willows. Willows and birch found within the riparian shrub communities are often adjacent to a strip of closed-canopy conifer-dominated forest that provides thermal cover and snow interception. The combination of shrub communities and closed-canopy mature riparian forests offer a highly suitable habitat mosaic for moose (Jung et al. 2009).

During the winter, moose are influenced by snow depth, snow density and hardness. Moose movements begin to be impeded at snow depths of 70 cm, and moose strongly avoid areas with >100 cm of snow. Moose generally winter in areas where snow depths are less than 70 cm (Coady 1974, Franzmann 1981). In mountainous areas, where snow accumulation can vary substantially, this can result in strong patterns of seasonal range use, with moose avoiding mid an upper elevation where snow accumulation is higher. For example, in the Pelly-Macmillan River area (Central Yukon), moose concentrated along the major river valleys during late winter, where the combination of shallower snow under mature forest canopies and dense willows in wetland areas provided moose with optimal habitat (O'Donoghue 2005). However, snow is not expected to strongly influence the distribution or habitat selection in the RSA in most years. This is due to the relatively modest elevation range within the RSA. The average maximum snow depths of approximately 80 cm are just on the edge of the range that moose avoid (EDI Environmental Dynamics Inc. 2021). Over much of the winter, snow depths are less than 70 cm.

Predation is recognized as a major factor affecting the dynamic of moose populations (Gasaway et al. 1992, Ballard and Van Ballenberghe 2007). In general, prey species select security habitats at multiple scales based on various factors that can affect their perceived predation risk. Perceived security is also a dynamic factor that varies over time and is dependent on the density and behaviour of predators, including humans. Moose population growth and density in Yukon are thought to be limited by wolves (Hayes et al. 2003). Consequently, moose may avoid habitats that increase the potential for wolf encounters. However, predator avoidance may be a more prominent factor in habitat selection at the landscape scale than within a home range (Dussault et al. 2005). Habitat types with taller and denser vegetation likely provide some protection from wolves during winter. Habitat types that provide cover from predators may also contain taller trees that intercept snow, reducing snow depth and reducing the energy required to move.

At a minimum, security habitat should conceal a moose from predators. It can be assumed the security habitat for moose can be provided by any forest stand of adequate density with trees and shrubs taller than 2 m. Security cover for moose is most critical during spring calving when cow moose seek out islands and gravel bars on river floodplains for calving. At calving time, cow moose and calves can find secure habitat in dense deciduous or mixedwood stands, or tall shrubs with canopy cover >50% (MacCracken et al. 1997). During winter, deep, and persistent snow has been shown to have a greater impact on the physical condition of moose and thus increasing its risk of predation. Within one study (Dickie et al. 2020), moose seem to select riparian areas to facilitate movement instead of selecting them only for foraging opportunities. In the RSA, most wildlife trails were observed adjacent to riparian areas.

Photo 5-1. A moose observed adjacent to a narrow treed riparian area in the RSA (Photo provided by Palmer Environmental 2019).

Photo 5-2. Shrubby riparian area, on the edge of a burn, where willows have been browsed by moose.

5.2.3 DISTURBANCE

5.2.3.1 Fire

Burns are often a major factor affecting the distribution and abundance of moose across the boreal forest, with densities peaking 20 to 25 years after fire (LeResche 1974). Studies have shown that moose populations are often denser in burned areas where browse is of higher quality and greater abundance than adjacent, unburned areas (Gasaway et al. 1989). Moose have been reported selecting previously burned habitats that are 10–30 years old (Maier et al. 2005) and less than 40 years old (Wasser et al. 2011). Overall, fire creates favourable forage conditions for moose when regenerating shrubs are available for browse.

Several large wildfires have affected the RSA, occurring between 1959 and 2018. Areas that were affected by fire, and are still regenerating, were labelled with a fire disturbance code in the ELC vegetation maps. For older burn areas, the adjacent non-burned area was compared to the burn area to see if there was a noticeable difference in vegetation. Areas that did not have a noticeable difference were not characterized as fire disturbed as they were considered regenerated. The appropriate structural stage was assigned to reflect the stage of regeneration.

The post-fire successional pathways for many of the ecosystem units in the RSA were the same or very similar, making the differentiation of ecosystem units based on revegetation difficult. For example, almost all ecosystem units regenerate initially with deciduous shrubs (willow and scrub birch) and a mix of spruce and deciduous trees (primarily paper birch), and, as succession progresses, the prominence of spruce increases and deciduous shrubs and trees decreases. Often the post-fire succession also varied within an ecosystem unit depending on several factors, including the number and frequency of fires, the intensity of the fire, and the amount of permafrost present before and after the fire. Field observations suggest that hot fires likely melted a larger portion of the permafrost, permanently altering the moisture regime of the affected area; therefore, site moisture regimes are altered, and some sites do not return to the same ecosystem unit that had been established before the fire. From a moose habitat perspective, the result is that, except for some ecosystem units in riparian areas, the abundance of browse species is affected more by regeneration status and structural stage than ecosystem unit type.

The current structural stage for some of the more recent fire-disturbed areas was difficult to determine due to the range in age and variety of the imagery. To be consistent, the mappers assigned a shrub structural stage to all fire disturbed areas unless there was strong evidence suggestion another structural stage (i.e., a plot stating it was graminoid dominant, Photo 5-3).

Photo 5-3. Recent burn in a graminoid structural stage. Generally, regenerating shrubs become available as browse to moose about 10 years after fire disturbance.

5.2.3.2 Linear Features

Linear features are the primary type of anthropogenic disturbance in the Project area. However, there are many uncertainties regarding the extent, impacts, and recovery status of linear features in the area. Linear features include narrow, linear clearings on the landscape, typically used for transportation and seismic exploration activities. The Project area has numerous 2D seismic lines (e.g., Photo 5-4) and winter roads from previous exploration activities dating back to the 1960s. The majority of 2D exploration occurred between 1961 and 1984. Some 2D exploration occurred in 2001 that incorporated LIS techniques (Access Consulting Group and EBA Engineering Consultants Ltd. 2001, GEOTIR 2014). More recently, approximately 2,200 km of 3D low-impact seismic (LIS) exploration was conducted in a 325 km² area between November 2013 and April 2014 (GEOTIR 2014). This 3D exploration grid is near the centre of the Project area, spanning north and south of the Dempster Highway.

Linear features can affect predation risk on moose. Facilitated predation operates by increasing the spatiotemporal overlap and interactions between wolves and prey species (Serrouya et al. 2016, Dickie et al. 2020). The magnitude and extent of such overlap are dependent on the extent and use of linear features across the contiguous woodland habitat. Linear features may enhance predation rates by increasing predator abundance via travel corridors and, ultimately, by optimizing hunting efficiency (Serrouya et al. 2016, Dickie et al. 2017, DeMars and Boutin 2018). The degree to which facilitated predation operates and affects prey species is context dependent. The primary features possibly associated with facilitated predation in the Project area are winter roads/trails, 2D and 3D seismic lines, and the Dempster Highway. In winter, clearing and compaction of snow on linear features by plowing or snowmobiles can elevate predator movements (Keim et al. 2019b), further exacerbating predation risk.

The Dempster Highway runs roughly southwest to northeast through the southern half of the RSA. The RSA includes numerous winter roads (15 m average width) from previous exploration activities dating back to the 1960s. The Project will be accessed via existing and new winter roads. Moose have been shown to avoid human development and activity, but response varies by season, sex, and population. Reduced use by moose has been documented near roads (Rolley and Keith 1980).

Moose use of seismic lines is variable. In a study completed in northern Alberta by Dickie et al. (2020), moose selected to be closer to riparian areas and avoided being closer to linear features. Another study demonstrated that seismic lines could increase encounter rates between prey and predator by facilitating predator movement (McKenzie et al. 2012). Moose, wolves and even people tend to move faster on linear features since these features create a path with less visual and physical resistance to movement but in some cases the ease of movement can increase the risk of prey species encountering a predator. Dickie et al. (2020) noted that moose had tendency to move faster while on linear features which could support the theory that moose perceive LFs as a risk to wolf encounters.

Many uncertainties surrounding the ecological impacts and recovery potentials for linear features, particularly of 2D and 3D seismic lines, in the taiga ecosystem that characterizes Eagle Plains. EDI completed a linear feature study. The purpose of that study was to systematically describe and quantify the current conditions of linear features across the RSA by providing a baseline inventory and assessing the successional and functional status of linear features. Six types of successional pathways were defined on linear features in the Eagle Plains area (Table 5-1; after Simpson 2008).

Most sites surveyed (79%) were undergoing normal succession, and that vegetation was either in a low shrub (56.1%) or tall shrub (29.0%) structural stage along the linear features sampled. Almost all 3D plots were at a low shrub structural stage (67% less than 1 m), while 2D plots and winter roads were distributed more evenly through low shrub, tall shrub, and forested structural stages (21% greater than 4 m and 5% greater than 8 m). The analyses suggested that 2D seismic lines regenerate to a more shrub-dominated community relative to pre-disturbance conditions, 3D seismic lines had lower woody cover than off-line plots after five years of regeneration, and fire has the potential to increase shrub and tree growth on linear disturbances. Sightlines along linear features decreased substantially as the height of vegetation increased, and ease of travel along linear features decreased with the amount of woody cover. Fire played an important role in shaping functional recovery by increasing the amount of woody cover and the structural stage of vegetation.

Under normal succession, 2D seismic lines had 12% to 19% greater mean shrub cover than the corresponding off-line sites in burnt and unburnt conditions, respectively. In unburnt conditions, 2D seismic lines had considerably shorter and sparser trees than paired off-line plots, but in burnt conditions, the 2D lines showed denser trees. Burn status appeared to influence some successional classes. Magnified succession was more common at burnt sites (19 burnt versus 5 unburnt), while stagnated succession was more common at unburnt sites (3 burnt versus 7 unburnt). Sites on a normal successional trajectory did not appear to have any relationship to burnt status, while other successional classes were too uncommon to draw any conclusions.

Studies focusing on the use of linear features by moose are limited. However, Keim et al. (2019a) found that moose used 3D seismic lines the least and used well-defined 2D seismic lines and pipelines the most.

Photo 5-4. Example of a low shrub 2D seismic line within the RSA.

Table 5-1. Descriptions of successional classes documented in the RSA (Simpson 2008).

Successional Class	Description
Normal succession	Similar to adjacent forest, but at an earlier seral stage. E.g., young trees that may be surrounded by early successional shrub and forb or graminoid species. Disturbance is likely only the removal of trees and shrubs, with little to no disturbance to soil or permafrost.
Magnified succession	Increased moisture and nutrient availability due to soil disturbance. Often new seral species due to removal of original trees and shrubs. Resulting vegetation is likely shrub or deciduous tree dominant, typically with more productive growth than adjacent sites. Disturbance is likely the removal of trees and shrubs, with significant disturbance to soil or permafrost.
Retrogressive succession	Removal of insulating peat layer causes a change in the soil thermal regime. Active permafrost layer depth increases, releasing water content. Resulting habitat is likely moss, graminoid, forb, or low shrub dominated, with high moisture content. Disturbance includes the complete removal of trees and shrubs, and soil or active permafrost layer.
Successional stagnation	Suspension of succession at herb or low shrub stage. Likely dominated by graminoids; area may have been seeded. Check line age to differentiate from normal succession. Disturbance to soil or permafrost is likely. Ground may have been compacted.
No succession	No ecological differences except that the forest opening is linear instead of random. Disturbance is likely only the removal of trees and shrubs, with little to no disturbance to soil or permafrost.
Recent disturbance	Newer seismic line where successional patterns cannot yet be determined. Line age was checked to differentiate from other successional patterns.

5.2.4 HABITAT SUMMARY

The late winter season is often a difficult time for moose due to the limited availability of forage and increased energetic demands to move through crusted or deep snow. A winter habitat suitability map was developed for moose in the RSA to identify high-suitability winter forage habitat areas. Moose select winter habitat based on three criteria: food availability, snow conditions, and predator avoidance (Dussault et al. 2005). Within the RSA, moose primarily select winter habitat based on browse availability.

The development of the moose habitat model will focus on the following key points:

- Habitat use is believed to be driven by forage availability.
- Winter is the most limiting season for forage availability.
- Winter forage in the RSA is primarily willow species.
- Areas with high willow cover in the RSA are riparian areas, burn areas and some mesic and moist ecosystem units with moderate willow understory.
- Elevation and snow are not likely a significant factor given the limited topography within the RSA; and
- Linear features like seismic lines and trails may provide small patches with elevated willow cover, but their extent are too small to affect habitat selection.

Willows are the primary winter food for moose and signs of moose browsing were commonly observed in the areas that contain abundant willow during the Project baseline surveys. As willow is an early succession species, the shrub is most abundant in disturbed areas such as burns. Anthropogenic disturbances in the RSA, such as 2D seismic lines, may also have a high willow cover, but the extent of these areas is too small to provide significant forage opportunities to moose. Outside of regenerating areas, the high cover of willows is mainly associated with riparian shrublands along streams and disclimax shrublands within the RSA.

5.2.5 HABITAT SUITABILITY MAPPING

Habitat suitability mapping identifies the current ability of an ecosystem unit to provide certain life requisites for a given wildlife species or provide the environmental conditions needed for cover, food and space. A habitat suitability rating is a value given to each structural stage of each ecosystem unit in a project area. The rating is the suitability value assigned to a habitat for its potential to support a particular species for a specified season and activity. It is often expressed as a percentage of the best habitat. It also reflects the species' expected use of a habitat (Resources Inventory Committee 1999c). Habitat ratings are a product of knowledge and assumptions.

The important role of vegetation is incorporated into any wildlife habitat evaluation. Biophysical factors which are considered to influence wildlife habitats can include vegetation type, slope, aspect, and other geographic features. Since vegetation cover type is an expression of various biophysical conditions such as soil moisture, aspect, and relief, it generally offers a current and valid prediction of habitat for many terrestrial wildlife species, at least at broad scales.

The wildlife habitat evaluation is essentially a modelling process that has two primary requirements:

1. Good knowledge of the habitat needs of a species, and how these habitat needs relate to the described ecosystem units; and
2. A standard approach to establishing wildlife species-habitat relationships and ratings for ecosystem units consistently.

The suitability maps use ecosystem attributes for assigning suitability values to a polygon. Wildlife habitat suitability ratings are a widely applicable method of wildlife habitat assessments. While there are recognized limitations to any habitat evaluation and assessment procedure, suitability ratings using ecosystem unit classification have the following advantages (Resources Inventory Committee 1999c):

1. It is predictive.
2. The methodology is consistent.
3. Large areas can be covered.
4. It is flexible and can be applied to a range of map scales, wildlife species, and general to detailed habitat assessments.
5. It provides strategic planning for habitat management.
6. It ties the wildlife resource to other resource uses (e.g., forestry, recreation, and corridor analyses).

The results of this type of model can provide information on the suitability, amount and distribution of potential moose foraging habitat within the RSA.

5.3 METHODS

The moose habitat suitability model was based on habitat suitability mapping standards and methodology (Resources Inventory Committee 1999c). This methodology is commonly used in habitat assessment. The habitat suitability methodology involves three key steps:

1. Selection of relevant habitat variables to include in the model.
2. Development of rating scores for each habitat variable.
3. Building a relationship among the variables to produce overall habitat suitability scores.

A moose winter forage habitat suitability model was developed based on professional opinion and the availability of suitable datasets. Land cover datasets (vegetation, linear disturbances, and fire history) were considered for the suitability modelling. Other variables were considered but not included in the model. They were assumed to correlate with the vegetation cover types and associated structural stages.

5.3.1 RATING SCHEME

This model uses a categorical rating scheme where each category represents an ordinal measure of habitat suitability. The number of categories used in a rating scheme reflects knowledge of the species' ecology and habitat use (Resources Inventory Committee 1999c). For species like moose, where our understanding of the

species and the availability of relevant base environmental data to support habitat modelling is relatively good, 4- and 6-class schemes are typically used. A 6-class system was initially chosen to rank the base habitat units because the 6-class system facilitated finer differentiation of ratings across the numerous habitat types that occur in the RSA (Table 5-2). However, for interpretive purposes, the ratings were generalized into a 4-class system for most model outputs. In the 4-class system, High and Moderately-High were combined into one category (High) and Nil and Very Low were combined into one category (Nil/Very Low).

High and Moderately High suitability habitat provides some of the best winter foraging opportunities for moose within the RSA. Moderate suitability habitat provides some winter foraging opportunities. Low and very low-quality habitat has limited winter foraging opportunities for moose in the RSA. Nil suitability habitat provides no winter foraging opportunities. It is often associated with features without vegetation (e.g., rivers, streams, roads) or with very sparse vegetation cover.

Within the RSA, the highest rated areas included natural shrublands and regenerating burns in riparian areas, as well as small extents of deciduous and mixed-wood ecosystems on mesic and moist sites. Moderate rated areas were predominantly regenerating burns on mesic to wet sites. Low rated sites were mostly undisturbed stands of open, stunted spruce on mesic to wet sites, ranging from tall shrub to old forest structural stages. Differentiating ratings between Moderate and Low areas was often difficult. Many sites, both burned and unburned, had average willow cover less than 15%, with high variation in cover among sites in the same ecosystem units. Generally, 7% willow cover was used as the threshold to differentiate between Moderate and Low sites. This is a relatively low value of willow cover but using a higher threshold would have resulted in large areas of regenerating burn being classified the same (Low) as undisturbed areas. In Eagle Plains, a substantial amount of total winter forage appears to occur within large areas with relatively low willow cover (i.e., the Moderate suitability areas).

Although the vegetation field data confirmed that the amount of shrubby browse (i.e., willow cover) was greater in fire disturbed areas than undisturbed areas, the amount of browse in regenerating burns was not as high as reported in some other studies. For example, the percent cover of willow in burns in the most common ecosystem unit, EU33-Moist Spruce Labrador Tea, was 11% compared to 7% in unburned areas. As a result of this pattern, areas with fire disturbance attributes in the ecosystem mapping database were generally rated one class higher than the same ecosystem unit that was not burned (mostly Moderate for burns and Low for unburned areas).

Table 5-2. Rating scheme used to rate moose habitat suitability.

Rating	Code	HS Score	Description
High	1	95	Suitable. Conditions at optimal. The best foraging opportunities for moose are expected to be found in these areas of the RSA. Willow percent cover is greater than 15%. Includes both disclimax and seral shrublands areas.
Moderately High	2	75	Suitable. Conditions near optimal. Above average foraging opportunities for moose is expected to be found in these areas. Willow percent cover also typically greater than 15% but, on average, less than High.
Moderate	3	50	Suitable. Suitability is lower than optimal conditions but meet minimum requirements from an energy balance perspective. Willow percent cover generally ranges between 7% to 15%.

Rating	Code	HS Score	Description
			Although willow cover is moderate to low in absolute terms, the large extent in this rating category contributes a substantial amount of the total available forage across the RSA.
Low	4	30	Suitability Unknown. Areas in this rating class offer some forage but the amount is so low and dispersed that the energetic return of using these areas are, on average, mostly negative. Willow species present but typically less than 7% cover.
Very Low	5	10	Unsuitable. Willow species presence and cover is usually less than 2%. Moose are expected to strongly avoid these areas.
Nil	6	0	Unsuitable. Willow presence not expected.

5.3.2 SELECTION OF RELEVANT HABITAT VARIABLES

Potentially relevant foraging habitat variables were identified from published literature, other habitat models, and personal experience. A suite of different habitat variables was identified as candidates in this habitat model, based on their known importance to winter foraging ecology (Table 5-3). The variables were evaluated for inclusion based on availability in GIS database, the ecological relevance to moose in the RSA, and relationships found in other studies. Based on these criteria, ecosystem unit, structural stage data and fire disturbance, all from the ELC mapping database, were included in the moose habitat modelling. Other variables were not included in the model as they were not expected to play a major role in winter habitat use by moose or because they were correlated with one of the three selected variables.

Distance to riparian areas was considered for inclusion in the model. Riparian areas are important foraging habitats for moose (Clarke et al. 2017, McCulley et al. 2017). Within the RSA, riparian areas generally contain abundant browse species relative to the adjacent ecological units. The ELC developed ecosystem units specific to riparian habitats. The ecosystem unit data accurately represent increased habitat suitability in riparian areas found as narrow strips along most watercourse and drainages in the RSA. Therefore, a variable for distance to riparian was redundant and was not included in the model.

Elevation was considered as a variable for inclusion in the model. In winter, moose generally occur at lower elevations to minimize the energetic costs of travelling through deep snow. Moose generally start avoiding areas with >70 cm of snow and rarely occur in areas with >100 cm. However, elevation within the rolling topography of the RSA does not vary substantially (range = 343–752 masl) and was likely not a significant driver of moose distribution. Therefore, elevation was not included as a variable in the model.

Slope was considered as a variable for inclusion in the model. Moose avoid very steep slopes (i.e., generally >35 degrees). In more southerly locations, moose will select moderately steep, south aspect slopes in winter where the combination of slope and aspect reduces snow depth and favours shrubby browse cover. However, steep slopes >35 degrees do not occur in the area, and south aspect slopes do not play a significant role in snow depths at this northern latitude. Therefore, slope was not included as a variable in the model.

Linear features were considered for inclusion in the model. LFs were surveyed in the RSA as a companion study for exploration project proposal (EDI Environmental Dynamics, unpublished study). LFs that were classified as 2D had an average width of 5.4 m and, under normal succession, had greater mean shrub cover than the corresponding off-line sites. The 3D lines had narrower widths and were not as shrubby, or shrubs

were not consistent in shrub cover and species present. The few winter roads also were not consistent in available browse species. The greater shrub cover does not signify the presence of higher quality browse species such as willows. The combination of shrub species cover found within LFs, and the small extent of LF did not warrant including them as a variable in the model because these two factors would not substantially affect habitat use by moose.

Table 5-3. Summary of habitat variables commonly associated with moose habitat suitability from published literature relevant to the Regional Study Area.

Habitat Variable	Ecological Rational	Included in Model (Yes or No)
Ecosystem Unit (ELC)	Ecosystems units have specific vegetation communities associated with them and are the best predictor of winter browse species occurrence.	Yes
Structural Stage (ELC)	Moose typically select shrub structural stages or open mature forest habitats as forage habitat.	Yes
Distance to Riparian	Any shrubby feature influenced by a creek or stream was given a riparian code in the ELC. ELC data more accurately represent increased habitat quality in riparian forests than the distance to riparian	No
Elevation	Elevation can strongly affect snowpack depth, with depths >70 cm limiting winter movements by moose. The limited range in elevation within RSA (343 – 752 m), combined with average winter snowpacks just reaching critical depths for moose, is assumed to be insufficient to affect moose distribution in winter.	No
Slope	Moose avoid steep slopes (>35%) and prefer south-facing slopes. A combination of slope and aspect reduces snow depth and favors shrubby browse cover. However, steep slopes >35 degrees do not occur in the area, and south aspect slopes do not play a significant roll in snow depths at this northern latitude.	No
Fire History (ELC)	Fire may increase forage habitat quality for moose, but it is dependent on time since the disturbance and ecosystem unit. The ELC mapping accounts for the fire history by using the structural stage and a disturbance code.	Yes
Linear features	Moose may avoid linear features due to increased predation risk depending on the region. Linear features may provide foraging opportunities. Linear features within the RSA may affect habitat quality positively or negatively, dependent on ecosystem unit and time since disturbance.	No

5.3.2.1 Ecological and Landscape Classification Based Variables

Ecosystems units have specific vegetation communities associated with them and are the best predictor available of winter browse species occurrence. Moose typically select shrub structural stages or open mature forest habitats as forage habitats. The ecosystem unit and structural stage variables are based on the recently completed ELC mapping of the RSA. A summary of ELC methods and results are presented here. Refer to

the separate baseline report for more detailed information about the ELC mapping (EDI Environmental Dynamics Inc 2021).

Ecosystem Unit Variable

ELC mapping refers to an integrated approach to mapping and classifying units of land according to their ecological similarity (Environment Yukon 2016a). ELC mapping aims to provide information on the biological and physical characteristics of various landscape components to facilitate a range of interpretations and assist in sustainable management (Rowe and Sheard 1981, Environment Yukon 2016a). For example, defining ecosystem units (i.e., ecosites, ecological communities) with similar vegetation, site and soil characteristics can provide information on the current condition of vegetation, can facilitate the development of vegetation mitigation measures during infrastructure development and aid in assessing habitat suitability for wildlife across a landscape.

To best meet the needs of the Project, a manual ELC mapping approach was completed, where mappers examine and interpret digital ortho-imagery to delineate and attribute polygons with ecological information manually. Using existing GIS datasets, this method typically provides a higher level of detail and accuracy than predictive modelling approaches. The mapping and classification methodology conforms to the Yukon Ecological and Landscape Classification and Mapping Guidelines, Version 1.0 (Environment Yukon 2016a), and the Standard for Terrestrial Ecosystem Mapping in British Columbia (Resources Inventory Committee 1998b) were used as guidelines.

To complete the ELC mapping of the RSA, new broad-ecosystem classification units were developed that had similar floristic composition and clearly interpretable ecological context in terms of site-scale climate, landscape position, substrate, hydrology conditions, and moisture and nutrient regimes. The goal was to develop Project-specific ecosystem units representing the range of ecological communities within the RSA while being reliably and repeatedly identifiable from a mapping perspective. The final ELC system used for the Project merged the methodology outlined by the YBEC system with aspects of the BEC system used in BC and referenced some of the existing units.

The most common ecosystem unit mapped in the RSA is Moist Spruce – Labrador Tea (Code 33) (44%) followed by Moist Spruce – Alder – Labrador Tea (Code 34) (12%) and Mesic Black Spruce – Alaska Paper Birch (Code 04) (9%) (Table 5-4). The least common (0%) ecosystem units mapped in the RSA are Dry Sparsely Vegetation (Code 10) and Mesic Birch – Willow (Code 02), and Moist Birch – Willow (Code 36). Both Birch – Willow ecosystem units are influenced by anthropogenic disturbances. Other less common ecosystem units that occur more naturally are Dry Aspen (Code 17), Mesic White Spruce – Alaska Paper Birch – Alder (Code 03), and Wet Shrub Scrub Birch – Graminoid (Code 45).

Table 5-4. Ecosystem units mapped in the Eagle Plains RSA.

Code	Name	Total Area (ha)	% of RSA	Average percent cover of *Salix* sp.
10	Sparsely Vegetated	2.6	0.0	No data
14	Dry Spruce-Lichen (Conifer)	1,826.5	0.8	5.3%
15	Dry Aspen-Lichen (Deciduous)	280.8	0.1	No data
16	Dry Spruce-Birch-Lichen (Mixedwood)	2,103.6	0.9	4.5%
17	Dry Aspen (Deciduous)	80.1	0.0	No data
02	Mesic Birch - Willow	90.5	0.0	22.0%
03	Mesic White Spruce – Alaska Paper Birch – Alder	98.3	0.0	No data
04	Mesic Black Spruce – Alaska Paper Birch (Mixedwood)	21,150.0	8.9	4.6%
05	Mesic Alaska Paper Birch (Deciduous)	11,496.0	4.8	12.5%
06	Mesic Black Spruce – Labrador Tea (Conifer)	7,463.5	3.1	12.2%
20	Shrubby Riparian Birch – Willow	860.2	0.4	27.6%
21	Riparian White Spruce – Prickly Rose	192.1	0.1	12.0%
22	Riparian Spruce – Birch - Willow	674.4	0.3	15.3%
23	Drainage Shrubby Riparian	4,454.2	1.9	57.0%
31	Moist Shrub \ Scrub Birch – Labrador Tea – Willow	9,129.9	3.8	14.2%
33	Moist Spruce – Labrador Tea	103,696.5	43.5	6.6%
34	Moist Spruce – Alder – Labrador Tea	27,428.6	11.5	6.0%
35	Moist Spruce – Scrub birch – Labrador Tea	12,163.3	5.1	5.5%
36	Moist Birch – Willow	33.4	0.0	39.0%
41	Wet Shrub – Tamarack	177.3	0.1	1.7%
42	Wet Shrub – Black Spruce – Tussock Cottongrass	14,517.0	6.1	4.3%
43	Wet Shrub – Black Spruce - Sphagnum	3,315.6	1.4	5.6%
44	Wet Shrub – Scrub Birch – Tussock Cottongrass	6,844.7	2.9	8.3%
45	Wet Shrub – Scrub Birch – Graminoid	98.7	0.0	10.0%
46	Wet Black Spruce – Labrador Tea – Cladonia	2,498.0	1.0	7.0%
47	Wet Black Spruce – Tussock Cottongrass – Sphagnum	4,232.3	1.8	4.0%
48	Wet Black Spruce – Carex	196.6	0.1	14.0%
B1	Bog – Black spruce – Lichen	764.7	0.3	0.0%
B2	Bog – Black Spruce – Sphagnum	1,960.9	0.8	2.0%

RZ	Road	58.9	0.0	0
	Total Area	238,640		

Structural Stage Variable

Within the ELC database, the structural stage attribute (Table 5-5) describes the appearance of a stand or vegetation community and defined by the codes and criteria listed in the Field Manual for Describing Yukon Ecosystems (Environment Yukon 2017).

Most of the RSA is mapped in a Shrub structural stage (74%), with 45% of the RSA in a Low Shrub structural stage (Table 5-5). Approximately 1% of the RSA is in an Old Forest structural stage, and 21% is in a Mature Forest structural stage.

Table 5-5. Structural stages mapped in the Eagle Plains RSA.

Code	Structural Stage	Criteria	Area (ha)	% of RSA
1	Non-vegetated	No vegetation or less than 5% established vegetation, often due to recent disturbance (e.g., placer mining) or unvegetated rock.	8.0	0
2	Sparse / cryptogram	Either the initial stages of primary and secondary succession or a cryptogram community maintained by environmental conditions; sparsely vegetated or dominated by bryophytes and lichens; may be prolonged where there is little or no soil development (e.g., bedrock).	76.9	0.03
2a	Sparse (5–10% vegetation cover)	5–10% vegetation cover.	2.6	0
2b	Bryoid	Bryophyte-dominated	0	0
2c	Lichen	Lichen-dominated	0	0

Code	Structural Stage	Criteria	Area (ha)	% of RSA
3	Herb	Early successional stage or herbaceous communities maintained by environmental conditions or disturbance (e.g., wetlands, post-fire forest succession); herb dominated, including forbs, graminoids and ferns; some invading or residual shrubs and trees may be present but are usually sparse or absent; many herbaceous communities are continually maintained in this stage.	7.8	0
3a	Forb - dominated	Herbaceous communities dominated (greater than 1/2 of the total herb cover) by non-graminoid herbs, including ferns.	0	0
3b	Graminoid – dominated	Herbaceous communities dominated (greater than 1/2 of the total herb cover) by grasses, sedges, reeds and rushes.	161.1	0.07
3c	Aquatic	Herbaceous communities dominated (greater than 1/2 of the total herb cover) by floating or submerged aquatic plants; does not include sedges growing in marshes with standing water.	0	0
3d	Dwarf shrub	Communities dominated (greater than 1/2 of the total herb cover) by dwarf woody species, such as kinnikinnick or dwarf willows.	0	0
4	Shrub	Early successional stage or shrub communities maintained by environmental conditions or disturbance (e.g., wetlands, flooding, post-fire forest succession); dominated by shrubby vegetation; either dominated by shrubby vegetation, including tree seedlings/saplings, or if sparsely vegetated overall, the dominance of shrubs characterizes the community as a shrubland. This may include sites where trees are stunted due to the presence of permafrost, preventing the stand from reaching a higher structural stage.	10,196.7	4.3
4a	Tall shrub	Communities dominated by tall shrub layer vegetation - woody plants > 2m tall and ≤ 7 cm dbh; may be a successional stage or may be in this stage perpetually due to environmental conditions or disturbance.	57,934.3	24.3
4b	Low shrub	Communities dominated by low shrub layer vegetation - woody plants < 2m tall; may be a successional stage or may be in this stage perpetually due to environmental conditions or disturbance.	107,861.2	45.2
5	Pole sapling	Trees > 5m tall and > 7 cm dbh, typically densely stocked. Self-thinning and vertical structure are not yet evident in the canopy. Younger stands are vigorous (usually > 15–20 years old); older stagnated stands (up to 100 years old) are also included; time since disturbance usually < 40 years; up to 100+ years for dense (5000 – 15000+ stems per ha) stagnant stands.	554.8	0.2
6	Young Forest	Self-thinning has become evident, and the forest canopy has begun to differentiate into distinct layers. A more open stand than the pole/sapling stage.	8,322.6	3.5

Code	Structural Stage	Criteria	Area (ha)	% of RSA
7	Mature Forest	Trees established after the last stand-replacing disturbance have matured; a second cycle of shade tolerant trees may have become established; shrub and herb understories become well developed as the canopy opens up.	50,518.9	21.2
8	Old Forest	Stands of old age with complex structure; patchy shrub and herb understories are typical; regeneration is usually of shade-tolerant species with composition similar to the overstory. Fire maintained stands may have a 'single-storied' appearance. Very old stands having complex structure with abundant large-sized trees, snags and CWD; snags and CWD occurring in all stages of decomposition; stands are comprised entirely of shade-tolerant overstory species with well-established canopy gaps.	2,302.7	1.0
n/a	Not Applicable (River, etc.)		692.4	0.3
	Total RSA		**238,640**	

5.3.2.2 Fire History

Fire disturbance was considered as a variable in the model. Numerous studies in boreal and sub-boreal regions have found that moose select areas regenerating from fires. Recent burns and post-fire clearings are generally considered optimal foraging habitat for moose. Forest fires are a significant component of the landscape ecology of the Eagle Plains Ecoregion. Typically, regenerating burns contain higher cover of shrubby browse species than undisturbed areas. This includes both deciduous shrubs like willow, as well as sapling deciduous trees like aspen and paper birch. Although burns are classified as Low and Tall Shrub in the ELC, structural stage alone does not uniquely identify them. Large extents of disclimax, stunted black and white spruce ecosystem unit types were also classified as Tall Shrub.

Numerous studies and data from the ELC mapping, indicate that fire disturbance results in increased shrubby browse cover during the Low and Tall Shrub structural stages of regeneration, and that regenerating burns are selected by moose in winter. Therefore, fire disturbance was included in the model.

5.3.3 WILDLIFE HABITAT RATINGS

Qualitative, categorical habitat suitability ratings were developed for each combination of ecosystem unit and structural stage in a lookup table format. For the Shrub structural stages separate ratings were provided depending on whether the area was recently burned or not. The difference in the amount of browse cover was minimal in other structural stages according to burn status and burned and unburned areas were rated equivalently. The development of ratings was based on expert opinion and primarily by the following assumptions:

- Winter habitat suitability is primarily driven by the amount of shrubby browse species that are predicted to occur and especially the percent cover of willow species. The average percent cover

of willow species by ecosystem unit per structural stage was calculated using vegetation data collected during baseline surveys (Section 5.6.1).

- Low shrub structural stages, including disclimax shrublands (wetlands and shrubby drainages) and regenerating burns, generally offer the highest value forage and are generally rated High.
- The suitability of tall shrub areas depends on disturbance status. Tall shrub areas regenerating from fire disturbance are also rated Moderate (mostly) to High, depending on the ecosystem unit. However, Tall shrub stages also include extensive areas of disclimax stunted spruce (including multiple EUs) that generally offer low to moderate browse species, which are rated accordingly.
- Older structural stages (5–8) can have similar browse and are mostly rated depending on the EU (Table 5-4). On average stage 7 and 8 tend to have slightly more browse than stages 5 and 6.

Every combination of ecosystem unit and structural stage was assigned in initial habitat suitability score based on a 6-class rating scheme (Table 5-6). If there was no structural stage listed for an ecosystem unit, it received a rating of 6 (Nil) for moose winter forage.

The extent of areas with high cover of preferred browse species (mostly willow) is limited in the RSA. The ecosystem unit by structural stage combinations with >15% willow cover was generally rated High (1) and Moderately High (2) and account for only 12% of the extent in the RSA (Photo 5-5 to Photo 5-9). Large extents of the RSA have relatively low willow cover of 5–15% and were rated as Moderate (3) and Low (4) (Photo 5-10 to Photo 5-14). Differentiating the classifications between Low and Moderate was difficult because the differences in willow presence among different sites were not consistent, and variation in willow cover within the same site type was large (i.e., resulting in overlapping confidence intervals across sites). The basis for classifying sites as Low or Moderate considered (i) average cover of willow from field plots (>7% favouring classification to Moderate), (ii) fire history (fire disturbance within 40 years favouring classification to Moderate), and (iii) a qualitative assessment of the potential for each EU and structural stage combination to support willow and other browse species.

Although Moderate and Low rated habitats have relatively low cover of willow in an absolute sense, they likely provide a substantial proportion of total winter forage for moose in the RSA due to the large extents that Moderate and Low suitability habitats cover. That is, in Eagle Plains the overall, total availability of winter forage for moose appears to be distributed in relatively low levels across large portions of the RSA, versus being concentrated in relatively small portions of the landscape, which is typical in more mountainous portions of Yukon.

Overall, EUs in sparsely vegetated or herbaceous structural stages, non-vegetated EUs and certain wetland EUs were assigned Very Low (5) or Nil (6) ratings unless the presence of willow cover was observed (Photo 5-15 and Photo 5-16).

The effect of fire disturbance in boreal ecosystems in enhancing moose browse as the stand regenerates through the low shrub and tall shrub structural stages are well documented. Although evidence of this was observed in Eagle Plains, the degree to which regenerating burns resulted in an elevated cover of browse

species was somewhat muted compared to values reported in other studies. For example, for the most extensive EU, Moist Spruce-Labrador Tea (code 33) (comprising 43% of the RSA), the average percent cover of willow was 11% in burns compared to 6% in unburned areas (Photo 5-11 and Photo 5-12). Similar patterns were evident for most other moist and wet EUs. On average, fire disturbance resulted in a modest increase in willow cover. As a result, areas with fire disturbance within the last 40 years were generally rated one class higher than unburned areas. Most frequently, this resulted in a rating change from Low to Moderate.

5.3.4 MODEL STRUCTURE

In the ELC map, each polygon contains up to three components. For example, a polygon could contain 80% EU34-Moist Spruce – Alder – Labrador Tea and 20% EU22-Shrubby Riparian Birch – Willow. These composite polygons occur because the pattern of ecosystem distribution occurs as a set of small patches that are too small to map as separate individual polygons. To account for this issue of composite polygons, habitat ratings were applied in two ways (1) an area weighted average of the habitat suitability scores for the components within each polygon, and (2) the proportion of High suitability habitat in each polygon.

The area-weighted average score was calculated using the habitat suitability scores from Table 5-2 and the decile proportion for each polygon component, following equation:

$$ELC_r = \frac{\sum_{i=1}^{n} w_i X_i}{\sum_{i=1}^{n} w_i}$$

Where ELC_r is the weighted average score, w_i is the decile proportion for each polygon component, and X_i is the habitat rating for each polygon component from Table 5-2. An example is provided in Table 5-7 for a polygon with two components:

Although this weighted average approach is a good approach for summarizing average habitat suitability across the study area, it has the disadvantage that, with the averaging process, you lose track of the occurrence of small extents of High suitability areas. This issue is addressed in the second version of model outputs, mapping the proportion of High suitability habitats within each polygon.

The two types of outputs compliment each other for assessment and management at different scales. The weighted average output is intended to be used for strategic assessments and planning, such as assessing the overall effects of the Project on moose habitat, or to compare the relative suitability of moose habitat in one sub-watershed to another. The proportion of High suitability habitat can be used to support finer-scale operational measures, such as locating roads and well sites to avoid high suitability winter moose habitat.

Although the initial habitat ratings for each ecosystem unit/structural stage/fire disturbance combination used a 6-class rating scheme, the composite ratings of the ELC polygon scores were generalized to a 4-class system for simpler interpretation, essentially combining Moderately High and High, and Nil and Very Low.

Due to the small size of many of the High and Moderately High habitats areas, they were frequently formed the second or third component of composite ELC polygons. Consequently, these areas of High were often 'lost' when calculating the weighted average rating for the polygon (i.e., the polygon they were in ended up being rated Moderate or even Low overall). To account for this issue, the amount and location of High and Moderately High areas were examined separately from the polygon weighted average score. This was done by mapping the amount of High and Moderately High areas in each polygon. For example, a polygon with a weighted average habitat score of Low, might contain 20% High+Moderately High.

Table 5-7. An example of a multiple component polygon habitat scoring.

Component	Proportion	Ecosystem Unit	Structural stage	Burn Status	Habitat Score
1	0.8	Moist Spruce – Alder – Labrador Tea	Tall Shrub	Not Burnt	30
2	0.2	Shrubby Riparian Birch – Willow	Low Shrub	Not Burnt	95

ELCr = 0.8*30 + 0.2*95 = 43, which corresponds to an overall categorical rating of Low

5.4 RESULTS AND DISCUSSION

The amounts of predicted moose winter habitat in the RSA are presented for the finer-scale 6-class rating scheme before averaging scores within ELC polygons in Table 5-8, and the consolidated 4-class rating scheme after averaging scores within ELC polygons, in Table 5-9. As mentioned in the Methods, the 4-class scheme essentially combines the High and Moderately High classes and the Nil and Very Low from the 6-class scheme. The 6-class scheme was originally used because it was assumed that there would be greater amounts of areas in the high and low ends of the habitat suitability gradient. However, since the amounts of highest and lowest suitability habitat are so low (i.e., 2.5% High and 0.4% Nil) it makes sense to use the 4-class scheme from this point forward.

The model results indicate that High-suitability winter moose habitat (12%) is limited, and that the remaining area is approximately split between Moderate and Low, with Nil/Very Low areas only accounting for approximately 1% of the RSA. The distribution of winter moose habitat shows clear spatial patterns across the RSA, when examining the average habitat suitability scores across ELC polygons (Map 5-1) and the percent of High-suitability habitats occurring in each polygon (Map 5-2 and Map 5-3). In the map of the average suitability scores (Map 5-1), areas of Moderate suitability are concentrated in the southern half and along the western and northern boundary in the northern portion of the RSA. These areas often correspond to regenerating burns. In the northern half of the RSA, much of the Chance Creek watershed is rated Low, corresponding to a lack of fire disturbance and dominance of open canopy, stunted spruce ecosystems, which offer limited browse for moose. High-suitability winter habitat is found scattered across the RSA, generally in much smaller patches than areas of Moderate and Low. High suitability areas are often in narrow riparian strips along streams and non-confined drainage areas (Map 5-2), but also includes certain deciduous and mixed-wood ecosystem units, like the Mesic Alaska Paper Birch (code 05), which accounts for the concentration of High suitability habitats in the northwest portion of Map 5-3.

This pattern of having a relatively large portion of the landscape in Moderate suitability winter habitat is different than occurs in other parts of Yukon, especially in more mountainous areas, where suitable winter habitat (i.e., High and Moderate suitability) are often constrained by elevation, snow depths and greater distribution of diverse vegetation communities (McCulley et al. 2017). In Eagle Plains, a substantial amount (74%) of the RSA is in a shrub structural stage mostly dominated by scrub birch and Labrador tea and almost half (44%) of the RSA is described as the Moist Spruce – Labrador tea ecological unit which are large areas with relatively low willow cover (i.e., the Moderate suitability areas).

The pattern of winter habitat across the RSA is likely to affect the broad distribution of moose. Due to the scattered occurrence of High suitability habitat across the RSA, some moose are expected to occur across the RSA. However, local densities are likely to be vary in relation to the portions of Low and Moderate that form the matrix of habitat at a larger scale. Where most of the habitat matrix is Low, such as across most of the Chance watershed, moose densities are expected to be relatively low and habitat use is expected to be largely constrained to the scattered patches of High. Where most of the habitat matrix is Moderate, such as the southern half of the RSA, moose densities are expected to be substantially higher; and, although moose use is

expected to still be relatively higher in the High habitats, considerable use of the Moderate suitability matrix is also expected.

Table 5-8. Estimated amounts of moose winter forage habitat across the Eagle Plains RSA using a 6-class rating scheme.

Habitat Rating	Area (ha)	Area (% of RSA)
High	5,961.9	2.5%
Moderately High	23,736.7	9.9%
Moderate	111,561.7	46.7%
Low	94,068.2	39.4%
Very Low	2,492.4	1.0%
Nil	842.6	0.4%
Total Area	238,663.5	100%

Table 5-9. Estimated amounts of moose winter forage habitat across Eagle Plains RSA averaging suitability scores within ELC polygons and generalizing to a 4-class rating scheme.

Average Habitat Suitability	Area (ha)	Area (% of RSA)
High	16,944.4	7.10%
Moderate	145,394.1	60.92%
Low	74,514.5	31.22%
Nil/Very Low	1,810.5	0.76%
Total	238,663.5	100%

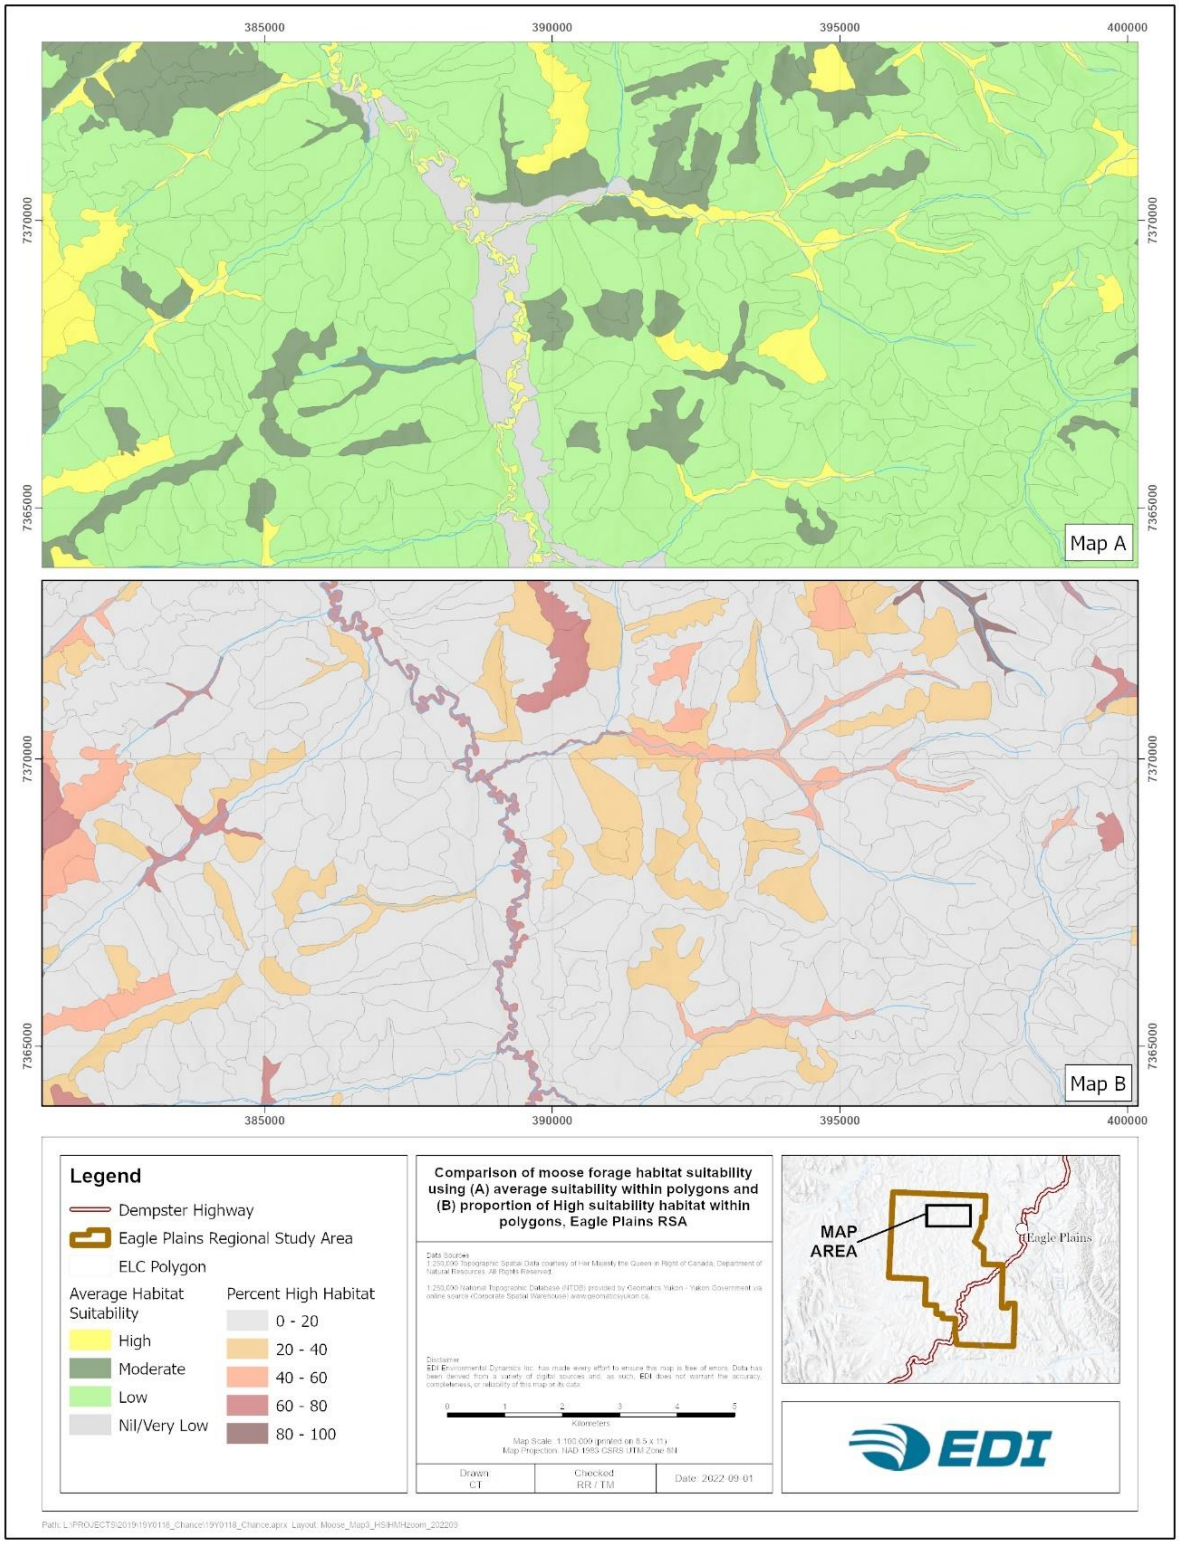
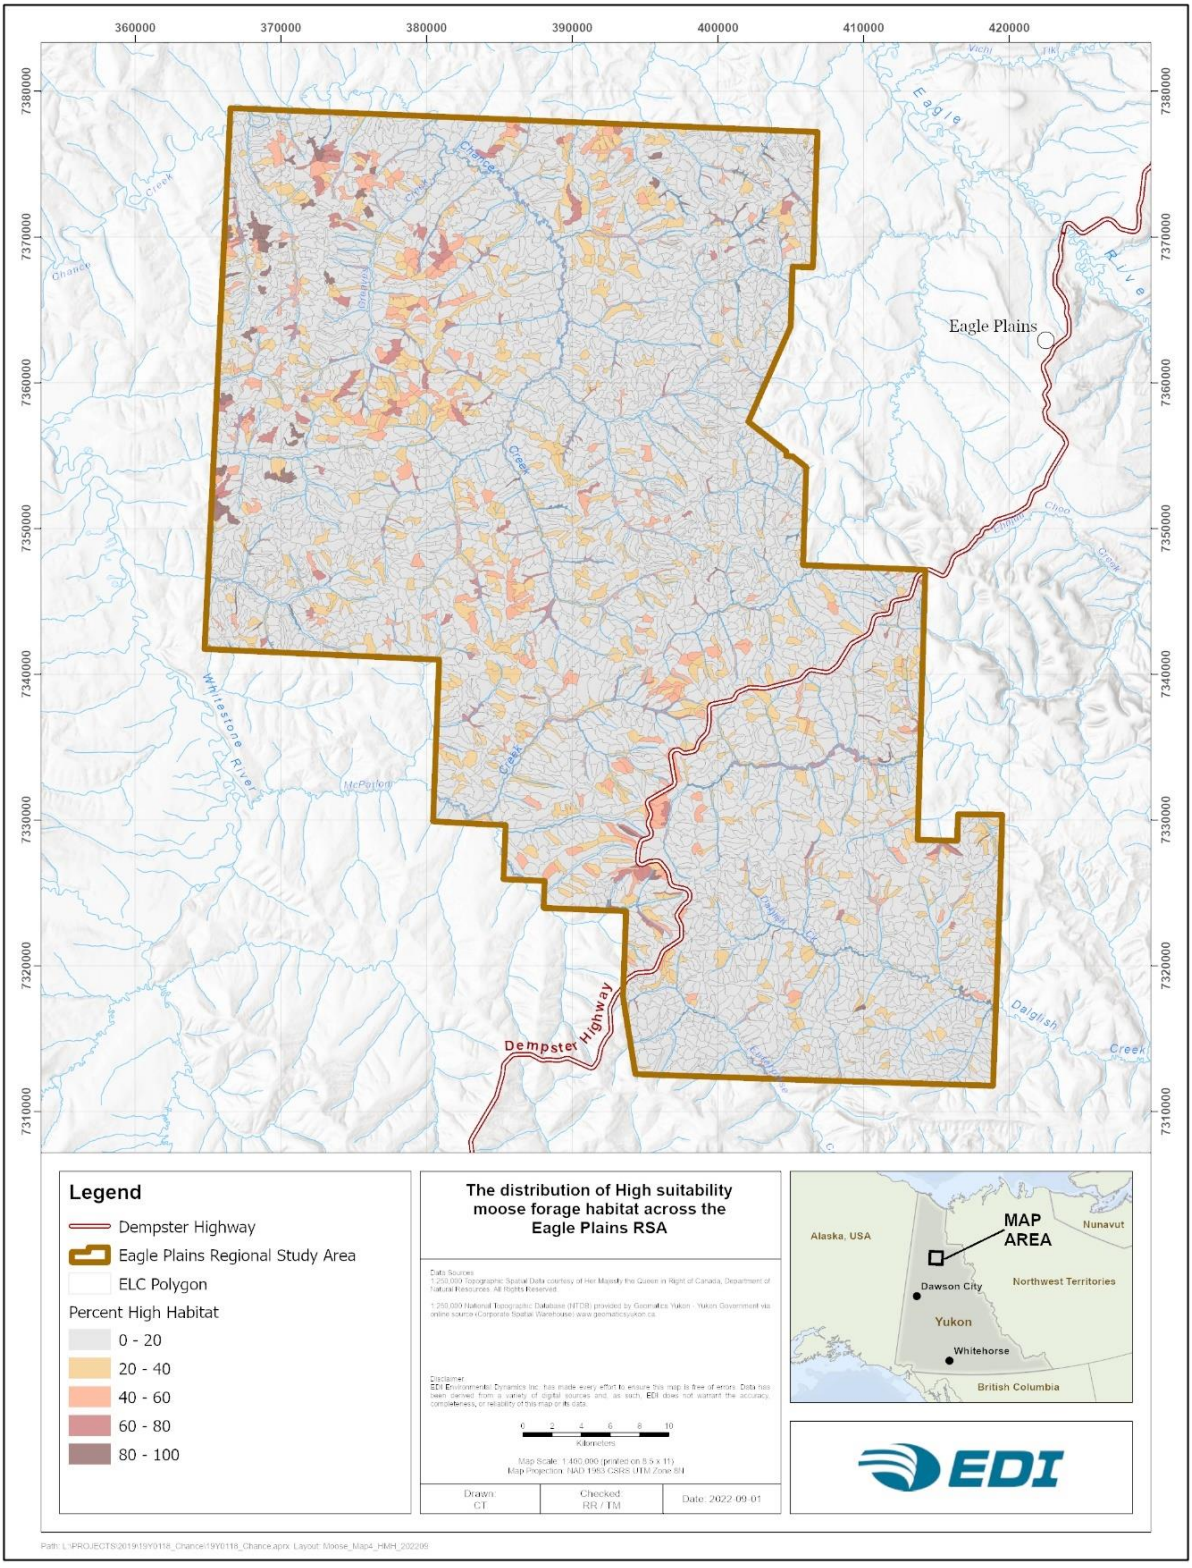


Map 5-2. Comparison of moose forage habitat suitability using (A) average suitability within polygons and (B) proportion of High suitability habitat within polygons, Eagle Plains RSA.



Map 5-3. The distribution of High suitability moose forage habitat across the Eagle Plains RSA.

5.5 SUMMARY

The suitability, amount, and distribution of potential habitat for moose were quantified across the RSA using a habitat suitability model. The habitat model was for foraging habitat during winter because this life requisite and season are believed to be the most limiting to moose in the RSA. The model consisted of qualitative ratings applied to combinations of three variables from the ELC mapping: ecosystem unit, structural stage and fire disturbance. High suitability habitats consisted of disclimax shrublands, most commonly associated with riparian areas. Moderate suitability habitats were dominated by regenerating burns but also included small areas of mixed and deciduous forests with shrubby understories. Low suitability habitats were mostly open canopy, stunted spruce forests. High-suitability moose winter foraging habitat is limited across the RSA (12%), but Moderate habitat is extensive (43%). Although moose are expected to select the High-suitability areas preferentially, a substantial amount of total winter forage appears to occur within large areas with relatively low willow cover (i.e., the Moderate suitability areas). Due to the scattered occurrence of High-suitability habitat across the RSA, some moose are expected to occur across the RSA in winter. However, local densities are likely to vary with the portions of Low and Moderate habitats that form the habitat matrix at a larger scale.

6 CARIBOU

The Porcupine Caribou Technical Committee (PCTC) provided telemetry data and seasonal range polygons for the Porcupine Caribou Herd (PCH). Technical discussions and feedback provided by the PCTC also helped align subsequent analyses conducted in this section. This section and much of the technical content reflect responses to their detailed technical review.

6.1 PURPOSE AND OBJECTIVES

Caribou were selected as a VC for the Project due to their importance to the Gwich'in people for subsistence hunting and their cultural and ecological values. The Project occurs exclusively within the range of the PCH, which is a subpopulation of the barren-ground subspecies of caribou (*Rangifer tarandus groenlandicus*). Within the North Yukon Land Use Plan, the PCH is considered "the most significant and culturally important wildlife resource in the planning region" (Vuntut Gwitchin Government and Yukon Government 2009). The herd has been the mainstay of Gwich'in culture for centuries. It is considered a keystone species whose presence or absence influences the composition and dynamics of the wildlife communities and ecosystems in North Yukon. The PCH is a migratory herd with an extensive annual range that spans most of North Yukon and a large area in north-eastern Alaska. The PCH overlaps the Project area primarily during the rut/late fall and winter seasons.

This section summarizes existing information about the ecology of the PCH, and, using telemetry data and analysis outputs to: i) Quantify the degree of seasonal range overlap by the PCH with the RSA during fall and winter, when seasonal range use overlaps the RSA; ii) Quantify habitat use patterns and selection by the PCH during fall and winter; iii) Quantify movement rates and residency periods of the PCH during fall and winter; and, iv) Quantify the potential effects of linear features on the occurrence and movements of the PCH.

6.1.1 SPATIAL BOUNDARIES

Three spatial extents were considered as part of this study:

- The Eagle Plains Project RSA (2,386 km²)
- The Eagle Plains Ecoregion (20,400 km²), and
- The Yukon portion of the PCH's rut and late fall and winter seasonal ranges (65,000 km² and 58,000 km², respectively).

The Eagle Plains Project RSA includes all proposed exploration areas. The RSA has relatively similar patterns of vegetation communities and historical exploration disturbances across it. The Eagle Plains Ecoregion (see Section 1.3) encompasses the Project RSA and provides an ecologically similar area, beyond the proposed exploration areas, that allows certain comparisons between the RSA and adjacent undisturbed areas (e.g., habitat distribution and within-season movement patterns).

The Yukon portion of the PCH's fall and winter seasonal ranges is the largest extent and covers much of North Yukon. This area occurs predominantly within the Taiga Cordillera Ecozone. This Ecozone covers most of the northern Yukon and the southwest corner of the NWT. The Taiga Cordillera includes mountainous areas (e.g., British Mountains, Richardson Mountains, and North Ogilvie Mountains) separated by subdued basins (e.g., Eagle Plains, Old Crow Flats, and Old Crow Basin). The area consists of glaciated and unglaciated terrain and continuous permafrost. The climate in the Taiga Cordillera is variable from its northern to southern extent, with summers ranging from cool to warm with extended periods of daylight, while winters are generally long, cold, and dark. The vegetation in the taiga is dominated by stunted, open spruce forests, which result from short, cool growing seasons, and poor soils over permafrost (Ecological Stratification Working Group 1995). This extent was used to reference spatially broad questions, such as the PCH's seasonal distribution and movement patterns.

6.2 GENERAL ECOLOGY OF THE PORCUPINE CARIBOU HERD

6.2.1 CONSERVATION STATUS

The PCH is a subpopulation of barren-ground caribou in Canada, known for large aggregations of individuals, dramatic population fluctuations, lengthy migrations, and significant cultural and social value to northern Indigenous peoples and other Canadians (COSEWIC 2016). All caribou belong to one species, *Rangifer tarandus*. Within Canada, caribou populations are classified within 12 "Designatable Units" based on a suite of biological, genetic, and evolutionary traits (COSEWIC 2011). All 14–15 subpopulations of barren-ground caribou are considered part of one Designatable Unit (DU 3). Barren-ground caribou were assessed as Threatened by COSEWIC (COSEWIC 2016). The subspecies is not listed on Schedule 1 of the federal SARA. Within Yukon, barren-ground caribou are considered Vulnerable/Apparently Secure (Yukon Government 2020).

6.2.2 SEASONAL RANGES AND MOVEMENTS

Like most barren-ground caribou subpopulations, the PCH has a large annual range and makes long-distance migrations, hundreds or thousands of kilometres, among different seasonal ranges. Often, seasonal ranges vary across and within years in response to variation in forage availability, snow cover, and predation or parasite risk (Russell et al. 1993). The PCH's annual range extends approximately 250,000 km² from Alaska, through Yukon, and into the western edge of NWT. The herd undertakes long-distance migrations across seasonal ranges necessary for key aspects of their life cycle. Eight (8) primary life cycle periods occur for the PCH (Porcupine Caribou Technical Committee 1993). Key information for the eight periods are summarized in Table 6-1 (using information from Russell et al. 1993, Porcupine Caribou Technical Committee 1993, Ryder et al. 2007). The Porcupine Caribou Technical Committee (1993) assessed the relative importance of seasonal ranges using six criteria: energy balance, reproductive contribution, tolerance to disturbance, escape requirements, the intensity of use, and whether alternative habitats are available. Although all seasons are important to meeting the annual life requisites of the PCH, the calving and post-calving seasons are considered

of highest importance and fall and winter are considered of lowest importance (Porcupine Caribou Technical Committee 1993).

Key information associated with each of the eight seasons is provided below, elaborating on summary information in Table 6-1, and including a combination of scientific knowledge (Russell et al. 1993, Porcupine Caribou Technical Committee 1993, Ryder et al. 2007) and traditional ecological knowledge (Sherry and Vuntut Gwitchin First Nation 1999, Ryder et al. 2007). Typical patterns of seasonal range use are shown in Map 6-1. After calving on the north slope and Arctic coastal plains, the PCH typically splits in two, with portions of the herd moving southwest in Alaska and southeast in Yukon. Animals in the Yukon typically follow a clockwise movement through the seasonal ranges from the calving grounds on the north slope, to the British Mountains in summer, to the Richardson Mountains in late summer, dispersing widely and variably across northern Yukon (as far south as the Ogilvie Mountains) in fall and winter, before returning north to the coastal plains in spring. The PCH can potentially overlap the RSA primarily in the rut/late fall and winter periods.

During the Calving and Post-Calving periods cows and bulls tend to occupy different habitats and exhibit different movement patterns, so their ranges are described separately for these periods. During the relatively short calving period (June 1–10), cows occur in the Arctic coastal plains and adjacent uplands and foothills in Alaska and Yukon. Concentrated use often occurs in the Jago Uplands between the Hulahula and Aichilik rivers in Alaska. The calving season is one of the seasons of greatest importance (rank 1) (Porcupine Caribou Technical Committee 1993). Adult females are generally in their poorest body condition and have the largest energy deficits. The calving period is critical to the survival and development of calves (i.e., the source of initial annual population recruitment). The herd occurs in a relatively concentrated range, which appears to offer reduced predation risk and abundant forage that coincides with the timing of calving, and no alternative areas of similar value are available.

During the Post-Calving and Movement period (June 11–30) cows (and new calves) travel away from the calving areas. Cows that calved in the Yukon tend to move west into Alaska. Often, movements are higher into the foothills and uplands, following melting snow and newly emerging vegetation. However, the herd can occur anywhere from the coastline well into the foothills during this period. Selection of local habitats to avoid insect harassment is often a factor by the end of June. The Post-Calving period is also considered a period of highest importance (rank 1) (Porcupine Caribou Technical Committee 1993). Lactating females have their highest energy demands. Movement rates and group sizes increase through June, and cow/calf groups are believed to be relatively intolerant to disturbance.

During the calving to post-calving movement period (June 1–30) most bulls, juveniles, and non-productive cows occur in north Yukon between the Babbage and Firth rivers across a range of habitats within the coastal plains and the British Mountains. Animals tend to be quite mobile and follow plant emergence across habitats and elevations as spring progresses. This period is considered to have relatively low importance (rank 3) for bulls and non-productive cows (Porcupine Caribou Technical Committee 1993) because they are not tending young-of-the-year, high-quality forage is becoming abundant, and insect harassment is limited.

During Early Summer (July 1–15), both cows and bulls remain concentrated in the general north slope area, but the overall range continues to expand. Group sizes increase to the tens of thousands, and movement rates can average 25 km per day. Early summer often marks the beginning of the split of the herd between Alaska and Canada. In Alaska, distribution is widespread into the Brooks Range, and, in Canada, animals typically move into the southern British Mountains by mid-July. Local habitat use is driven by both selection for high-quality forage and insect avoidance. Insect avoidance strategies include using coastal areas adjacent to the Beaufort Sea (often primarily females) and higher elevation snow patches and barren ground in the Brooks Ranges and British Mountains (mostly males). Early summer is considered to have an importance rank of 2. Though food is generally abundant, the energy balance is limited by insect avoidance, resulting in reduced feeding times and selection of areas with less forage. Animals are still susceptible to disturbance, but tolerance is higher than during the calving and post-calving periods (e.g., calves have greater mobility, and more range is available due to snow melt).

By mid-summer (July 16–August 7), the majority of the PCH has left the coastal plains. Animals in Alaska have moved into the southern portion of the Brooks Range, and animals in Yukon have moved southeast into, or are en route to, the northern Richardson Mountains. Daily movement rates remain high through the mid-summer period, and though group sizes are often still large, groups are often breaking up and more dispersed than the aggregations that occur during post-calving and early summer. Mid-summer has an importance rating of 2 for the same reasons identified for early summer. Mid-summer is the period of potentially highest insect harassment, and, similar to early summer, habitat selection may favour insect avoidance over areas with the highest forage. Lactating females suffering insect harassment may be in an energy deficit.

During late summer and fall migration (August 8–October 7), insect harassment declines dramatically. Forage quality and abundance also begin to decline but are generally still abundant. Caribou exhibit high feeding rates during this period and gain fat reserves for the winter. During this period, the herd breaks up into smaller groups and disperses widely across North Yukon, mostly staying north of the treeline for most of the period. Fall migration often follows terrain features like ridges and valleys, but movement routes are unpredictable from year to year. Late-summer and fall migration is considered to have less importance (rank 3) due to the abatement of insect harassment, the relative abundance of forage across a variety of habitat types, the dispersed distribution of the herd, and relatively high tolerance to disturbance (Porcupine Caribou Technical Committee 1993).

The rut and late fall (October 8–November 30) continue to be a period of broad distribution and movement by the PCH, including widespread movement south of the treeline. In Yukon, the rut can occur from the Richardson Mountains to the southern Ogilvie Mountains. The areas where the rut occurs do not appear to have affinity from year to year. Rather, the rut appears to occur wherever the herd happens to be at that time along the fall migration. The rut and late fall period has the lowest level of importance(rank 4), due to the lack of insects, large range extent, ample food, the dispersed distribution of the herd, and relatively high tolerance to disturbance (Porcupine Caribou Technical Committee 1993).

During early, mid, and late winter (December 1–March 31), the PCH is at its most dispersed stage, both in terms of the extent of the range it uses and group aggregations. Average daily movement distances (2 km per

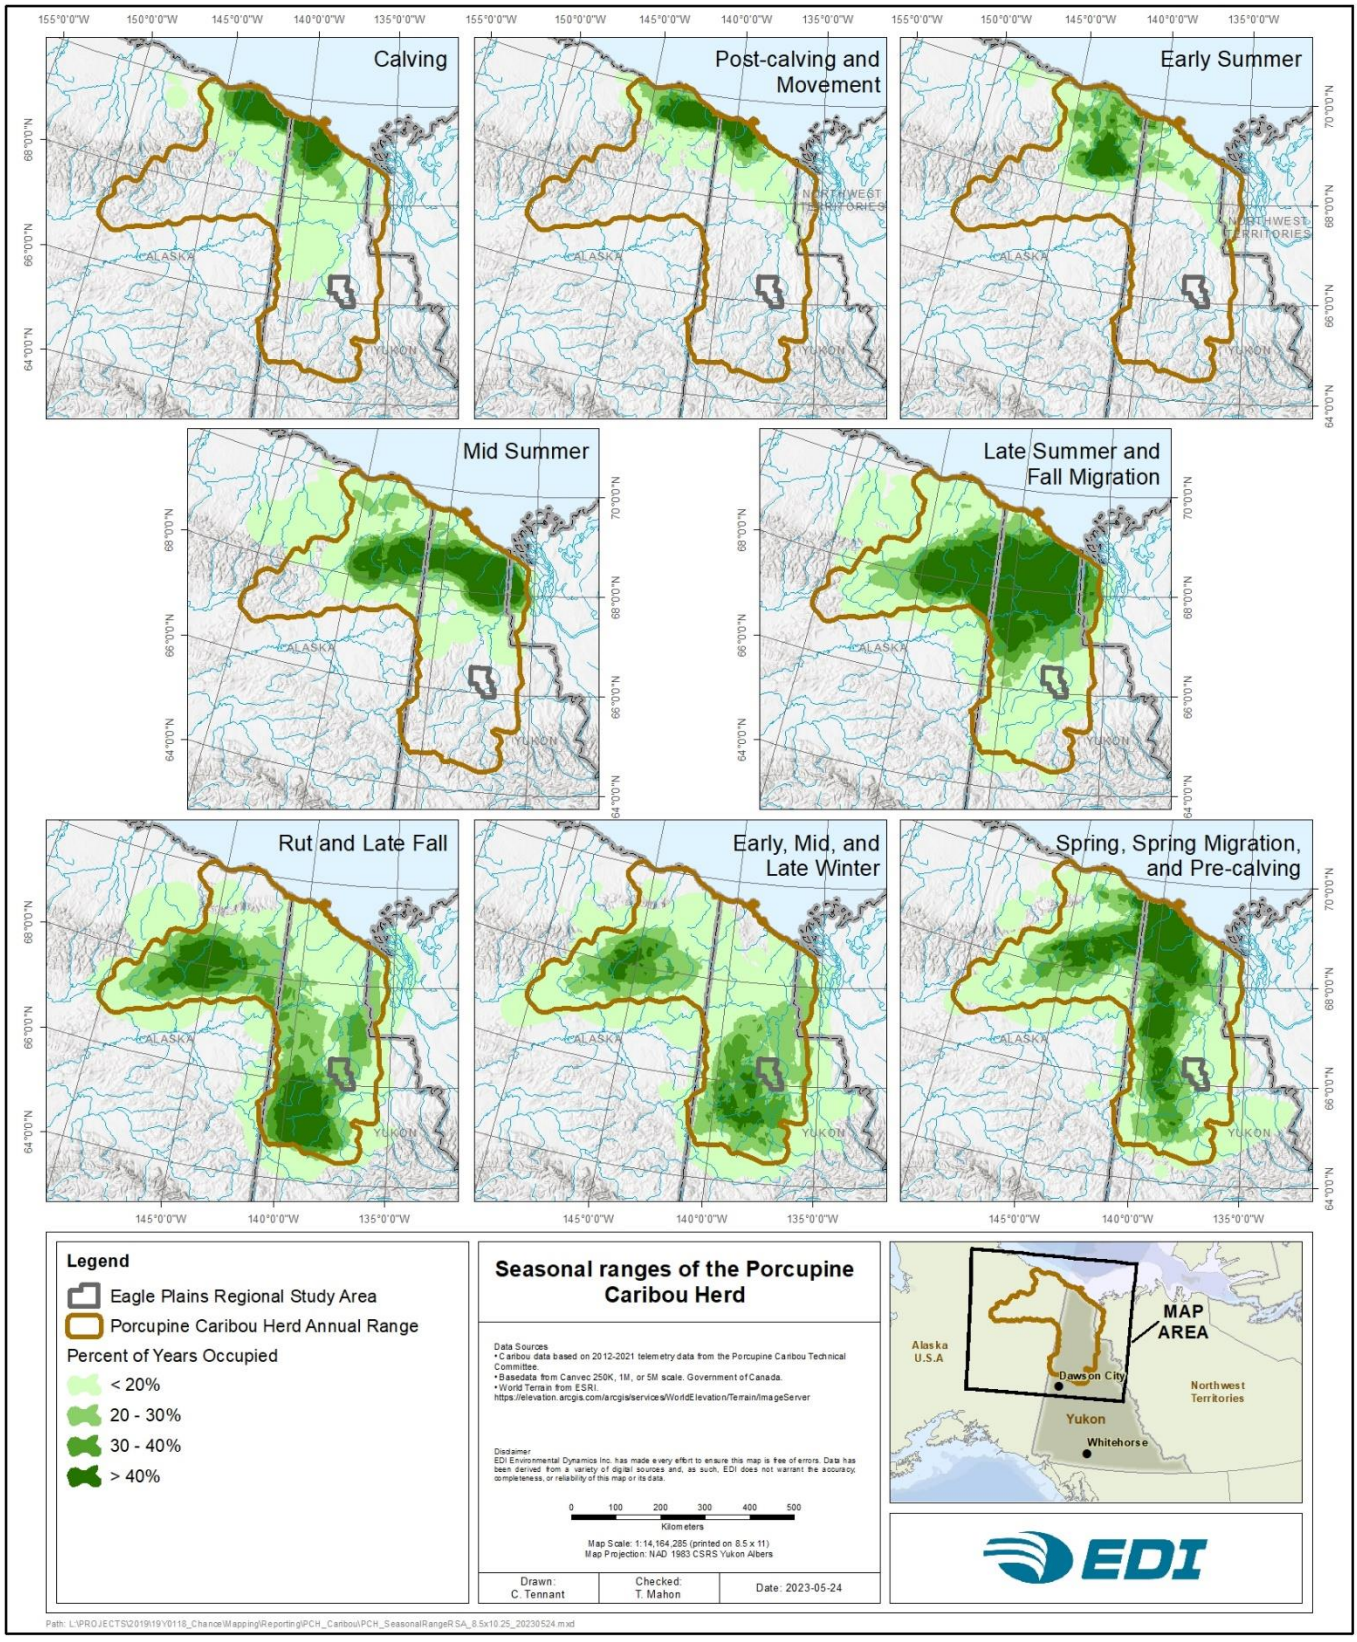
day [km/day] to 5 km/day) (Russell and Gunn 2017) are lower than in other seasons, except for cows during calving (Russell and Gunn 2017). Winter range use varies from year to year, depending on snow depth and condition. In Yukon, during deep snow years, use is concentrated in the Richardson Mountains and the Ogilvie-Hart basins. The Whitestone River and Eagle Plains areas are used more in low snow years. Forage during winter consists primarily of lichens. Unlike reports for some other caribou herds, winter habitat is generally not considered limiting for the PCH (Russell et al. 1993). In shallow to average snow years, the caribou maintain neutral to surplus energy balances (Russell et al. 1993). The PCH is relatively tolerant to human activity during the winter (Porcupine Caribou Technical Committee 1993). Similar to the rut and late fall period, winter has the lowest level of importance (rank 4) due to the lack of insects, large range extent, ample food, the dispersed distribution of the herd, and relatively high tolerance to disturbance (Porcupine Caribou Technical Committee 1993).

During the spring, spring migration, and pre-calving season, (April 1–May 31) caribou begin moving north toward the calving grounds. Average daily movement rates increase from approximately 6 km/day at the start of the season to approximately 24 km/day through May. Similar to the fall migration, no well-defined migration corridors are used consistently from year-to-year during spring migration, but certain terrain feature types like ridges and valleys are regularly used. During spring migration, local snow conditions often affect movement patterns and routes. In years or locations with low snow levels, migration tends to be more dispersed. In years or locations with high snow levels, movements tend to be more concentrated along trail networks on ridges (Porcupine Caribou Technical Committee 1993). Caribou, especially pregnant cows, typically enter an energy deficit during spring due to reduced forage availability as they leave the lichen-rich taiga and before forbs have emerged; in addition, higher energy expenditure is associated with migration. Spring is rated as higher in importance than winter, but still relatively low overall (rank 3), due to lack of association with specific habitats, relatively low threats from predators, and lack of insect harassment (Porcupine Caribou Technical Committee 1993).

Table 6-1. Key life cycle periods for the Porcupine Caribou Herd (after Porcupine Caribou Technical Committee 1993). The Porcupine Caribou Herd overlaps the Project Regional Study Area during Rut and Late Fall and Early, Mid, and Late Winter.

Season	Dates	Characteristics	Importance*
Early, Mid, and Late Winter	Dec. 1 – Mar. 31	The herd is at its most dispersed at this time across 2 winter ranges: in Yukon, mostly south of the Porcupine River in boreal taiga and in Alaska, centred in the Chandalar River/Arctic Village area. Winter range use varies from year to year, depending on snow depth and condition. Caribou at this time of year are relatively tolerant to human activity. In shallow to normal snow years, animals can gain weight.	4
Spring, Spring Migration, and Pre-Calving	Apr. 1 – May 31	Herd distribution varies depending on snowmelt; migration routes vary yearly. Pregnant females are typically in an energy deficit due to reduced forage once they leave the lichen-rich taiga.	3
Calving (cows)	June 1 – 10	Calving occurs on the coastal plain of NE Alaska and, to a lesser degree, NW Yukon. This area offers reduced predators and abundant spring forage; no alternative range is available. Cows are at the lowest point of physical condition and are least tolerant to human disturbance.	1
Post-Calving and Movement (cows)	June 11 – 30	As calves develop over the first two weeks of life, the cows and calves tend to aggregate into larger groups and increase movement rates to track plant green-up. The post-calving period imposes high energetic demands on lactating females, and cow/calf groups are relatively intolerant of disturbance. The post-calving range is primarily in Alaska, and cows that calved in Yukon tend to move west along the foothills into Arctic National Wildlife Refuge. Insect avoidance can affect distribution by the end of June.	1
Calving to Movement (bulls)	June 1 – 30	Bulls, non-pregnant cows, and subadults tend to concentrate east of the calving grounds in northern Yukon. Animals track the progression of green-up from the coastal plains to the northern foothills and into intermountain regions.	3
Early Summer	July 1 – 15	Cows continue to require a high-energy intake for milk production, but insect avoidance also drives distribution. Key areas selected for insect avoidance are the coastal plain adjacent to the Beaufort Sea (mostly cows/calves) and mountains in the Brooks and British Mountains (mostly bulls and cows without calves). Long-distance movements during this period are also an insect avoidance behaviour.	2
Mid Summer	July 16 – Aug. 7	Mid-summer continues to be a period of high insect harassment. Two areas are consistently used – the northern Richardson Mountains in Yukon and the southern portion of the Brooks Range in Alaska. Females with cows may be in energy deficit.	2
Late Summer and Fall Migration	Aug. 8 – Oct. 7	As insect activity declines, the herd disperses widely but mostly stays north of the tree line until the latter part of the period – in Alaska south of the Brooks Range and in Yukon north of the Porcupine River. Animals exhibit high feeding rates and gain fat for the winter.	3
Rut and Late Fall	Oct 8 – Nov. 30	The region where rut occurs has no affinity from year to year; rut occurs wherever the herd happens to be along fall migration. In Yukon, distribution can occur from the southern Ogilvie Mountains to the Richardson Mountains.	4

* 1 = highest importance, 4 = lowest.



Map 6-1. Seasonal ranges of the Porcupine Caribou Herd from 2012–2021.

6.2.3 DIET AND HABITAT

Barren-ground caribou are generalist foragers who feed on grasses, sedges, forbs, lichens, and shrubs during the growing season. During winter lichens constitute the primary forage of most barren-ground caribou populations (Photo 6-1 and Photo 6-2). Over three winters, the composition of PCH fecal samples was similar, consisting of, on average, 64% fruticose lichens, 11% evergreen shrubs, 8% moss, 6% horsetails, and 5% foliose lichens (Russell et al. 1993).

Russell et al. (1993) surveyed lichen distribution across the Yukon portion of the PCH range. Fruiticose lichens were widespread across survey plots and overall biomass estimates were similar to values reported in other western barren-ground caribou ranges (Joly and Cameron 2018). Within the PCH's Yukon range, lichen biomass varied across regions, habitat (range) types and stand ages. Average lichen biomass varied substantially among regions, with the highest biomass occurring in Eagle Plains (78.3 g/m^2), followed by North Fork Pass (45.0 g/m^2), Chapman Lake (33.6 g/m^2), Ogilvie Valley (32.5 g/m^2), and Richardson Mountains (29.9 g/m^2). In terms of habitat type, lichen biomass varied over three-fold across the seven habitats (range) that Russell et al. (1993) surveyed. Open conifer forest types had the greatest lichen biomass, and the forb herbaceous type had the lowest.

In terms of stand age, the generally accepted theory is that lichen biomass is greatly reduced following a fire, increases in abundance up to 125–175 years, and decreases as lichens are overtaken by mosses and shrubs (Klein 1982). Field surveys by Russell et al. (1993) found that lichen biomass in the PCH range was actually highest in stands <50 years since fire, and that lichen biomass decreased across all subsequent older age classes, to a nearly 50% reduction in the oldest age class (>270 years) (Photo 6-3). This local data suggests that younger stands may make a greater contribution to lichen forage than previously believed. Russell et al. (1993) emphasizes the importance of a mosaic of stand age classes, resulting primarily from wildlife, to maintaining lichen biomass at the regional level over time.

Although habitat selection is often driven by forge availability, especially in winter, reducing predation risk (Latham et al. 2011) and minimizing exposure to insect harassment during summer (Russell and Nixon 1990) also factor into habitat selection by caribou.

6.2.3.1 Effects of Snow

The regional patterns of PCH distribution in winter vary among years, often related to snow accumulation, which can limit forage availability (Russell et al. 1993). During the 1970s and 1980s, the distribution of the PCH in winter varied in a regular pattern across four regions with different snow regimes: Yukon/Alaska border, Richardson Mountains, Ogilvie/Hart region, and the Whitestone/Eagle region (Russell et al. 1993).

On average, the Ogilvie/Hart region had the lowest mean snow accumulation. During winters when most animals occupied this region snow depths were normal to high across the overall winter range. Heavy snows in the north early in the season seemed to emphasize concentrated use in this region, pushing animals to the south during the fall migration and rut. Once animals moved into the Ogilvie/Hart basin they typically remained in the region, taking advantage of the comparatively shallow snows, until spring migration.

During the winters when most Yukon wintering animals occupied the Richardson Mountains, snow depths tended to be normal to above normal. Strong winds in the Richardson Mountains resulted in uneven snow distribution, with many areas having reduced snowpacks, including some areas being blown completely bare. During the winters when most Yukon wintering animals occupied the Whitestone/Eagle area, snowpacks were invariably below normal. This area generally had the highest lichen biomass, but snow depths appeared prohibitive during years with normal to deep snow. In the two years when most of the Yukon wintering animals occupied the Yukon/Alaska border area (overlapping with the Fortymile Herd), snows were deeper than average in all other wintering areas.

Photo 6-1. Mesic, mature forest, with mat-forming terrestrial lichens in the Eagle Plains RSA.

Photo 6-2. Lichen communities are often diverse in Eagle Plains. This lichen mat includes *Cladonia spp.* (lighter green) that are preferred forage for caribou, as well as *Stereocaulon spp.* (darker grey) and *Flavocetraria spp.*, which are both also eaten by caribou but less preferred.

Photo 6-3. Lichen cover is generally reduced in regenerating burns. However, EDI observed high lichen abundance in some regenerating burns, consistent with previous work by other researchers (Russell et al. 1993).

6.2.4 POPULATION LEVELS AND TREND

Although most barren-ground caribou subpopulations are declining (COSEWIC 2016), the PCH numbers have increased over the last two decades. The last successful population survey in 2017 estimated the population at 218,457 (95% CI = 202,106 – 234,808) caribou (Porcupine Caribou Technical Committee 2019). Population surveys of the PCH began in the 1970s. The objective is to survey the herd every two to three years, but that period is sometimes extended depending on herd behaviour (aggregation patterns), funding, and logistical issues. Since the first survey in 1972, the PCH has had two periods of population growth, with an interceding decline (Figure 6-1). From 1972 to 1979 the population was relatively stable at just over 100,000 animals. By 1989 the herd had increased to approximately 178,000. Over the next 12 years, the herd declined by 55,000 to 123,000 in 2001. By 2010, the herd had recovered to 169,000 and increased to 218,000 in the last survey in 2017. During the latest growth phase, 2010 to 2017, the estimated population growth rate of 3.7% is almost identical to the growth rate during the 1972 to 1989 growth phase (Porcupine Caribou Technical Committee 2019).

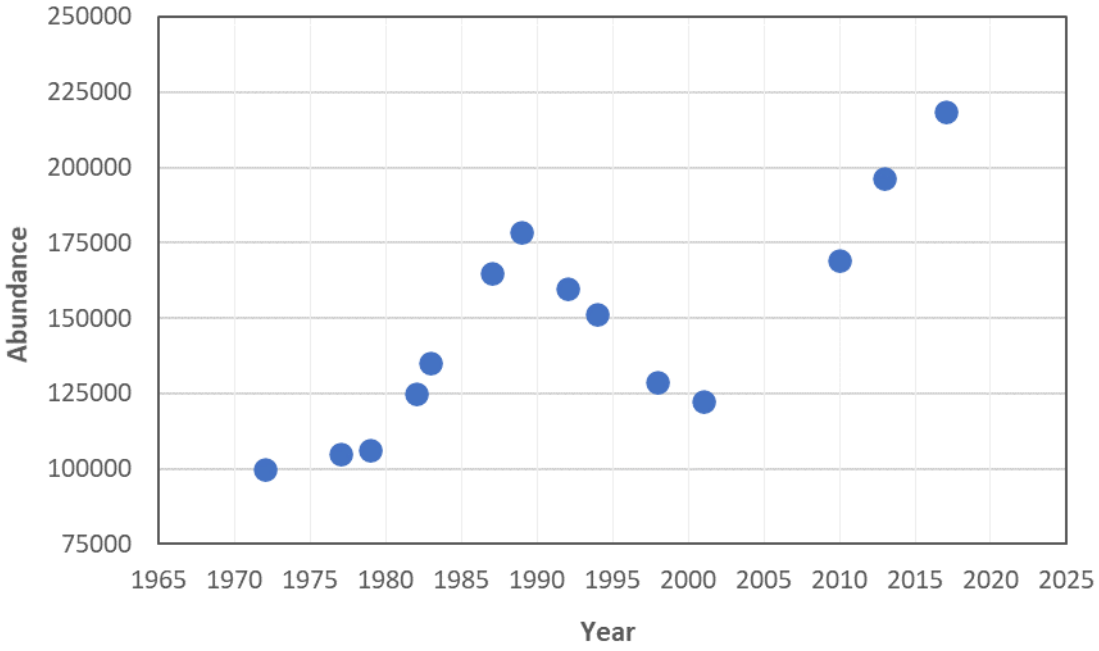


Figure 6-1. The population size of the Porcupine Caribou Herd from 1972 to 2017 (Porcupine Caribou Technical Committee 2019).

6.2.5 POPULATION DYNAMICS

Large magnitude population fluctuations are a key ecological trait of barren-ground caribou. Subpopulations (herds) often experience declines of >80% and increases >500%, which occur over several decades and caribou generations (COSEWIC 2016). Based on scientific studies and Indigenous Traditional Knowledge, the interval between population highs varies from approximately 30–80 years among subpopulations (Ferguson et al. 1998, Gunn 2003, COSEWIC 2016). There has long been debate about whether the intervals

between population highs and lows, and the population levels that occur at highs and lows, are regular enough to be considered cycles (Gunn 2003, COSEWIC 2016, Bongelli et al. 2020). A recent analytical study found that historical population fluctuations of the barren-ground caribou population overall and 9 of 11 sub-populations fit a sine-cyclic model with periods ranging from 26–55 years (Bongelli et al. 2020). However, COSEWIC (2016) points out that cumulative changes in the environment, habitat, climate, and harvest regimes for many caribou subpopulations are without historical precedent, and therefore it is uncertain whether future populations patterns will follow historical patterns.

Despite large magnitude changes in the abundance of barren-ground caribou, there is still a poor understanding of how limiting factors regulate population change. Predation, human harvest[1], parasites and disease, and food supply are all considered limiting factors of barren-ground caribou (COSEWIC 2016); however, no single factor has been conclusively demonstrated as a primary limiting factor across subpopulations and over time. Despite strong advocacy for certain factors by certain researchers (e.g., for predation by Bergerud (1996)), the weight of evidence is that population dynamics involve complex interactions among limiting factors that vary over time and among subpopulations (Klein 1991, Whitten 1996). Over the 50 years that the PCH has been monitored, the population has not exhibited population fluctuations as large as other barren-ground caribou populations (COSEWIC 2016). This may be due to the large annual and seasonal ranges and diversity of habitats across ranges (Russell et al. 1993, Whitten 1996). Whitten (1996) suggests that periods of decline are caused by nutritional stress and predation exacerbated by adverse weather. Population growth during periods of favourable weather is dampened by a combination of poor nutrition, predation, and human harvest and disease. No true density dependent regulation or equilibrium was observed for the PCH from the 1970s to early 1990s (Whitten 1996).

6.2.6 LIMITING FACTORS

6.2.6.1 Food Supply and Overgrazing

The amount and distribution of forage have implications for population distribution and demography of barren-ground caribou (COSEWIC 2016). In general, food limitation is most prevalent during winter, when caribou diet consists primarily of lichen, and does not pose a constraint to caribou from late-spring through fall when graminoids, forbs, and deciduous shrubs are bountiful and predominate their diet (Thompson and McCourt 1981, Russell et al. 1993). Lichen availability depends on both density-dependent and density-independent factors, but the degree to which either is a limiting factor depends on ecological context. For example, density-dependent competition for forage, when local densities are high, and competition is intense, can cause overgrazing of lichen and reduce its abundance (Ferguson et al. 2001, Joly 2009). Recovery of lichen communities following overgrazing can take more than 20 years (Klein 1987).

[1]Human harvest is considered a natural population factor for barren-ground caribou because hunting has occurred for centuries (Sherry and Vuntut Gwitchin First Nation 1999, COSEWIC 2016). However, it is recognized that the nature of hunting has dramatically changed over the last century with the advent of high-powered rifles and snowmobiles.

The potential for lichen supply to regulate caribou herd size and demography is most likely for herds with small ranges on low productivity tundra islands (e.g., Klein 1987). For large, widely-distributed herds, it is more likely that density-independent factors, such as climate and natural disturbance, contribute to limitations in lichen supply that affect caribou distribution (Gunn et al. 2011). Lichen is a slow-growing food source; its distribution is affected by fire (see Joly 2009) and its accessibility depends on regional snow conditions, such as snow hardness and depth (Collins and Smith 1991, COSEWIC 2016). Therefore, caribou tend to shift winter ranges and foraging locations based on burn and snow conditions so that they may access areas with higher lichen abundance (Jandt et al. 2008, Pedersen et al. 2021). In the PCH, annual variation in the distribution of caribou during winter is thought to be a result of caribou tracking available and accessible lichen patches (Russell et al. 1993, WMAC 2009).

The potential for food supply, especially lichen, to regulate the PCH is limited because of their large annual and seasonal ranges and the diversity of habitats (e.g., several broad ecoregions) found within those ranges. Variation in distribution and range use may counteract any limitations on food supply at local scales (Hinkes et al. 2005). PCH migration from the tundra, at the northern extent of their range, to the taiga cordillera, at the southern extent of their range, may serve as a strategy to maximize the available food supply. Overall, the PCH winter range is relatively rich in lichen resources and is comparable to, or better than, those of other herds that winter in taiga regions (Russell et al. 1993).

Forest Fires

Forest fires are a significant natural disturbance agent in taiga forests and play a substantial role in the availability of caribou forage, especially lichen. Occasional fires are important to maintaining lichen biomass at a landscape level. Peak lichen biomass is generally associated with forests 125-1750 years old before lichen volumes decrease due to competition from other species like moss and shrubs (Klein 1982). However, frequent fires can reduce the extent of mature and old forests where productive lichen biomass occurs. For example, forest fires in the winter range of the Bathurst Herd reduced the area of forest by 30% between 1990 and 2000 (Chen et al. 2013). More broadly, the average area burned by large fires in Canada's taiga has increased since the 1960s (Krezek-Hanes et al. 2010). Climate change modelling suggests a further increase in fire extent of 25% by 2030 and 75% by the end of the century (Wotton et al. 2010). Generally, caribou avoid burned areas in winter for several decades until lichen biomass increases to the point where it is favourable for caribou to forage. Changes in landscape vegetation patterns due to fire are believed to affect regional seasonal use areas and migration routes of caribou (Gunn et al. 2011).

The PCTC monitors the extent of burn areas across the forested portion of the PCH annual range; since 1960, 18% of the area has burned (Porcupine Caribou Technical Committee 2021a). The five-year average of the area burned in the Yukon portion of the PCH annual range is 1,552 km² (Porcupine Caribou Technical Committee 2021a).

6.2.6.2 Predation

Wolves are the primary predators of barren-ground caribou (COSEWIC 2016). However, grizzly bears can also be significant predators of caribou, especially calves (Gau et al. 2002). Predation is an important factor

affecting many facets of caribou ecology, as caribou movements and habitat choices are often made to minimize exposure to predators (Bergerud 1996). One of the hypotheses about why barren-ground caribou migrate is that it reduces predation risk. The idea is that moving throughout the year limits the numerical response of wolves (Hayes and Russell 2000). In the NWT, wolf densities in the arctic tundra calving grounds were only 22% compared to wolf densities in the taiga, where the herd wintered. However, as caribou numbers increase, their range expands, causing some caribou to return earlier to the ranges of taiga denning wolves, which results allows wolf numbers to increase (Heard et al. 1996).

A study of wolf predation on the PCH estimated that wolves killed about 7,600 adult caribou each year, regardless of herd size (Hayes and Russell 2000). In 1992 this corresponded to a predation rate of 5.8%, or about one-third of adult mortality. As the PCH declined through the 1990s, the predation rate by wolves increased from 5.8% to 7.4%. Migratory movements effectively reduced wolf predation during the calving through summer seasons due to the combination of smaller ranges and lower densities of wolves in the arctic tundra. Only 16% of the mortality occurred during the calving/summer seasons compared to 84% during the fall and winter seasons, when wolves were predominantly in the taiga zone.

Generally, wolf predation does not appear to regulate barren-ground caribou subpopulations (Crête and Huot 1993, Messier 1995, Hayes and Russell 2000). Hayes and Russell (2000) estimated that the predation rate would have had to be near twice the observed level to cause the PCH to decline during their study. However, the limiting effect of predation increases as population size decreases, which can result in a cumulative effect with other limiting factors as the population declines (COSEWIC 2016).

6.2.6.3 Hunting

Human hunting of barren-ground caribou has occurred for centuries over much of the species range in North America (Sherry and Vuntut Gwitchin First Nation 1999, COSEWIC 2016). Although humans and caribou have co-existed for centuries, technological changes (e.g., high-powered rifles, snowmobiles, and aircraft) and social changes (e.g., commercial hunting) have changed the potential effects human hunting can have on some barren-ground caribou populations (COSEWIC 2016). Over the last half-century, there has been clear evidence of population-level impacts from harvesting. From 2008 to 2011 the estimated harvest rate on north Baffin Island was 41%. During the mid-2010s harvest rates of the Southampton population were considered well beyond sustainable limits (COSEWIC 2016). Harvest is more likely to pose a threat when population monitoring data is poor and/or harvest management decisions lag population declines. For example, in the Bathurst subpopulation, a constant harvesting level during a period of population decline resulted in an increase in the harvest rate (i.e., as a percent of population size) from 2–4% to 10–16% of abundance (Boulanger et al. 2011).

There is no simple, sustainable harvest level applicable to all barren-ground caribou populations. Effects of harvesting depend on herd size, population trend, and the proportion of females that are harvested (Boulanger and Adamczewski 2016). Harvesting may also interact with other limiting factors, such as predation and weather (Klein 1991). Most harvest plans target a total harvest rate of 0–5%, depending on herd status, and with restrictions on harvesting females (e.g., Environment and Natural Resources 2013).

Recognizing the importance of effective harvest management for both the conservation and continued long-term harvest of the Porcupine Caribou, the Porcupine Caribou Management Board led the development of a comprehensive *Harvest Management Plan for the Porcupine Caribou Herd in Canada* (HMP) in 2010 (Porcupine Caribou Management Board et al. 2010)[2]. Key components of the plan include the determination of specific management actions related to the estimated herd size and a set of general best hunting practices. Management actions are determined each year using a set of six population indicators: 1) estimated herd size, 2) harvest information, 3) adult cow survival, 4) calf birth rate, 5) calf survival to nine months, and 6) body condition. In addition, descriptive indicators from people on the land include caribou health, hunting success, and weather conditions that affect caribou. The results from the indicators are rolled up into a 4-class colour chart, and management actions are specified for each colour zone. Management actions become more restrictive across each zone once the herd falls below 115,000 animals, including ceremonial harvests only below 45,000 animals (Porcupine Caribou Management Board et al. 2010).

Implementation of the HMP is guided by a formal Implementation Plan (Porcupine Caribou Management Board 2016). Key components of the Implementation Plan are to 1) guide annual monitoring of the population indictors and harvest levels, 2) provide a forum for all the HMP Parties to review and discuss the population indicators and harvest levels and 3) provide an annual recommended harvest management colour zone plus any additional management actions that are deemed appropriate. Population indictors are monitored each year by the PCTC and summarized in an annual report (e.g., Porcupine Caribou Technical Committee 2021). Annual harvest levels are monitored by each Party or user group and are compiled by the PCTC into an annual report (e.g., Porcupine Caribou Technical Committee 2021b). Each year, the HMP Parties hold an annual meeting to discuss the results of the population and harvest monitoring and determine the harvest management zone for the following year and any additional management actions the Parties feel may be required.

Over the eight-year period, 2013–2014 to 2020–2021, the annual reported harvest rates of Porcupine Caribou have ranged from 749 to 3,367 caribou. The reported annual harvest rates are considered the minimum estimated harvest (Porcupine Caribou Management Board 2022). Due to reporting challenges faced by some Parties, significant harvest may be missed in some regions in some years. Notwithstanding the reporting challenges, the reported Canadian harvest is estimated to be between 1% and 2% of the 2017 population estimate of 218,000 caribou and is not considered a threat to population decline (Porcupine Caribou Management Board 2022). The comprehensive measures within the HMP to monitor and respond to declines in the PCH (i.e., by reducing harvest) provide a solid system to minimize the potential effects that harvesting could have on the herd.

[2] The HMP was agreed to by eight Parties with authorities and responsibilities managing the PCH within Canada, including Gwich'in Tribal Council, Inuvialuit Game Council, Vuntut Gwitch'in Government, Trʻondëk Hwëchʻin Government, First Nation of Na-Cho Nyäk Dun, Government of the Northwest Territories, Government of Yukon, and Government of Canada.

6.2.6.4 Parasites and Disease

Biting and parasitic insects, pathogens (i.e., viruses and bacteria) and internal parasites are important factors in caribou ecology and population dynamics (Gunn and Irvine 2003, Kutz et al. 2012, COSEWIC 2016).

Harassment by parasitic insects can be a key driver of behaviour, movement, and body condition of caribou during summer (Downes et al. 1986, Russell and Nixon 1990). Warble flies (*Hypoderma tarandi*) and nose botflies (*Cephenemyia trompe*), both of the family Oestridae, are the primary source of harassment for Arctic caribou, though mosquitoes (Culicidae), blackflies (Simuliidae), and horseflies (Tabanidae) also are known to cause harassment (Downes et al. 1986, Toupin et al. 1996, Witter et al. 2012a). There are two primary harmful effects of insects. The direct effects of the parasitic burden can result in decreased body condition and reproduction (Albon et al. 2002, Cuyler et al. 2012). Indirect effects include the behavioural response to avoid insects, which includes a reduction in time spent foraging, increased energy expenditure, and selection of low-quality habitats such as ridge tops, coastal regions, snow patches, and unvegetated areas (Downes et al. 1986, Russell and Nixon 1990, Walsh et al. 1992, Toupin et al. 1996, Witter et al. 2012a). These behavioural responses can result in reduced body condition going into the winter with negative implications for survival and fecundity (Russell et al. 1993, Cuyler et al. 2012).

The responses of caribou to disease and other parasites are less evident and less studied than responses to insects. Most occurrences of disease and internal parasites in caribou are at subclinical levels (not severe enough to produce observable symptoms) but can still result in reduced body condition and fitness (Gunn and Irvine 2003). A range of pathogens and parasites observed in caribou includes viruses, bacteria (e.g. brucellosis), helminths (e.g., roundworms, tapeworms, and flukes) and protozoa (Tessaro and Forbes 1986, Gunn and Irvine 2003, Kutz et al. 2012, COSEWIC 2016). Gunn and Irvine (2003) suggest that caribou may have evolved foraging strategies to minimize exposure to parasites. Similar to parasitic insects, internal parasites can reduce caribou body condition and pregnancy rates resulting in population-level impacts (Albon et al. 2002, Kutz et al. 2012).

6.2.6.5 Climate Change

Climate change can potentially affect barren-ground caribou populations negatively and positively through various mechanisms. A recent literature review on this topic identified five primary factors that affect caribou population dynamics that could be affected by climate change: (i) summer range conditions, (ii) parasites and disease, (iii) movement, migration, and distribution, (iv) extreme weather and icing events, and (v) winter range conditions (Mallory and Boyce 2018). The effects of these factors are likely to be complex and interact with climate and non-climate-related factors that will result in substantial local variation and uncertainty in potential outcomes to caribou (Cebrian et al. 2008, COSEWIC 2016).

On balance, climate change is predicted to have mostly positive effects on the summer range condition of barren-ground caribou. Increasing temperatures will likely lead to longer growing seasons, increases in plant productivity, and an earlier onset of spring. Pearson et al. (2013) predict dramatic increases of 29-68% in above-ground plant biomass in the arctic by 2050. These effects could increase caribou body condition and reproductive success by lengthening the summer period of food availability, by increasing the amount of

forage and providing earlier access to forage (i.e., relative to the energetically demanding periods of birthing and lactation) (Tews et al. 2007, Cebrian et al. 2008, Mallory and Boyce 2018). This prediction is supported by a 20-year study in Norway, 1994–2015, where reindeer body mass resulted from greater plant productivity associated with warmer summer temperatures (Albon et al. 2017). In the PCH, earlier and warmer springs over the last thirty years have resulted in more food available for nursing cows, correlated with higher early calf survival (Griffith et al. 2002). However, positive effects on caribou summer range may not occur uniformly across all ranges. Some researchers have suggested the potential for a trophic mismatch between the timing of caribou and vegetation phenologies (Vors and Boyce 2009). Also, a predicted shift to greater cover of woody shrubs may be negative to caribou because shrubs tend to have greater chemical and structural defenses against herbivory and lower available protein than other forage such as grasses, forbs and sedges (Thompson and Barboza 2014).

Most studies suggest that climate change is predicted to increase the potential effects of parasitic insects and disease on barren-ground caribou (Mallory and Boyce 2018). Warmer and longer summers are likely to increase the length and severity of insect harassment, leading to lower body condition of caribou, including lactating cows and calves (Witter et al. 2012b). Climate change is also predicted to increase parasitism by other taxa, such as protozoans and helminths, and the northern expansion of some parasitic species has already been observed (Kutz et al. 2013). Certain ungulate diseases are also expanding northward as the climate warms (Arifin et al. 2020). Arctic ecosystems and species may be more susceptible to the spread of parasites and diseases than southern populations because they have had less exposure and opportunity to develop resistance from an evolutionary perspective.

Extreme weather, such as icing events, large changes in snowfall patterns, and summer heat episodes, is predicted to increase with climate change and negatively affect caribou (Mallory and Boyce 2018). Restricted or total loss of access to forage due to icing in the winter range can significantly affect survival and body condition for barren-ground caribou (Tyler 2010, Hansen et al. 2014). These events tend to be more catastrophic in the high Arctic but have been reported broadly across caribou ranges; including within the VGFN territory where the refreezing of wet snow one winter restricted access to food and greatly affected the health of a caribou herd (Sherry and Vuntut Gwitchin First Nation 1999, p. 186). Ice crusts on snow can also negatively affect travel abilities, body condition, and predation risk of caribou (Griffith et al. 2002). Deep snowpacks can reduce the availability of terrestrial lichen forage in winter. The Porcupine Caribou are known to vary winter range use in response to regional weather patterns (Russell et al. 1993). Changes to regional snow patterns may make areas, such as Eagle Plains, less available to the herd (Russell and Gunn 2017).

Several studies have predicted that climate change could affect the movements, migration and distribution of barren-ground caribou (Mallory and Boyce 2018). Effects are predicted to be most dramatic for subpopulations that travel over ice during the winter and where warming temperatures are already reducing the extent and duration of ice (Poole et al. 2010). Changes in regional snow conditions predicted due to climate change can also affect the migration patterns and seasonal distributions of barren-ground caribou. Russell et al. (1993) observed that the PCH adjusted the concentration of winter range use in relation to winter snowpacks. Areas such as Eagle Plains, which receive the greatest use during low snow years may become less available if regional snowpacks increase. Other studies have indicated that snow depths and snow conditions

(e.g., crusting) affect the migration routes, behaviours, and energetic costs of Porcupine Caribou during spring migrations (Whitten 1996, Griffith et al. 2002).

During winter, many barren-ground caribou subpopulations forage primarily on terrestrial lichen. Climate change is predicted to reduce terrestrial lichen biomass due to increased productivity from other plants (notably shrubs) and, in the boreal/taiga forest, due to increased forest fires (Mallory and Boyce 2018). Some studies indicate the area burned each year in northern Canada could double by the end of the century (Wotton et al. 2010). The potential adverse effects of climate change on caribou winter range depend mainly on the assumption that caribou require lichen-rich diets in winter. Some researchers have long questioned the need for lichens during the winter (Bergerud 1974), and more recent studies suggest that winter diets dominated by graminoids rather than lichens were not detrimental to caribou populations (Heggberget et al. 2002, van der Wal 2006). However, in the Western Arctic Herd a decline in recruitment and abundance in the herd occurred when the winter diet showed increased graminoids and decreased lichens being consumed (Joly 2009). In the past, the conditions of winter range and winter weather were not considered to be limiting to the PCH (Russell et al. 1993, Porcupine Caribou Technical Committee 1993). However, the combination of reduced lichen forage, deeper snow in some areas, and extreme weather events that are predicted to occur with climate change has the potential to increase the limiting effect of the winter range on the PCH.

6.3 PORCUPINE CARIBOU HERD MANAGEMENT

There is a long history of co-management of the PCH among indigenous, state, territorial and federal governments, with international and national management boards formalizing in the mid-1980s. Canada and the United States of America co-manage the herd under the *Agreement Between the Government of Canada and the Government of the United States of America on the Conservation of the Porcupine Caribou Herd (1987)*. The International Porcupine Caribou Board (IPCB) is comprised of Canadian and American representatives. The Porcupine Caribou Management Board (PCMB) is a co-management board for the Canadian portion of the herd's range, formed under the *Porcupine Caribou Management Agreement (1985)*. The *Porcupine Caribou Management Agreement (1985)* was established to coordinate management efforts toward conserving the herd and maintaining and protecting special harvesting rights in the Porcupine Caribou for indigenous users while providing for other users to share in the harvest. The PCMB and IPCB have led or contributed to the development of several plans for the PCH, including:

- *Plan for the International Conservation of the Porcupine Caribou Herd (1987),*
- *Wildlife Conservation and Management Plan for Yukon North Slope (2002),*
- *Porcupine Caribou Harvest Management Plan (2010)* and an associated *Implementation Plan (2010, revised 2016),*
- *Porcupine Caribou Herd Strategic Framework 2015-16 to 2019-20.*

The international agreement also provided for a joint technical committee to coordinate research and monitoring activities and advise the IPCB on scientific matters surrounding the herd. This committee, known

as the "Porcupine Caribou Technical Committee" (PCTC), has been functioning since the 1970s. Over time, the PCTC has taken on the role of advising the Canadian PCMB and the IPCB. The PCTC comprises biologists and scientists from Yukon, Alaskan, Canadian and American government agencies, university researchers, and other caribou experts.

The PCTC leads most of the monitoring and research initiatives associated with the PCH on behalf of the PCMB and the IPCB. Core monitoring work that the PCTC does includes population abundance surveys (normally every two to five years depending on herd behaviour, funding, and logistics), population demographic monitoring (e.g., calf birth and survival rates and important age and sex ratios), seasonal movement monitoring (via GPS telemetry tracking), caribou body condition monitoring, habitat and human disturbance assessments, and annual snow surveys. Monitoring results are normally provided to the PCMB and the IPCB via annual reports (e.g., Porcupine Caribou Technical Committee 2019) and via presentations at the annual harvest meetings. The PCTC also intermittently conducts specific data analyses, such as habitat selection studies and seasonal range mapping, to support land use planning and other management initiatives.

6.3.1 PROTECTED AREAS AND MANAGEMENT AREAS AND PLANS

A network of parks protects the portion of the PCH annual range that occurs within Yukon, special management areas, conservation areas, wilderness areas, protected areas, ecological preserves, habitat protection areas, and IMA zones within the North Yukon Regional Land Use Plan and the Peel Watershed Regional Land Use Plan (Map 6-2). In total, 54% of the annual range of the PCH within Yukon falls within some type of protected area where industrial activity is prohibited, 36% of the annual range occurs within regional LUP IMA zones, and 9% of the annual range is not covered by any type of land management zonation. A summary of the overlap of different types of protected areas and management areas with the seasonal ranges of the PCH is provided in Table 6-2.

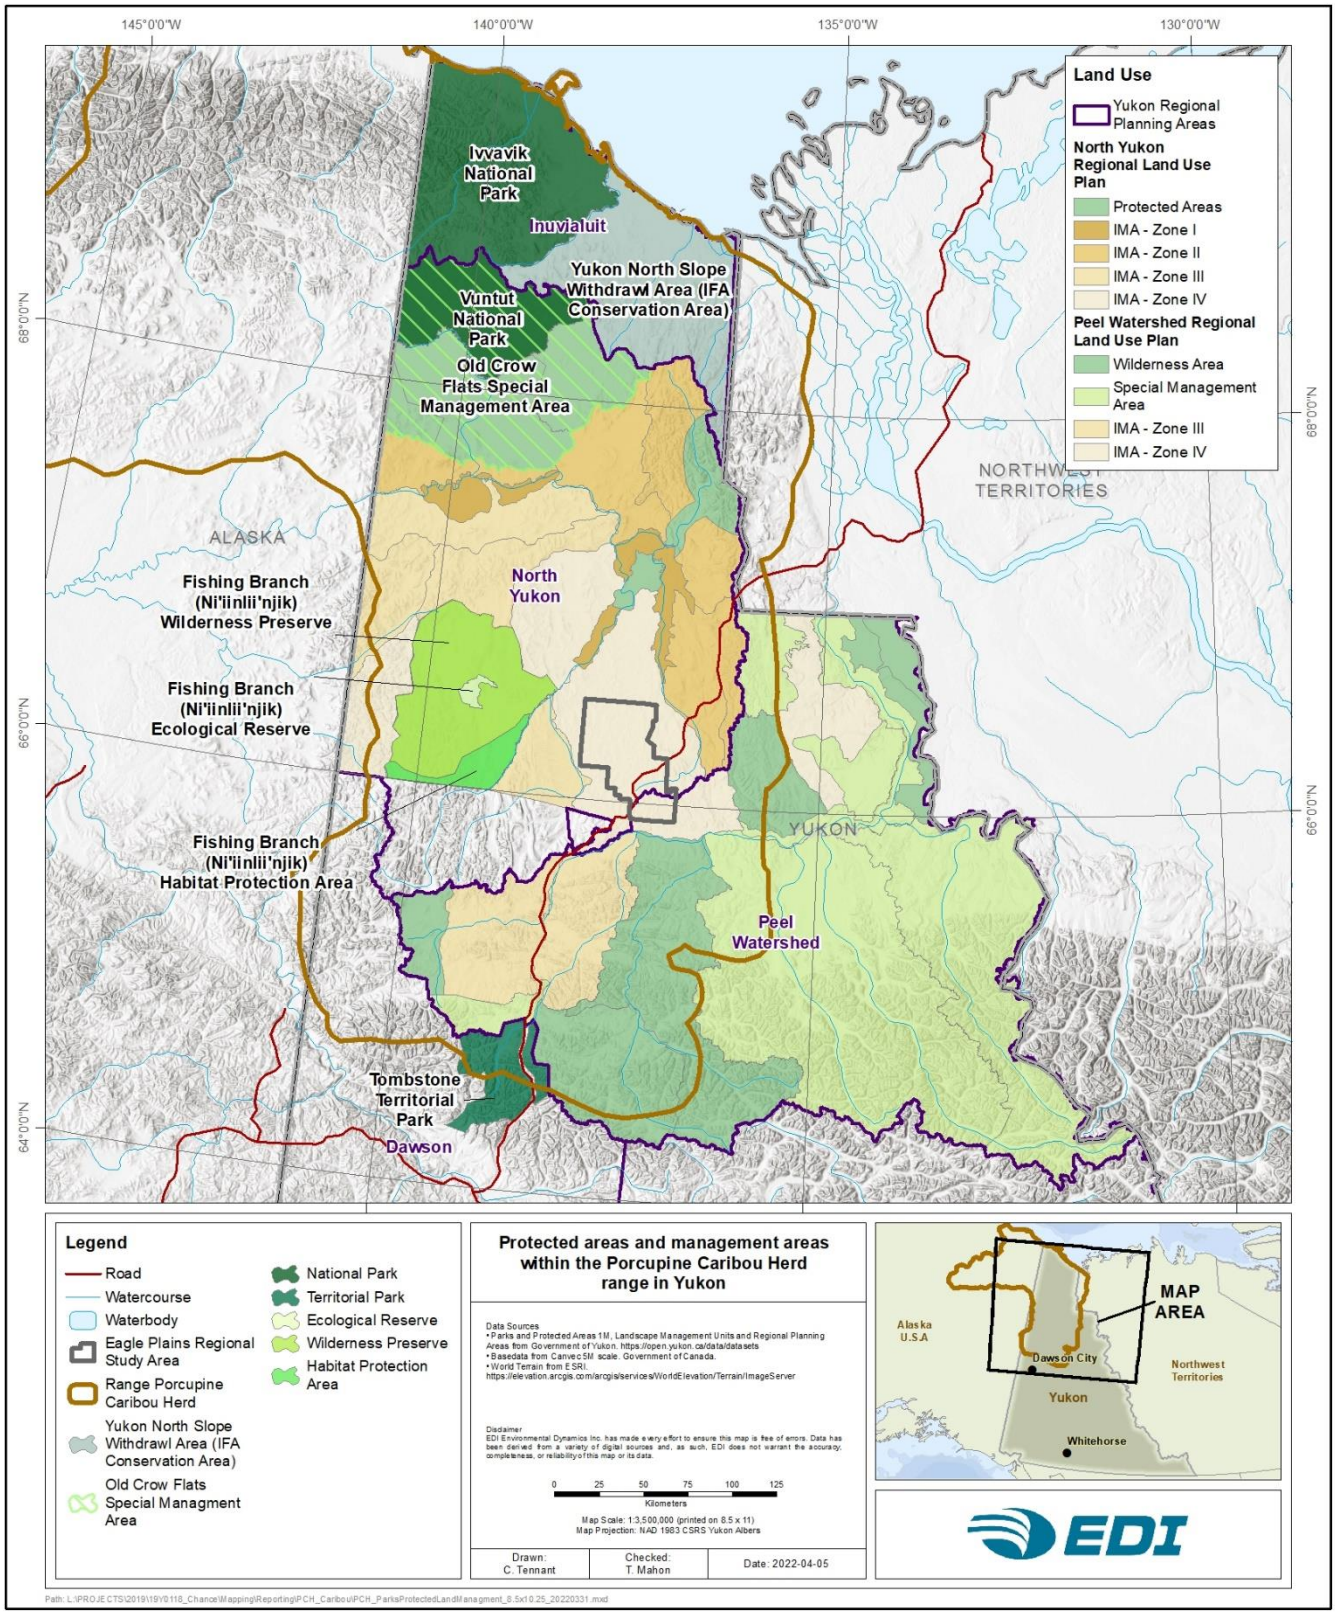
The Project is within the North Yukon Planning Region and Peel Watershed Planning Region and is subject to the NYLUP (Vuntut Gwitchin Government and Yukon Government 2009) and PWLUP (Peel Watershed Planning Commission 2019). The project falls within IMA Zone IV of both plans, a zone with lower ecological and cultural values and the highest permissible development of the four IMA zones. The NYLUP and PWLUP include management objectives and strategies to minimize the effects of human development activities on wildlife and wildlife habitat, generally, and specific objectives and strategies for caribou.

In addition to the Regional Land Use Plans, the Habitat Programs Section of the Yukon Department of Environment, Yukon Government maintains an inventory of important habitat areas for focal management species, including caribou, within the Wildlife Key Area Inventory (Environment Yukon 2014b). Wildlife Key Areas are specific geographic locations used by wildlife for critical, seasonal life functions, such as calving areas and mineral licks. No Wildlife Key Areas for caribou occur within the Project RSA (Government of Yukon 2015).

Table 6-2. Summary of the overlap of different types of protected areas and management areas with the seasonal ranges of the Porcupine Caribou Herd.

Season	Area (km²)	% of Seasonal Range					
		Protected Areas [1]	IMA I	IMA II	IMA III	IMA IV	Not Zoned
Early, Mid, Late Winter	58,090	37	2	8	19	18	15
Spring, Migration and Pre-calving	68,463	55	1	7	21	7	9
Calving	14,636	100	0	0	0	0	0
Post-Calving and Movement	7,622	100	0	0	0	0	0
Early Summer	5,901	100	0	0	0	0	0
Mid Summer	24,417	86	0	14	0	0	0
Late Summer and Fall Migration	57,928	60	4	15	13	8	0
Rut and Late Fall	65,249	31	3	10	23	13	20

[1] including parks, special management areas, conservation areas, wilderness areas, protected areas, ecological preserves, and habitat protection areas.



Map 6-2. Protected areas and management areas within the Porcupine Caribou Herd range in Yukon.

6.4 SEASONAL DISTRIBUTION

Considerable effort has been placed towards quantifying and mapping space use of PCH caribou in Yukon. Satellite-telemetry collaring programs have allowed for the tracking of individuals within the herd to delineate the herd's seasonal distributions. The PCTC supplied EDI with spatial polygons of PCH seasonal ranges spanning 37 years (1970–2016), which provided an opportunity to determine the amount of overlap between seasonal ranges and the RSA. Simple measures of overlap (%) can yield useful insight into the historical frequency of occupation and how PCH caribou are likely to interact with the Project.

The Project RSA overlaps a relatively small proportion of late fall (October 8 to November 30) and winter (December 1 to March 31) ranges. Most of the overlap occurs in portions of the ranges that are less frequently used on an annual basis. No overlap occurs with frequently used portions of late fall and winter ranges.

6.4.1 METHODS

The seasonal ranges used for this analysis consisted of mapped 'sensitive habitat' polygons provided by the PCTC that correspond to eight seasonal life cycle periods for the PCH (Porcupine Caribou Technical Committee 1993). Within each season, the PCTC identified four levels of use based on the frequency of overlap among annual estimates of seasonal home ranges computed for collared caribou, 1970–2016. The four use levels correspond to the proportion of years that home range estimates overlapped any given area: >40 %, 30–40 %, 20–30 %, and <20 %. The lowest category (<20 %) corresponds to very low use and is not considered part of the regular seasonal ranges of the PCH. The degree of overlap of the Project RSA with the PCH seasonal ranges was calculated in a GIS by measuring the overlap of the RSA with each 'frequency of use' category for each seasonal range. All eight life cycle periods were considered for the analysis, but only late fall (including rut, October 8 to November 30) and winter (December 1 to March 31) ranges overlapped the RSA. The overlap analysis was constrained to Yukon because fall and winter ranges in Yukon and Alaska are functionally discrete. Including the Alaskan ranges would dilute the degree of overlap of the RSA with the Yukon ranges.

6.4.2 RESULTS

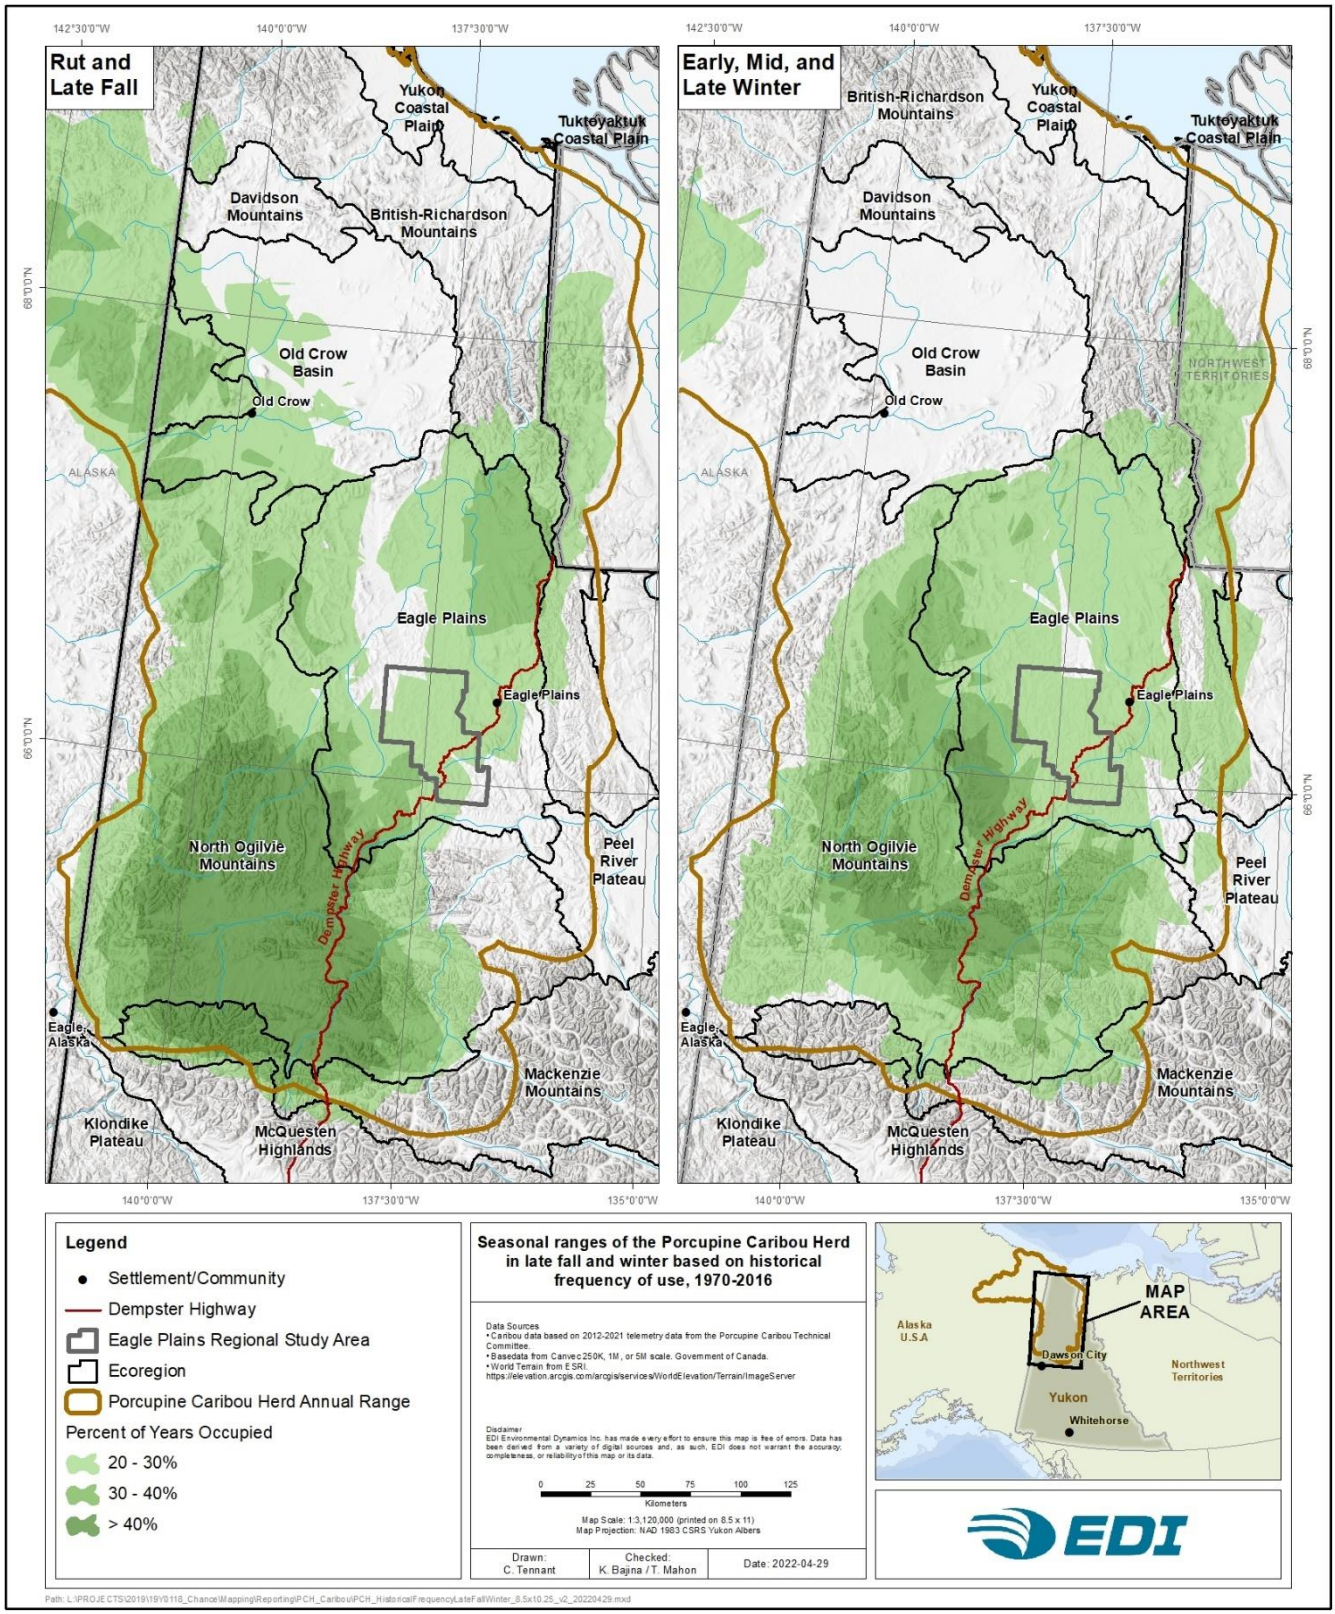
Only two seasonal life cycle periods had relatively frequent overlap (i.e., >20 % across years) with the RSA: (1) rut and late fall, and (2) early, mid, and late winter. For simplicity in this and subsequent analyses, these two periods are referred to as 'late fall' and 'winter' seasons. The RSA overlaps a relatively small portion of the seasonal ranges for both late fall and winter seasons: 5.97% in late fall and 6.54% in winter (Map 6-3). The greatest overlap occurred with the 20–30 % frequency of use areas; 5.90% and 6.12% of late fall and winter ranges, respectively (Table 6-3). No overlap occurred between the Project RSA and the most frequently used areas (>40 %) for either season.

PCH caribou have a wide-ranging distribution in late fall and winter and occupy a large portion of northern and central Yukon. Though some use occurs in the Project RSA and the broader Eagle Plains ecoregion, more frequent use occurs further southwest in the taiga cordillera of the North Ogilvie Mountains in late fall and

winter, and in the Richardson Mountains in late fall (Map 6-3). As discussed in the background sections, Section 6.2.2 *Seasonal Ranges and Movements* and Section 6.2.3.1 *Effects of Snow*, the distribution of the PCH in winter varies across four regions with different snow regimes: Yukon/Alaska border, Richardson Mountains, Ogilvie/Hart region, and the Whitestone/Eagle region (Russell et al. 1993). Use of the Whitestone/Eagle region is highest in years with lower than average snowpacks.

Table 6-3. Percent overlap of the Porcupine Caribou Herd late fall and winter ranges with the Project RSA based on the annual frequency of use by caribou, 1970–2016.

Seasonal Range	Annual Use by Caribou (%)	Percent Overlap with RSA (%)
Late Fall	< 20%	0.55
	20–30%	5.90
	30–40%	0.07
	> 40%	0.00
Winter	< 20%	0.07
	20–30%	6.12
	30–40%	0.42
	> 40%	0.00



Map 6-3. Annual frequency of use by the Porcupine Caribou Herd in late fall and winter ranges relative to the RSA, 1970–2016.

6.5 HABITAT USE

The general distribution of PCH caribou across seasons provides some context for their potential interaction with, and overlap of, the Project RSA. However, to caribou, all space on the landscape is not equivalent. Habitat needs to be considered to predict how often caribou might occur in the area based on the amount and distribution of necessary resources, such as forage. To better understand how PCH caribou use habitat across their late fall (including rut) and winter (i.e., early, mid, and late season) ranges, statistical models were developed to describe the relationship between caribou locations and relevant habitat components. These models considered habitat available to caribou broadly across their seasonal range. Habitat models were developed for late fall and winter using GPS location data (2012–2021) of satellite-collared caribou provided by the PCTC. Habitat model outputs were used to estimate the amount and distribution of habitat within the Project RSA and across the PCH's late fall and winter ranges.

The chosen models for late fall and winter performed reasonably well in predicting PCH caribou habitat selection based on several measures of model performance. Light macrolichen cover was the key driver of caribou habitat use in both seasons, though preference for lichen was strongest during winter. During late fall, caribou tended to select flat, mid-elevation regions near large waterbodies. During winter, caribou tended to select flat areas at low and high elevations while remaining distant from waterbodies. Caribou also avoided areas with dense conifer trees, shrub (deciduous and evergreen), forb, and graminoid cover. Base habitat models predicted the distribution and proportion of selected habitat in the Project RSA to be approximately equivalent during late fall and less during winter relative to the full extent of those seasonal ranges.

6.5.1 METHODS

6.5.1.1 Spatial Extent

Habitat modelling was conducted across the Yukon portion of the late fall and winter seasonal ranges defined in Section 6.5, *Seasonal Distribution* (i.e., areas with >20% frequency of annual use). Analyses were limited to the Yukon portion of late fall and winter ranges because of the potential differences in the ecology of caribou occupying Alaska versus Yukon. Using the full Yukon range yields the benefit of identifying broad patterns of habitat selection that affect the territory-wide distribution of the PCH. However, use of a broader scale may dilute patterns of habitat selection at local scales, e.g., only within Eagle Plains ecoregion. Whether such dilution leads to a loss of information depends on caribou habitat preferences in different ecoregions.

6.5.1.2 Data Preparation

The PCTC provided EDI with GPS location data (2012–2021) of satellite-collared PCH caribou. These data covered the entire annual range of the PCH and were reduced to include locations only within the late fall and winter range extents, as described above. The reduced data set consisted of 164 caribou in late fall and 172 caribou in winter. Most of these data (39.02% in late fall and 42.74% in winter) were attributed to locations collected in 2020–2021.

Spatial habitat data were acquired to relate caribou locations to environmental conditions within fall and winter seasonal ranges (as defined above) and, where appropriate, account for variation in conditions across time. For example, temporal changes (from 2010 to 2020) in the distribution of plant functional types (PFTs) due to grazing, fire, and climate-driven vegetation dynamics were captured using predicted top cover percentage (%) raster layers developed by Macander et al. (2022). Based on initial data exploration exercises, the PFTs that were considered ecologically relevant to habitat use of the PCH included light macrolichens (also see Macander et al. 2020), graminoids, forbs, evergreen shrubs, deciduous shrubs, and conifer trees. Data for topography on the landscape were acquired from a Digital Elevation Model (DEM; 1:250,000) for Yukon and were used to develop measures of absolute elevation (metres), slope percent (slope tool in the Spatial Analyst extension, ArcGIS 10.7; ESRI 2019), aspect (degrees), and a terrain ruggedness index (TRI; Sappington et al. 2007). A measure of relative elevation was created by combining absolute elevation and a simplified stream network (CanVec; nearest main watercourse from a 1:1,000,000 scale watercourse layer) and then employing the HAR tool from the Riparian Topography Toolbox in ArcGIS (Dilts 2015). A CanVec (1:1,000,000) waterbody layer was also used to map distances to waterbodies >1 ha. Caribou may use frozen waterbodies as an antipredator tactic to increase sightlines. They may also be mineral licks (Ferguson and Elkie 2005).

6.5.1.3 Statistical Models

Determining which resources (habitat features) are selected most often by animal populations is important because it provides information about how those animals meet fundamental requirements for survival and reproduction (Manly et al. 2002). Resource selection functions (RSF) are a statistical method that quantifies how resources are chosen by relating animal observations to resources available across the landscape. RSFs predict the probability of an animal occurring at specific locations (e.g., within a study extent) based on the combination of resources available at those locations. Results of a RSF can be mapped to identify important areas of resource selection for caribou and, therefore, can inform the conservation and management of the species.

Caribou observations were first overlayed with environmental spatial data layers to develop RSFs for PCH late fall and winter ranges. Environmental values were extracted for each known location of caribou plus ten times as many randomly sampled locations (spaced a minimum distance of 50 m apart). Availability was deemed global, so available locations were randomly selected within the late fall and winter study areas. Independence among observations of caribou was assumed by resampling caribou locations to a maximum of one per day. Available locations were compared to locations known to be occupied or 'used' by caribou to identify the combination of resource units preferred by caribou. Logistic regression was used to develop RSFs within a generalized linear mixed model framework. The general formula for logistic regression is as follows:

$$logit(P) = \beta_0 + \beta_1 x_1 \ldots \beta_n x_n + Y$$

where the predicted value P is dependent on the linear predictor ($\beta_0 + \beta_1 x_1 \ldots \beta_n x_n$) through a logit-link function, and x is the *i*-th environmental covariate and β is its associated coefficient. An interaction was included between Ecoregion and macrolichen cover to account for the varied distribution, and possibly selection, of lichen among ecoregions. An additional random effect term, Y, was added to account for (a) the

variation in habitat selection associated with each caribou year and (b) the unequal sample sizes among years. Large weights were applied to all available locations ($weight_{avail}$ = 1,000) relative to used locations ($weight_{used}$ = 1) to ensure that parameter estimates were not biased by the sampling ratio of used and available points (Muff et al. 2020). The linear predictor was used to calculate the probability of selection P:

$$P = \frac{e^{(\beta_0+\beta_1 x_1 \ldots \beta_n x_n+Y+E)}}{1+e^{(\beta_0+\beta_1 x_1 \ldots \beta_n x_n+Y+E)}}$$

where e is the natural exponential function and P is bounded by $0 < P < 1$.

6.5.1.4 Exploring Covariate Relationships

Before analyses, all continuous covariates, such as PFT top covers, elevation, slope, TRI, HAR, and distance to waterbodies, were standardized to have a mean of zero and a standard deviation of one. Standardizing the values across covariates ensures model convergence and improves the ability to rank the relative importance of each covariate in a model. The aspect was converted from continuous (degrees) to categorical (cardinal directions) based on 90° intervals. To prevent biased estimates of coefficients and inflated errors, multicollinearity among covariates was assessed using a correlation matrix (dropping variables with Pearson's product moment correlation $|r| > 0.7$ [see Dormann et al. 2013]) and variance inflation factor scores (dropping variables with VIF scores > 3 [Zuur et al. 2009]). For example, absolute and relative (HAR) elevation in winter were highly correlated (r = 0.69). The decision to choose one over the other was based on univariate response curves assessed using generalized additive modelling (GAM; see below). In other words, of the highly correlated covariates, the one with the greatest selection response (slope) was chosen. In this case, absolute elevation was retained over HAR.

Data exploration consisted of (1) univariate analyses with the response variable (i.e., used versus available), and (2) univariate and multivariate GAMs to assess the potential marginal effect of each covariate on the (non-linear) shape of the response curve (i.e., probability of use). These exercises informed model development. For example, rather than assuming a linear increase for percent light macrolichen cover, the variable was logarithmically transformed to fit the expectation that the probability of selection increased at incrementally smaller values as the quantity of lichen in a patch increased (Figure 6-2). Additionally, different patch sizes were considered for PFT covers by estimating the mean percent cover within 100 m, 500 m, and 1,000 m buffers around used and available points.

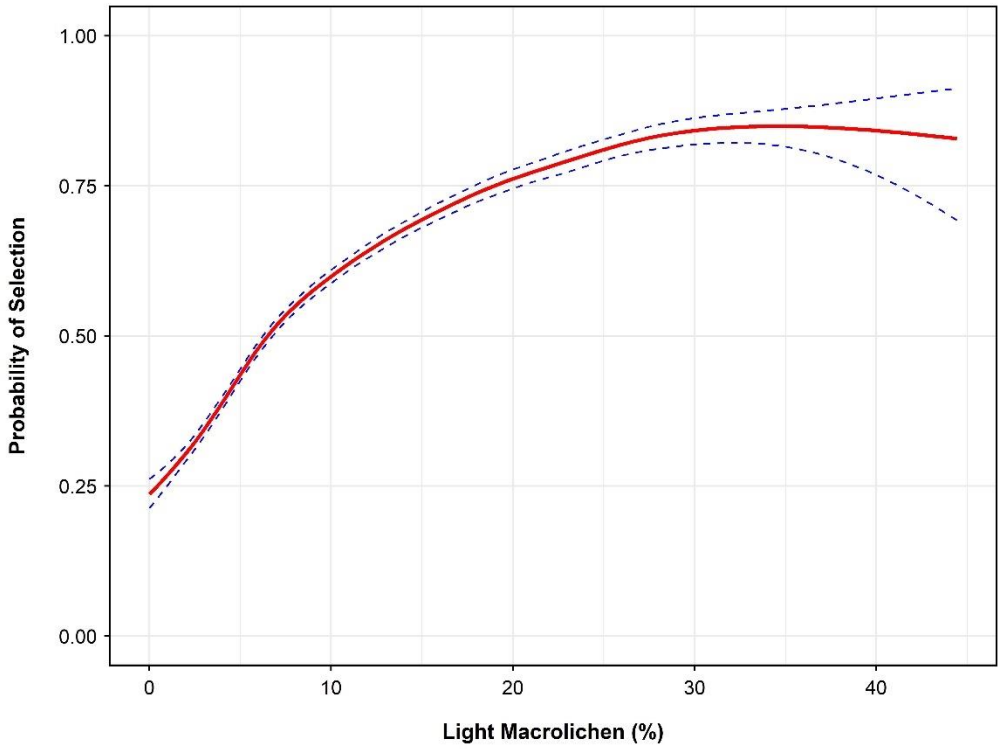


Figure 6-2. Generalized additive model assessing the probability of selection of light macrolichens by PCH during winter.

6.5.1.5 Model Selection and Validation

Habitat models were selected for late fall and winter by implementing 'full' models (with all relevant covariate terms) and assessing the variation explained by the inclusion of each covariate. The best models were chosen based on (1) statistical considerations using Akaike's information criterion (AIC; Burnham and Anderson 2002), which balances the trade-off in the amount of variance explained (i.e., model likelihood) with the number of parameters considered, and (2) ecological significance to caribou in the late fall and winter seasons. Since the goal of the model was prediction, as many covariates as necessary were retained. Thus, alternative candidate models were considered not by testing competing hypotheses but rather by dropping covariates with low magnitude (scaled) coefficients $< |0.1|$. Model diagnostics were run on simulated residuals to assess (a) goodness-of-fit (i.e., Kolmogorov-Smirnov test), (b) issues related to dispersion, (c) the frequency of outliers, (d) variance among categorical predictors, and (e) quantile regressions of observed versus expected residuals.

The predictive performance of late fall and winter models were assessed using a 5-fold cross-validation approach as per the steps outlined in Johnson et al. (2006). (1) The original data were partitioned into 5-fold groups. For each iteration of the evaluation procedures, four groups were combined into the training dataset. The remaining group was used as the testing dataset. (2) The RSF was estimated for each training dataset. (3) RSF values from the training dataset were predicted in a GIS and reclassified into 10 quantile rank bins. (4) Midpoint (median) values of raw RSF scores were calculated for each quantile bin. (5) Percent utilization was

calculated for each quantile bin using equation 4 in Johnson et al. (2006). (6) The number of used observations from the testing dataset that fell in each quantile bin were counted. (7) The number of expected observations from the testing dataset was calculated for each quantile bin using equation 5 in Johnson et al. (2006). (8) Observed versus expected counts and proportions from the testing dataset were compared and tested formally using linear regression, spearman's rank correlation, chi-square goodness-of-fit (i.e., observed versus expected counts), and tests of proportions for each quantile bin (i.e., chi-square observed versus expected proportions). These steps were repeated until each fold was used as the testing dataset. The 5-fold cross-validation procedure was implemented for several candidate models for both late fall and winter to determine whether simpler models yielded more accurate predictions.

6.5.1.6 Habitat Quality, Amount, and Distribution

Models selected for late fall and winter were used to generate predictive habitat maps across those seasonal ranges. These mapped predictions aimed to identify the amount and distribution of habitat available to PCH caribou. To facilitate the comparison of relative habitat quality across the study area, the RSF predictions were classified into four ordinal ratings: Very Low, Low, Moderate, and High. To help objectively define ecologically relevant classification of the RSF values we conducted a post-hoc selection-ratio test of the caribou locations against the RSF predictions. This approach identified the point within the RSF value range where values switch from avoided to being selected. The portion of the 'selected' RSF value range was divided at the midpoint into the Moderate and High ratings and the portion of the 'avoided' range was divided at the midpoint into the Very Low and Low ratings. For example, for RSF output with a range from 0 to 1, if the selection-ratio calculation determined the breakpoint between avoidance and selection occurred at 0.6, the habitat quality ratings would be Very Low = 0.0-0.3, Low = 0.3-0.6, Moderate = 0.6-0.8, and High = 0.8-1.0.

To determine the breakpoint within the RSF value range that switched from avoided to selected, the frequency distributions of mapped RSF predictions were partitioned into 50 quantile bins with each bin consisting of two-percentile intervals. Selection ratios were calculated for each quantile bin by associating mapped RSF predictions to used and available collar locations and then assigning each location to a quantile bin. The selection ratio for each bin was calculated as follows:

$$SR_{bin} = \frac{Used_{prop} - Avail_{prop}}{Avail_{prop}}$$

where $Used_{prop}$ and $Avail_{prop}$ are the proportion of used and available locations in each quantile bin. Selection ratios were used to categorize habitat quality into the discrete ratings discussed above (i.e., Very Low, Low, Moderate, and High). The bin at which selection ratios switched from negative to positive identified the threshold between Low and Moderate quality habitat. Very Low quality habitat was identified based on the midpoint between the smallest quantile bin and the Low/Moderate quality habitat threshold. Similarly, the midpoint between the Low/Moderate quality habitat threshold and the largest quantile bin differentiated Moderate and High quality habitat. For certain management questions or purposes, it may be adequate to just use two habitat classes—avoided or selected. Subdividing those into the four ratings provides further resolution for certain management questions or objectives. For example, when comparing different

road route options that must traverse an area of 'selected' habitat, potential impacts are expected to be minimized by locating the road in Moderate versus High habitat areas.

RSF frequency distributions were extremely right skewed so that very high RSF values were low in frequency. This issue arises when dealing with RSFs with 'infinitely weighted' available locations, which has become standard practice in recent years (e.g., Muff et al. 2020). In late fall and winter RSFs, the ratio of used to available locations was 1:10 with an additional large weight (i.e., 1,000) assigned to each available location. These large weights effectively reduce RSF predictions to very small decimal numbers and skews their distribution. To ensure that this skew did not underestimate the amount of High versus Moderate quality habitat, all RSF values equal to or greater than the 98th percentile were fixed at that value. Thus, there were effectively 49 quantile bins, in total, because all predictions in the 50th bin were assigned to the 49th bin.

To compare the amount and distribution of selected habitat within the Project RSA (~2,386 km^2) to the broader landscape, the amount of selected habitat was assessed within similar sized polygons across the seasonal ranges. A grid composed of 50 km x 50 km (2,500 km^2) cells was placed over the Yukon extent of the PCH ranges, and the proportion of selected habitat was assessed for each cell.

6.5.1.7 Statistical and Geospatial Software

All statistical analyses were completed in R software for Statistical Computing, version 4.1.0 (R Development Core Team 2020). Package 'mgcv' (Wood 2011) was used to develop and assess non-linearity in response-covariate relationships using generalized additive modelling. Package 'glmmTMB' (Brooks et al. 2017) was used to fit generalized mixed-effects models. In addition to visual assessment of covariate-response relationships, package 'DHARMa' (Hartig 2021) was used to assess simulated model residuals (e.g., goodness of fit, dispersion, outliers, heteroscedasticity). Package 'groupdata2' was used to partition data into training and testing datasets; it was especially useful for partitioning a consistent number of used and available locations among the data folds. All geospatial analyses were completed in R, version 4.1.0 (R Development Core Team 2020), QGIS (QGIS Development Team 2020), and ArcGIS, version 10.7 (ESRI 2020).

6.5.2 RESULTS AND DISCUSSION

6.5.2.1 Habitat Models

The selection of late fall and winter habitat models required an iterative model fitting, testing, and cross-validation process. The appropriate patch size (i.e., 100 m, 500 m, or 1,000 m) of each PFT was selected based on GAM plots to identify which patch size corresponded with the greatest change (slope) in selection. Initial model selection procedures determined that 'full' models, with all possible covariates, were the most parsimonious for late fall (No. 1 in Table 6-4) and winter (No. 1 in Table 6-5) RSFs. However, the 'full' model for late fall did not yield the best predictive performance based on the 5-fold cross-validation procedure. The best performing model for late fall excluded the effects of all PFTs except lichen (No. 3 in Table 6-4; Table 6-6), which yielded a better fit between observed and expected proportions across 10 quantile bins based on regression (i.e., higher R^2; intercepts closer to zero and slopes closer to one), tests of proportions

(i.e., greater number of equivalent observed/expected bins), and spearman rank correlations (i.e., larger correlation coefficients). See Section 5.6.1 for plots and summaries of 5-fold cross-validation results for the selected late fall RSF model. Regressions for each fold had very strong fits (all $R^2 > 0.93$) but did have intercepts that differed from zero and slopes that differed from one. The primary reason for this deviation was a greater number of observed proportions in the largest (10th) quantile bin, whereas all other bins were close to the line of unity (1:1 ratio). Spearman rank correlations were consistently very high (all $r > 0.98$ and $p < 0.001$). The mean number of bins in which observed proportions were no different than expected proportions, across all five folds, equalled 5.2 (low = 4, high = 8).

The best performing model for winter consisted of the full parameterization (No. 1 in Table 6-5; Table 6-7), which yielded a better fit between observed and expected proportions across 10 quantile bins based on regression (i.e., higher R^2; more intercepts closer to zero and slopes closer to one), tests of proportions (i.e., greater number of equivalent observed/expected bins), and spearman rank correlations (i.e., larger correlation coefficients) than any alternative candidate model. See Section 5.6.1 for plots and summaries of 5-fold cross-validation results for the selected winter RSF model. Regressions for each fold had strong fits (all $R^2 > 0.79$) and had intercepts that were no different than zero and slopes that were no different than one. Spearman rank correlations were consistently very high (all $r > 0.98$ and $p < 0.001$). The mean number of bins in which observed proportions were no different than expected proportions, across all five folds, equalled 5 (low = 3, high = 6). In conclusion, both late fall and winter model had a fair agreement between observed and expected proportions and had very high spearman rank correlations, which suggests that these models perform adequately for prediction (e.g., see Johnson and Russell 2014, White and Gregovich 2017, Johnson et al. 2020).

Habitat use varied moderately between late fall and winter. Although selection coefficients were highest for macrolichen cover and elevation in both seasons, the relationships varied somewhat, and the extent of Moderate and High rated habitat was reduced in winter compared to late fall. Selection (positive coefficient) for macrolichen cover, the most relevant plant functional type in either season, was greater in magnitude during winter (Table 6-7) than during late fall (Table 6-6). Though the magnitude of selection for macrolichen varied by ecoregion (i.e., interaction), the best-fitting patch size for the selection of macrolichen was consistently 100 m. However, patch size varied for other plant functional types considered during winter (Table 6-7; e.g., conifer tree cover versus forbs). During late fall, caribou selection (positive coefficients) of vegetation was solely driven by lichen cover. Meanwhile, during winter, caribou tended to avoid (negative coefficients) other PFTs such as conifer trees, forbs, graminoids, deciduous shrubs, and evergreen shrubs. The lack of selection/avoidance of other PFTs during late fall is likely the result of more diverse forage use in late fall than in winter and individual variation in habitat choice. Such variation is consistent with a broad habitat selection pattern at the population-level, which led to the poorer predictive performance of late fall models that included other PFT covers.

Preference of absolute elevation also varied between the seasons. Caribou occupied primarily mid elevations (approximately 750 m) during late fall (Table 6-6) but selected low and high elevations during winter (Table 6-7). Caribou also varied in their proximity to waterbodies >1 ha between seasons. Caribou tended to be closer to such waterbodies (negative coefficient) during late fall but remained farther (positive coefficient)

during winter. The ecological basis for these relationships to waterbodies is unclear, but the covariates were retained in the models because they improved predictive performance.

Coefficients associated with lichen cover were of the greatest magnitude, which suggests that the selection of lichen is the primary driver of habitat selection in late fall and winter. This pattern in vegetation use across both seasons is consistent with what is expected of PCH caribou diet and ecology (Thompson and McCourt 1981, Russell et al. 1993). Late fall and winter diets are mostly composed of lichens (and mosses). Though there is some evidence that caribou may forage on evergreen shrubs and deciduous shrubs during late fall (Russell et al. 1993), this pattern was weak, and these covariates were not included in the final model. Another similarity in selection among seasons was in terms of slope and aspect. Caribou avoided steep slopes (negative coefficients, logarithmic) and selected south- and west-facing aspects, which receive greater solar radiation than east- and north-facing aspects. This pattern could be attributed to productive lichen patches during both seasons and to decreased snow depth due to melt and wind during winter.i

Selection gradients (i.e., the degree of preference/avoidance) were greater during winter than late fall. This is likely because forage was more broadly available across different habitats due to lower snowpacks in late fall and because more locations in the late fall were likely associated with travelling than foraging. Though caribou distribution is broader in winter, there was clearly a stronger preference (positive coefficient) for light macrolichens and a stronger avoidance (negative coefficient) of areas with high cover of conifer trees. Stronger preference and avoidance in winter may result in more concentrated forage on lichen and from snow constraints on caribou distribution.

Temporal patterns of habitat selection also varied between late fall and winter. Habitat selection seemed to be fairly consistent across years in late fall but varied from winter to winter. A very small portion of the overall variance ($\sigma^2 = 0.00021$) in habitat selection could be explained by year effects during late fall. This model contributed little to the overall model likelihood and was penalized for an additional parameter ($AIC_\Delta = 2$); thus, year effects were not included for the late fall model. However, during winter, a year effect explained a sufficient amount of variation ($\sigma^2 = 0.013$) in habitat selection to warrant inclusion in the final model (i.e., $AIC_\Delta = -90.9$ with year effect). Variation among years was likely greater in winter due to the effects of snow across the landscape, which can broadly affect the distribution of PCH caribou and their foraging habits.

Snow accumulation and distribution is invariably an important factor affecting habitat selection by PCH caribou at multiple scales. At fine spatial scales, snow depth, density, and hardness can limit access to terrestrial lichens (Johnson et al. 2001). Although snow depth data were not available, elevation was considered as a suitable surrogate. In the winter RSF, caribou exhibited selection for low and high elevations and avoidance of mid elevations, where snowpacks are often deepest. Indeed, Pedersen et al. (2021) identified a significant correlation ($r > 0.6$) between elevation and snow depth in 33% of winters during their study of another barren-ground caribou herd, the Central Arctic Herd. The amount of snowfall and snowpack at broad spatial scales can cause the PCH to occupy different core wintering regions. For example, PCH caribou occupy the Ogilvie/Hart and Richardson Mountains regions on a rotational basis because these regions receive less snow than adjacent areas (Russell et al. 1993). This pattern is consistent with the current data, whereby GPS-collared PCH caribou occupied different ecoregions at different intensities (i.e., number of individuals and locations) across time.

Though snow depth could not be considered explicitly in habitat models, the variation estimated among years and differences in the use of ecoregions and elevations were considered to partially account for the influence of snow. These variables are considered coarse correlates of snowpack patterns across the landscape (Russell et al. 1993), yet, the exclusion of an explicit snowpack covariate does limit fine-scale predictions of how snow affects caribou resource selection. Ultimately, snow depth is probably the primary, ecologically relevant metric that would supplement the current covariate suite and provide greater insight on winter selection patterns. Available snow covariates were examined and deemed not to be useful. For example, information on snow prevalence, date of the first snow, or snow cover are not inherently useful because caribou (and other ungulates) are not constrained in their movements and foraging by shallow snow. Given these considerations, it was deemed more appropriate to account for the coarser effects of snow depth using ecoregion and elevation rather than using a snow cover that may be misleading both ecologically and mechanistically, resulting in a spurious correlation.

6.5.2.2 Predicted Habitat Distribution

Predicted habitat quality, amount, and distribution depended on the magnitude of resource selection and the distribution of habitat covariates across the landscape (i.e., primarily light macrolichen cover). Predictions from habitat models for late fall and winter were classified into four ordinal habitat quality ratings (i.e., Very Low, Low, Moderate, or High quality). See Section 6.9.2 for plots that demonstrate the switch from negative to positive selection ratios across quantile (two-percentile) bins for late fall (31st quantile bin [60th–62nd percentile]; Attachment Figure 11 and Attachment Figure 12) and winter (30th quantile bin [58th–60th percentile]; Attachment Figure 15 and Attachment Figure 16). Furthermore, Section 6.9.2 provides plots of (a) selection ratios associated with each habitat rating and (b) the proportion of the late fall and winter ranges composed of each habitat rating. In general, Very Low quality habitat had low, negative selection ratios while High quality habitat had high, positive selection ratios. Approximately 60% of the late fall and winter ranges consisted of avoided (Very Low and Low) habitat, and 40% consisted of selected (Moderate and High) habitat.

The distribution of habitat across the landscape differed between late fall (Map 6-4) and winter (Map 6-5) ranges. The proportion of selected late fall habitat in the Project RSA (0.404) was equivalent to the mean proportion in the broader late fall range when accounting for variance in that estimate (Table 6-8). In contrast, the proportion of selected winter habitat in the Project RSA (0.265) was substantially less than the mean proportion in the broader winter range (0.411) (Table 6-8). Though mean estimates of selected habitat in the broader late fall and winter ranges were approximately 0.40, there was considerable variation among the 50 km x 50 km cells used in the analyses. In the late fall range, the lowest and highest proportions of selected habitat were 0.140 and 0.881, respectively. Cells with the lowest proportions were located mostly along the western edge of the late fall range (i.e., high elevations in the North Ogilvie Mountains), and cells with the highest proportions were located mostly along the eastern edge of the late fall range (i.e., Eagle Plains ecoregion transitioning into Richardson Mountains). The lowest and highest proportions of selected habitat in the winter range were 0.106 and 0.764, respectively. Cells with the lowest proportions were located centrally in the winter range (i.e., Eagle Plains ecoregion) and cells with the highest proportions were located mostly along the eastern and southern edge of the winter range (i.e., Richardson mountains and North Ogilvie Mountains).

In the Project RSA, selected late fall habitat was concentrated at mid-elevation plateaus and depended on the amount of lichen cover. For example, a large patch of High quality habitat occurred adjacent (south side) to the Dempster Highway (inset in Map 6-4); this patch occurred on a large mid-elevation plateau, in proximity to waterbodies >1 ha in size, and relatively high amounts of lichen cover. In fact, several portions of the Dempster Highway intersected either Moderate or High quality habitat at mid-elevations and with moderate lichen cover. Across the broader landscape, the greatest amount of selected habitat occurred within the southern extent of the North Ogilvie Mountains ecoregion, the western extent of the British-Richardson Mountains ecoregion, and in large areas at the eastern extent of the Eagle Plains ecoregion (Map 6-4). Avoided habitat primarily occurred at low elevation valley bottoms or high elevations (> 750 m, e.g., at the peaks of British-Richardson Mountains) in areas with low lichen and vegetative cover.

Winter habitat occurred primarily at either valley bottoms with open stunted spruce or high elevations with sparse tree cover and high macrolichen cover. Selected habitat was also distant from large waterbodies and

wet environments containing forbs and graminoids, as well as areas with high cover of deciduous or evergreen shrub. In the RSA, selected habitat was localized in specific regions. For example, a large extent of High quality habitat occurred at the northern extent of the RSA, on the west side of Chance creek (Map 6-5). This area is low in elevation and has relatively high lichen cover. Two other large patches of High quality habitat occur at the southern extent of the RSA, both associated with low elevation and very high lichen cover. Although mid-elevations have relatively lower RSF predictions, in general, certain mid-elevation areas with high lichen cover, such as the areas along the Dempster Highway for late fall habitat are also predicted to offer Moderate or High quality winter habitat (inset in Map 6-4). Across the broader landscape, large extents of selected habitat occurred in the Richardson Mountains, the Ogilvie Mountains, and northern extents of Eagle Plains ecoregion. The greatest amount of avoided habitat (Very Low and Low) also occurred in Eagle Plains due to large areas of recent wildfire and its vast mid-elevation plateaus.

The use of multiple habitat ratings, as opposed to a binary classification (e.g., suitable versus unsuitable), was necessary to retain high resolution information on the distribution of habitat quality. For example, there were stark differences in the amount of lichen cover in areas of Moderate versus High quality habitat, and this can have implications for timing and extent of Project operations. Map 6-6 provides a comparison between winter habitat quality ratings and macrolichen cover in the Project RSA. There is a clear distinction between areas of high versus low macrolichen cover. There are several High quality ratings that occur along circular and N-S oriented ridges at the southwest corner of the RSA. Adjacent areas of similar elevation but with low macrolichen cover, transition from Moderate to Very Low in quality. Since macrolichen cover is the strongest driver of resource selection by PCH caribou during winter, it is important to be able to distinguish these high-value regions for management purposes.

Table 6-8. Proportion of selected (Moderate and High) caribou habitat in the Project RSA relative to the mean (and std. error) of 50 km x 50 km cells covering late fall and winter range extents.

Season	Scale	Proportion of Moderate and High Quality Habitat	Std. Error
Late Fall	Project RSA (2,387 km² total)	0.404	–
	Late Fall Range (88,149 km²) [1] (2,500 km² per cell) – 53 cells total	0.415	± 0.025
Winter	Project RSA (2,387 km² total)	0.265	–
	Winter Range (65,077 km²) [1] (2,500 km² per cell) – 40 cells total	0.411	± 0.026

[1] Late fall and winter ranges were subsampled using 2,500 km² cells (approximately the same size and the RSA) to facilitate estimation of mean and variance.

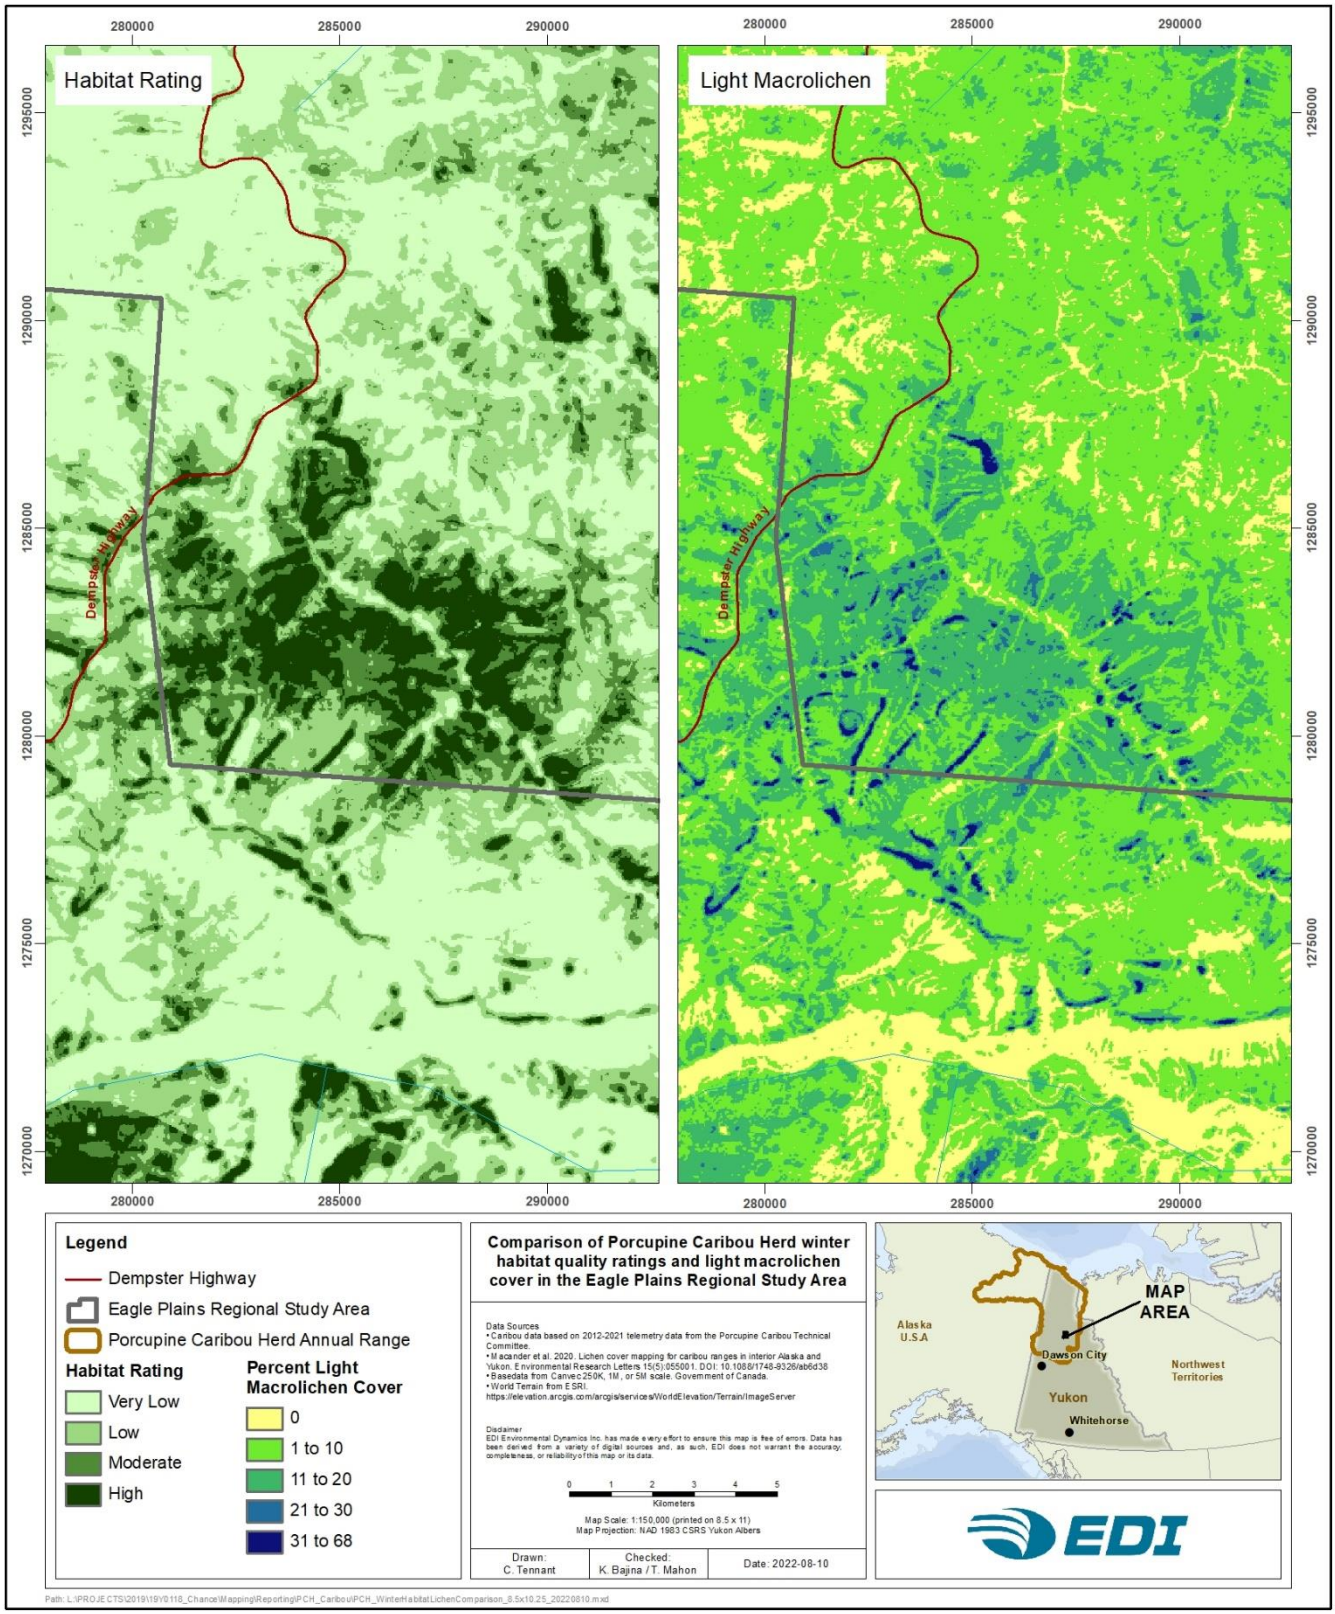


Map 6-6. Comparison of Porcupine Caribou Herd winter habitat quality ratings and light macrolichen cover in the Eagle Plains Regional Study Area.

6.6 MOVEMENT

In addition to habitat selection, movement patterns across the seasonal ranges and within the vicinity of the Project RSA are important to understanding how the PCH may interact with the Project. Metrics such as daily travel rates and duration of residency (i.e., how long caribou spend in an area before moving on) help quantify how caribou use the landscape and how they may react to features, such as the Dempster Highway. In addition to movement metrics, the spatial locations of travel movements can define areas of concentrated movement during migration. To better understand factors affecting PCH caribou movement, two analyses were conducted: (1) calculation of daily movement rates and residency times of caribou in the Project RSA relative to the broader landscape, and (2) delineation of movement paths to assess broad-scale movement patterns and the potential for caribou to interact with the Project.

The PCH typically exhibit movements of several kilometres per day in both late fall and winter. Late fall daily movements (8.7 km/day in the RSA) were substantially greater than those during winter (4.4 km/day in the RSA), and caribou tended to occupy portions of the landscape for shorter periods during late fall than during winter. Caribou residency times in both seasons were two-fold greater in the broader landscape than within the Project RSA, suggesting that, on average, the RSA, is used as more of a transitory area than other portions of the seasonal ranges. The locations and patterns of movement during late fall (i.e., the end of the fall migration period) was variable within and across years and, overall, there was little evidence of dedicated migration corridors. However, in late fall of 2015, several caribou made directed movements along the height of land parallel to the Dempster Highway, from the northeast to the southwest. Although a small number of movements crossed the Dempster Highway, most movements stayed north of the Dempster Highway, potentially reflecting avoidance of the Dempster Highway. However, this series of movements did cross numerous 2D seismic lines, winter roads and a large 3D seismic grid in the RSA.

6.6.1 METHODS

6.6.1.1 Daily Movement Rates and Residency Times

Daily movement rates and residency times were calculated for each radio-collared caribou that occurred in late fall and winter range extents. The locations of each caribou were resampled to obtain one GPS fix per day. Movement rates were calculated as the speed (km/day) travelled between consecutive relocations and residency time was calculated as the number of days within a specified area. Movement rates and residency times were calculated for caribou occurring within the Project RSA (2,387 km^2) and, to compare to the broader landscape, metrics were also calculated within 50 km x 50 km (2,500 km^2) grid cells that covered fall and winter ranges. Means and standard errors of movement rates and residency times were calculated for all 50 km x 50 km cells and compared to mean values in the Project RSA.

6.6.1.2 Migration Movements

Travel routes were delineated by developing occurrence-use polygons that assessed the trajectory of each collared caribou during late fall, 2012-2021. These polygons were created using Brownian bridge movement models (BBMMs), which account for autocorrelated movements in animal relocations and assume that an animal's trajectory follows a diffusion-based (Brownian motion) process (Horne et al. 2007). BBMMs were developed, and kernel density estimation was used to predict 95% utilization distributions (UDs) for each animal, assuming a GPS location error of 100 m and implementing a grid-cell size of 500 m. Analysis was bounded to a 100 km buffer around the RSA to identify spatially relevant movement trajectories. BBMMs and UD polygons were created using the R package 'adehabitatHR' (Calenge 2006).

6.6.2 RESULTS AND DISCUSSION

6.6.2.1 Daily Movement Rates and Residency Times

Mean daily movement rates and residency times varied considerably between late fall and winter and between the Project RSA and the broader landscape. On average, caribou tended to move faster during late fall than during winter, and this was evident both in the Project RSA and across the full late fall range. The movement rates between the Project RSA and the broader landscape were greatest during late fall, i.e., at least a two-fold difference in movement rates outside versus inside the RSA. A similar outcome was evident for residency time inside versus outside the Project RSA. In both seasons, the residency time was at least twice as long outside the RSA than within it (Table 6-9).

Patterns in movement and residency were consistent with what is known about PCH caribou ecology. Caribou are at their most dispersed in both late fall and winter. Except for cows during the calving period, daily movements are lowest in winter and second lowest in late fall (Russell and Gunn 2017). Normally, faster movement rates are associated with shorter residency periods, but this was not the case for the PCH in late fall (Table 6-9). During late fall, caribou in the RSA had slower movement rates but also had shorter residency periods compared to the broader late fall range. A review of the movement trajectories indicates that although travel rates were slower inside the RSA, those paths had greater directional bias (i.e., movement in a single direction) than paths outside the RSA, which exhibited much more tortuosity. These more directed movement paths resulted in shorter residency periods, despite the slower movement rates.

During winter, caribou movement rates inside the RSA were similar to the broader landscape, but, similar to late fall, their residency time inside the RSA was significantly shorter than in the broader late fall range. This suggests that similar to the pattern in late fall, caribou tended to pass through the RSA in winter more quickly than other portions of the broader winter range. This pattern may be explained by the lower predicted habitat quality within the RSA relative to the broader landscape (see Section 6.5.2.2, *Predicted Habitat Distribution*, above). The faster movements and shorter residency times in late fall compared to winter likely reflect the tail end of fall migration movements. Notwithstanding the important differences in movement patterns between late fall and winter, the key results of these analyses are that, in both late fall and winter, PCH caribou (1) travel

several kilometres per day, on average, and (2) the RSA (or similar sized areas outside the RSA) are used for a relatively short portion of the overall season.

Table 6-9. Mean daily movement rates and residency times of the Porcupine Caribou Herd in the Project RSA relative to the mean (and standard error) of 50 km x 50 km cells covering late fall and winter range extents.

Season	Scale[1]	Daily Movement (km/day)		Residency Time (days) [2]	
		Mean	Std. Error	Mean	Std. Error
Late Fall	Project RSA (2,387 km² total)	8.95	± 0.64	4.50 (8.33 %)	± 0.83
	Late Fall Range (88,149 km²) [1] (2,500 km² per cell) – 53 cells total	15.03	± 2.06	7.65 (14.17 %)	± 0.66
Winter	Project RSA (2,387 km² total)	4.02	± 0.64	15.69 (12.86 %)	± 5.11
	Winter Range (65,077 km²) [1] (2,500 km² per cell) – 40 cells total	4.77	± 0.51	25.93 (21.25 %)	± 2.13

[1] Late fall and winter ranges were subsampled using 2,500 km² cells (approximately the same size and the RSA) to facilitate estimation of mean and variance. Estimates of mean and variance within the RSA are derived from differences in rates and residencies of individual caribou.

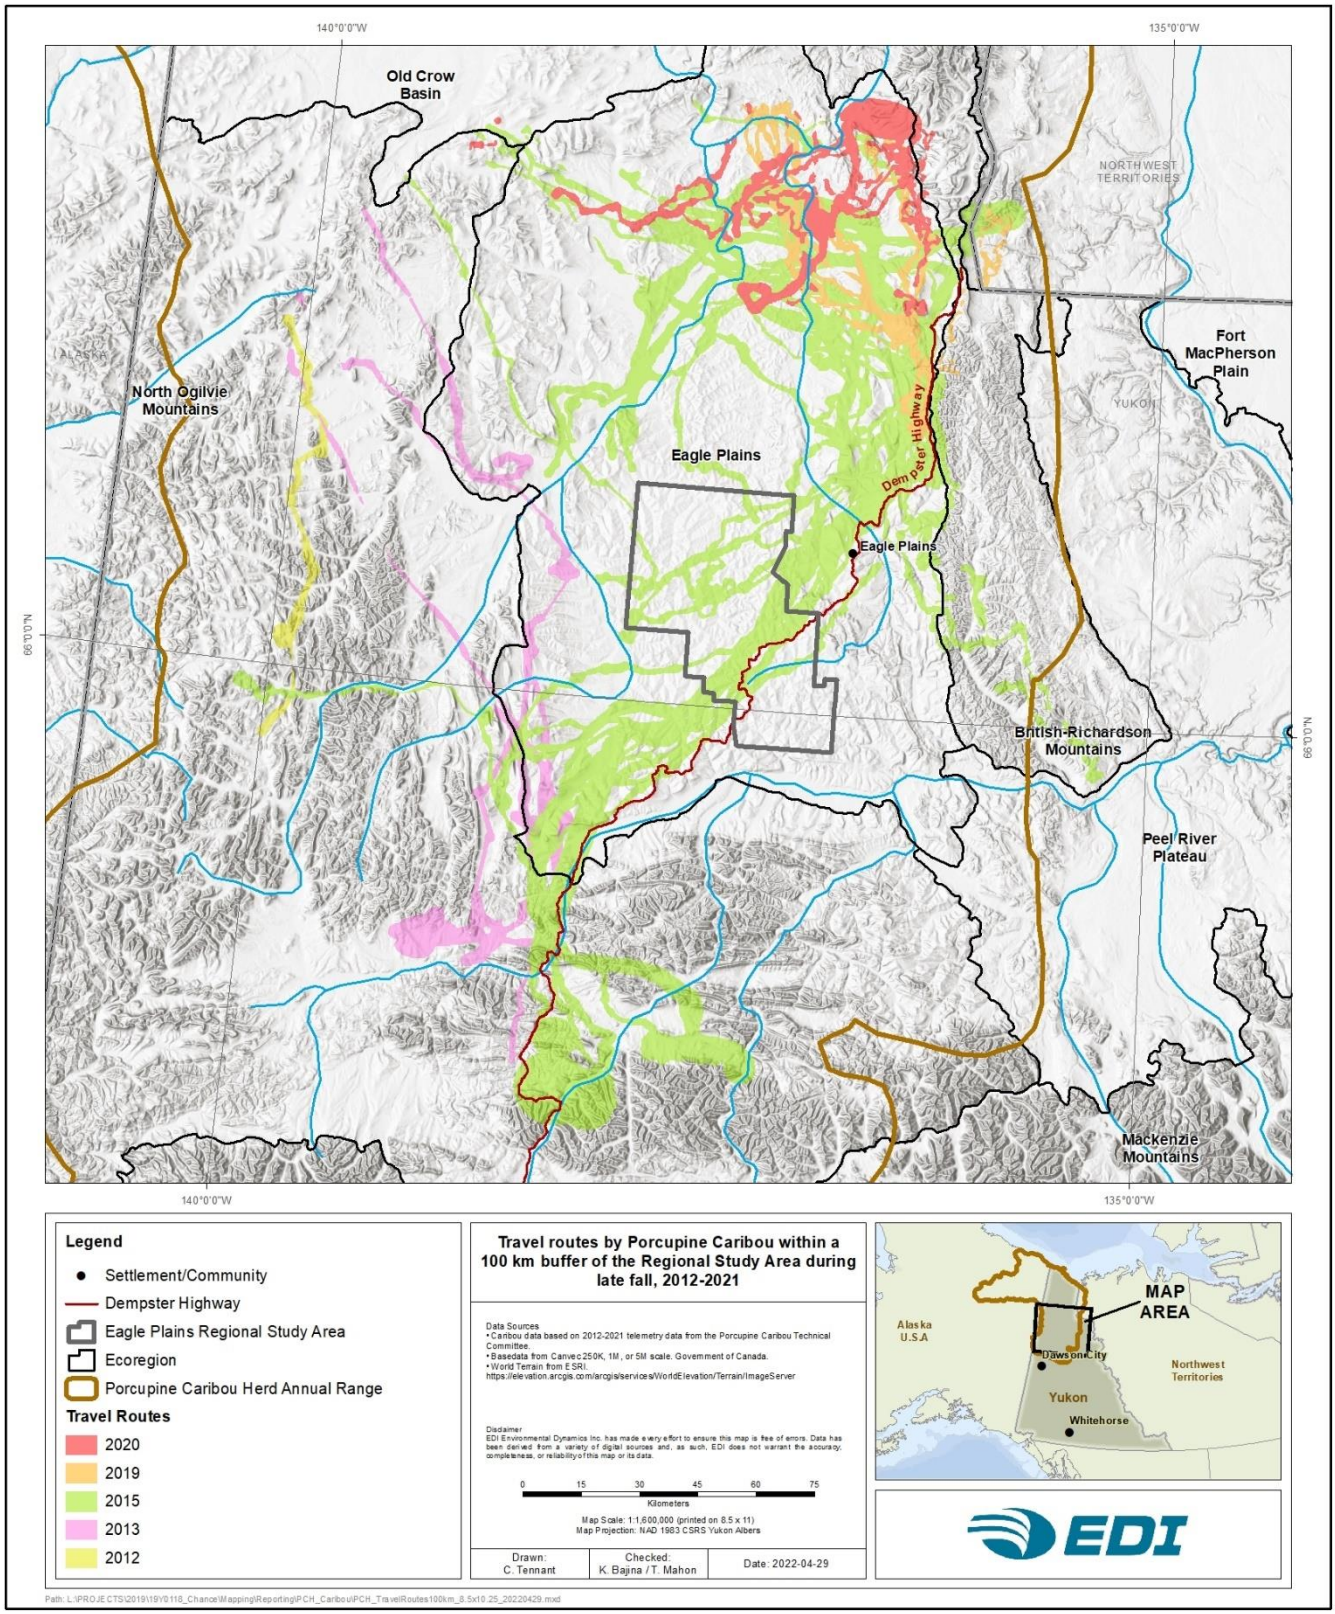
[2] Percent of the season indicated in brackets. Total days: late fall = 54 days, winter = 122 days.

6.6.2.2 Migration Movements

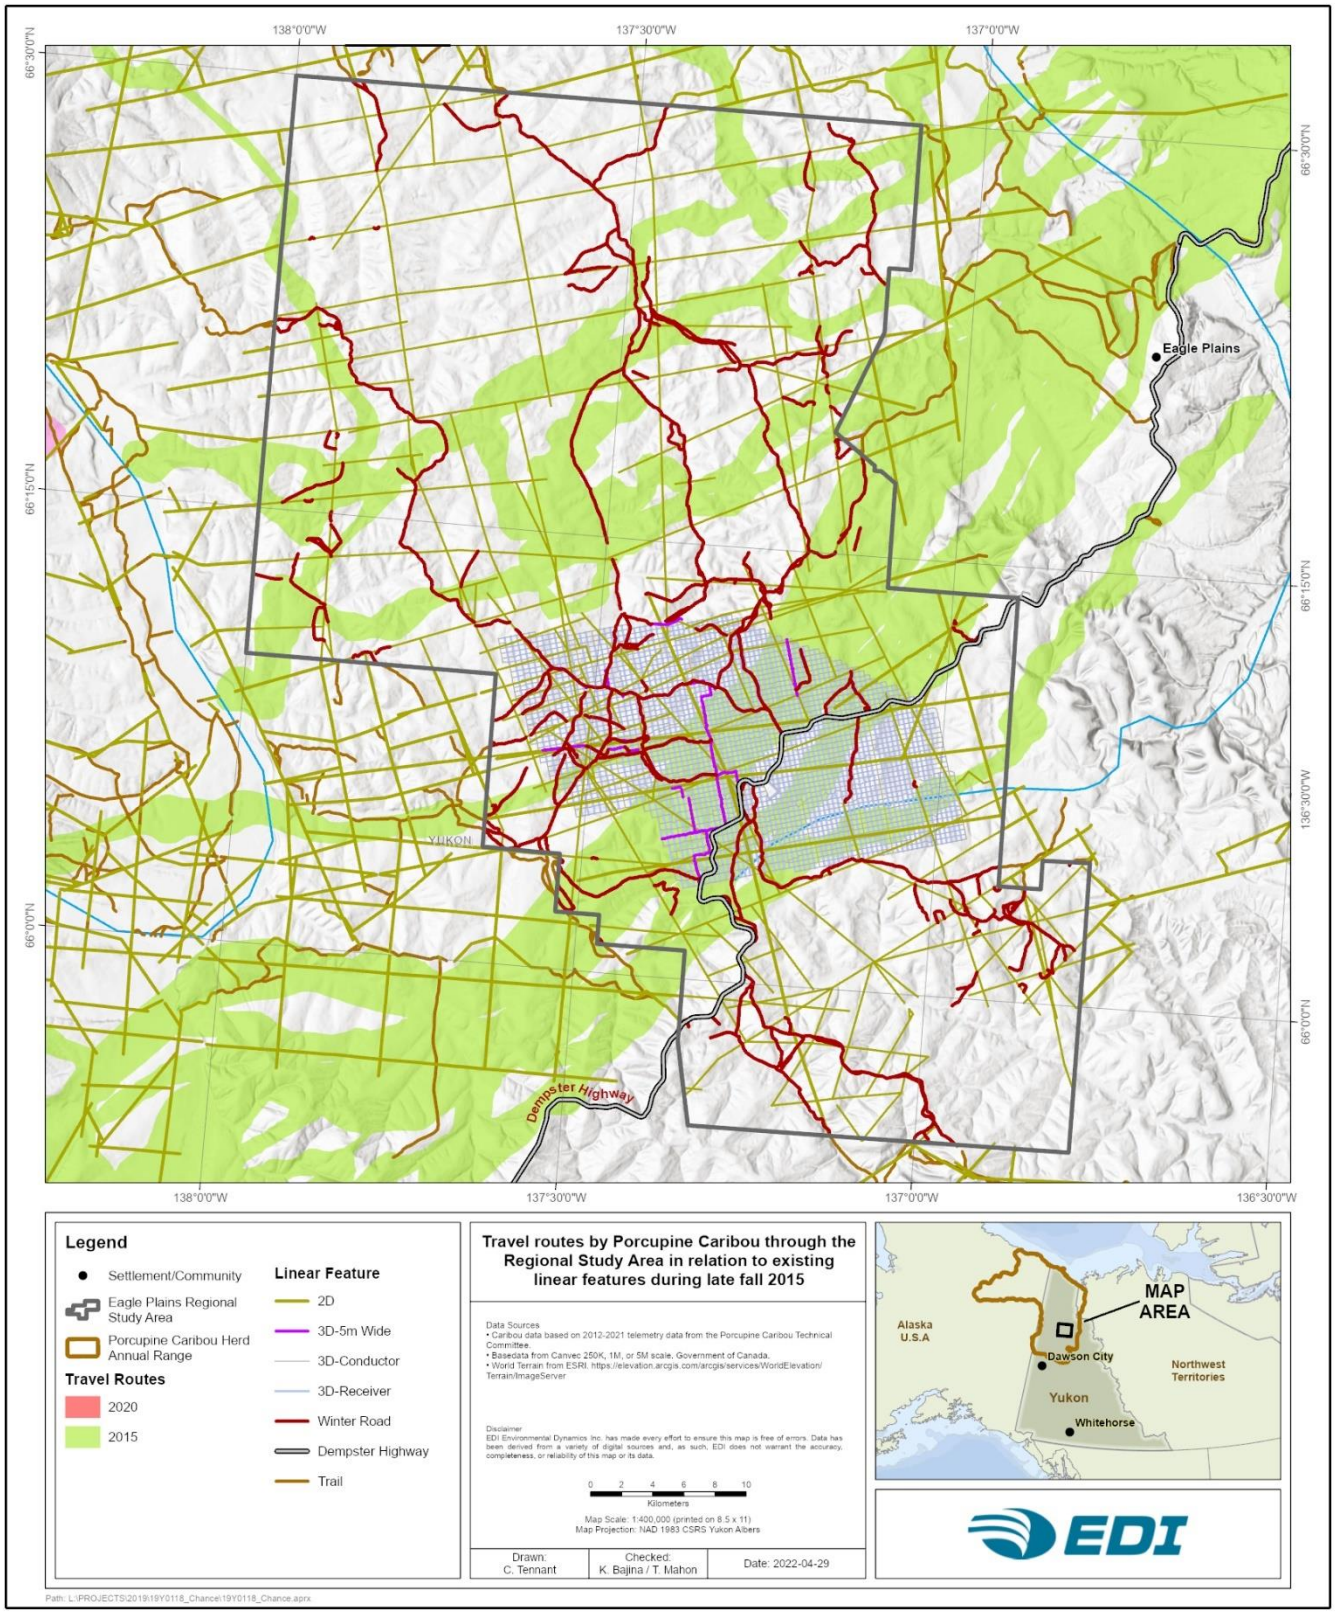
Travel routes through the Project RSA were only evident in late fall of 2015. At that time, 14 caribou travelled from the northeast quadrant of the Eagle Plains ecoregion to either the southwestern portions of that ecoregion or to the North Ogilvie Mountains, along the Dempster Highway (Map 6-7). Although two caribou did cross the highway in the vicinity of the RSA, most of the caribou (12) travelled parallel to the Dempster Highway, along its northwest side, before eventually crossing the highway south of the RSA in the Ogilvie Mountains (Map 6-7). The location of the movement routes in 2015 predominantly northwest of the Dempster Highway was previously noted by Russell and Gunn (2017), who suggested the caribou may have been avoiding crossing the highway. Although this is a valid hypothesis, supported by observations from VGFN elders (Sherry and Vuntut Gwitchin First Nation 1999, p. 288), it is important to note that the set of travel routes in 2015 did eventually cross the Dempster Highway south of the RSA in the Ogilvie Mountains. These crossings may be done at times of lower traffic such as nighttime, as elders had witnessed various unsuccessful attempts of herds to cross the Dempster as vehicles were passing during the day (Sherry and Vuntut Gwitchin First Nation 1999, p. 288). It is also important to note that travel routes in 2015 coincided with a broad, regional height of land (separating the Porcupine and Peel watersheds), which caribou sometimes travel on during migration movements (Russell et al. 1993). On an absolute scale, the height of land along the Dempster Highway, and proximate locations used by caribou as travel routes (~550–650 m), coincide with the mid elevations selected by caribou during fall (see Section 6.5.2.1, *Habitat Models*). The 12 caribou that

paralleled the Dempster Highway in the vicinity of the RSA did cross several inactive winter roads, numerous old 2D seismic lines, and a 350 km² area consisting of one-year-old 3D seismic exploration (Map 6-8).

Inferences about caribou movements are limited by the relatively small numbers of caribou that were collared (<0.1% of the herd annually) and the relatively small number of collared caribou that occurred within the RSA. Collared caribou only occurred in the Eagle Plains ecoregion in half of the years from 2012–2021; however, it is known from local knowledge that caribou occur in the ecoregion in most, if not all years. VGFN elders have discussed to importance of Eagle Plains for caribou winter habitat and noted that if caribou find a good feeding place with many trees, they will stay all winter (VGFN p185). During interviews in the late 1990's, they observed many caribou performing fighting, mating and rutting rituals around Blackstone Flats (Sherry and Vuntut Gwitchin First Nation 1999, p. 188). For the years when collared caribou were present in Eagle Plains, it is unknown how representative the collar locations are of the overall herd. For example, the concentration of travel routes through the RSA in 2015 suggests a potential movement corridor, but the proportion of caribou that is collared is too small to conclude this with confidence. The lack of movements in the same area in any other year does not support the idea that the cluster of movements in 2015 represent a regular travel corridor (but, again, this could reflect the small proportion of caribou collared).



Map 6-7. Travel routes identified for the Porcupine Caribou Herd within a 100 km buffer of the Project Regional Study Area during late fall, 2012–2021.



Map 6-8. Travel routes by Porcupine Caribou through the regional Study Area in relation to existing liner features during late fall 2015.

6.7 RELATIONSHIP TO LINEAR FEATURES

A key issue concerning the PCH is how anthropogenic development may alter caribou distribution, habitat use, and, ultimately, whether changes may influence population demography and access to the herd by First Nations and Inuvialuit harvesters. Linear features are the primary source of disturbance in the Project RSA and the broader Eagle Plains ecoregion. There is uncertainty about how caribou may respond to these features. To better understand the relationship between caribou and linear features, base habitat models were extended to assess the potential for habitat avoidance using a zone of influence (ZOI) framework. The ZOI delineates the area within which caribou behaviour is altered. ZOIs were estimated for three functionally distinct linear feature types (i.e., 2D seismic, winter roads and trails; 3D seismic; and the Dempster Highway). If ZOI estimates are statistically and ecologically significant (i.e., alter the selection of habitat and forage by caribou), they can be used to quantify effective habitat loss (i.e., perceived reduction in habitat quality by caribou due to avoidance) in the Project RSA and Eagle Plains ecoregion.

Statistical ZOIs were determined for 2D seismic lines (including winter roads and trails) in Eagle Plains in late fall and winter. However, confidence in those estimates is relatively low due to several factors. Statistical ZOIs were identified corresponding to 4 km avoidance of 2D seismic lines during late fall and 2 km avoidance of 2D seismic lines during winter. The analysis also identified that the PCH were attracted to the Dempster Highway and 3D seismic areas in both late fall and winter. Sufficient observations were associated with this pattern in relation to the Dempster Highway, but results for 3D seismic areas could be spurious due to a relatively low number of caribou locations in proximity to these features.

Although the analyses determined ZOIs associated with 2D seismic lines (and winter roads and trails), they should be interpreted with caution. (1) The magnitude of the ZOI effects was weak (i.e., including the ZOI effects in the habitat models had little effects on the habitat predictions). (2) Threshold distances estimated from ZOI analyses tend to be very sensitive to spatial and temporal contexts as well as the data and analytical methods used. Estimates of ZOIs can vary dramatically from year-to-year. This can include selecting to be closer to human features in some years and exhibiting dramatic difference in the threshold distances in years when human disturbances are thought to be avoided. The number of caribou locations in this study unevenly distributed with respect to the various linear features both spatially and across years. (3) The pattern of ZOI effects were not consistent with expectations and results from other studies. For example, having a 2 km ZOI for 2D lines and no ZOI for the Dempster Highway is counterintuitive. A previous study estimated a relatively large ZOIs for the Dempster (Johnson and Russell 2014). Based on these factors, it is recommended that these results not be used solely to estimate the effects of linear features on the PCH. Rather, it is recommended that the results be used in conjunction with results from other studies, adapted to the Eagle Plains setting and the ecology of the PCH, to develop a set of ZOIs for assessment and management purposes.

6.7.1 METHODS

A zone of influence framework evaluated the influence of linear features on PCH caribou distribution and habitat selection. Base habitat models developed for late fall and winter were extended by incorporating a 'distance to' covariate for each relevant linear feature and estimating the breakpoint beyond which the likelihood of observing caribou remained unchanged. If a ZOI was present, the likelihood of observing caribou would increase from linear feature footprint until the identified breakpoint. The primary method used to evaluate the presence and magnitude of a ZOI was a segmented regression approach (Boulanger et al. 2012, 2021).

Three functionally distinct types of linear features were considered based on their widths, densities, and extents in PCH fall and winter ranges: (1) 2D seismic, winter roads, and trails; (2) 3D seismic (grid); and (3) the Dempster Highway. The minimum distance between used/available locations and each feature was calculated and treated as a continuous covariate. To limit potential bias in ZOI estimates arising from broad-scale spatial patterns in distribution and habitat selection (see Boulanger et al. 2021, EDI Environmental Dynamics Inc. 2022b), GAMs were used to assess how the distribution of caribou changed at increasing distances from each linear feature type and to identify an 'iteration zone' to test for ZOIs. The iteration zone is defined as the boundary within which caribou distribution and habitat use are minimally affected by broad-scale patterns in climatic (e.g., snowfall) and biotic (e.g., caribou density and forage) processes. Practically, this refers to an initial range of distances (starting at 0 km) where selection is relatively flat (slope = 0) (see Boulanger et al. 2021). For example, during late fall, selection was fairly flat up to 100 km from the Dempster Highway, after which selection decreased sharply (see Attachment Figure 21 in Section 6.9.3). In other cases, such as the relationship to 2D lines during late fall, the slope was substantially greater than zero at very close distances (see Attachment Figure 19 in Section 6.9.3). Selection increased up until approximately 18 km, then sharply decreased until 25 km, and then, once again, sharply increased up until approximately 35 km. Given such non-linearity in the response, the iteration zone was identified within the first major bout of increase/decrease, i.e., within the first 25 km. This approach was taken in each case where a drastic, non-linear selection gradient occurred at very close distances to the linear feature.

Within the iteration zone, several distance thresholds were tested to identify a ZOI. The assumptions were that caribou presence would be reduced and resource selection altered within the threshold distance. We assigned all distances at or beyond the defined threshold the same distance value. For example, if a ZOI distance of 2 km was tested, then all distances up to 2 km retained their values (i.e., numbers ranging from 0 km to 1.99 km), but all distances at or greater than the ZOI were assigned a value of 2 km (e.g., 3 km or 4 km were assigned values of 2 km). A unique model was fit for each threshold tested, and the number of models corresponded to the outer boundary of the iteration zone identified for each linear feature type. In other words, if the iteration zone was deemed between 0 km and 25 km, then 25 models were tested — one for each kilometre interval. The best model, which corresponded with the most likely ZOI, was selected by evaluating the log-likelihoods of all models as a function of the distance thresholds. The highest log-likelihood corresponded with the model with the most statistical support (Boulanger et al. 2012). The magnitude of avoidance was estimated as the odds of caribou occurring at or beyond the ZOI relative to the odds of being on the linear feature (i.e., odds ratio = $e^{coefficient \times ZOI}$).

6.7.2 RESULTS AND DISCUSSION

The influence of linear features on PCH distribution and habitat selection varied between late fall and winter seasons and among functional linear feature types. ZOIs were detected for 2D seismic lines (including winter roads and trails) during late fall (4 km, Attachment Figure 25) and winter (2 km, Attachment Figure 28). These results were derived from analyses that considered only spatially relevant scales (i.e., iteration zones) (see GAM plots for 2D lines in Section 6.9.3). For example, relationships with 2D lines were evaluated only within the Eagle Plains ecoregion because most of these features occurred within this extent. The GAM plots in Section 6.9.3 also demonstrate that, though selection increased/decreased relative to 2D lines, these changes were low in magnitude. For example, within the iteration zones of 2D lines, there was an approximate 0.08 (or 8 %) increase in the probability of selection at far distances from these features. When estimated using a defined threshold, changes in the probability of selection necessarily increased (relative to GAMs) based on the imposed shape of the response (i.e., fitting a linear increase followed by a flat slope at distances equal to and beyond the ZOI). In practical terms, the odds of caribou occurring at distances equal to or beyond the ZOIs for 2D lines are 1.45 (odds ratio = $e^{0.000093 \times 4\ km}$) and 1.27 (odds ratio = $e^{0.00012 \times 2\ km}$) times greater, during late fall and winter, respectively, than the odds of caribou occurring on 2D lines. The ZOIs estimated for 2D lines in the current study were smaller than those previously estimated by Johnson and Russell (2014)—11 km from 1985–1998 and 6 km from 1999–2012 for wells, trails, winter roads, and seismic lines.

Although analysis of 2D seismic lines (including winter roads and trails) did identify statistically significant ZOIs, the results should be interpreted with caution. An important indicator to contextualize these results is whether estimated ZOIs influenced the selection of important habitat components. A comparison of coefficients between habitat models with and without ZOI terms provides a test of the ecological significance of estimated ZOIs (Boulanger et al. 2012). To accomplish this, predictions were made using the estimated ZOIs across the late fall and winter ranges to match the same spatial scale as base habitat models (see Table 6-10 and Table 6-11). During late fall, coefficients associated with macrolichen cover ($\beta_{lichen.base}$ = 0.694 ± 0.029 versus $\beta_{lichen.ZOI}$ = 0.689 ± 0.029) in Eagle Plains were invariant (Table 6-4 versus Table 6-10). Similarly, during winter, coefficients associated with lichen ($\beta_{lichen.base}$ = 1.119 ± 0.018 versus $\beta_{lichen.ZOI}$ = 1.114 ± 0.018) in Eagle Plains, and avoidance of other plant functional types, were consistent (Table 6-5 versus Table 6-11). So, even though ZOIs were determined for 2D lines, the magnitude of those effects was so small that it resulted in marginal changes to the habitat model predictions in both late fall and winter.

No ZOIs were detected for the Dempster Highway during either season. Instead, the segmented regression approach identified an attraction effect, rather than avoidance, for both late fall (9 km, Attachment Figure 27) and winter (11 km, Attachment Figure 30). Thus, caribou were more likely to occur within 9 km and 11 km of the Dempster Highway during late fall and winter, respectively, than beyond those distances. This result contradicts previous work by Johnson and Russell (2014), who identified ZOIs of major roads, including the Dempster Highway, to be as large as 30 km from 1985–1998 and 18.5 km during 1999–2012.

Similar to the results for the Dempster Highway, no ZOIs were determined for 3D seismic lines, but there is high uncertainty associated with those estimates due to the relatively small number of collared caribou that

interacted with the 3D seismic area. Attraction effects were found within 16 km and 4 km of 3D seismic lines during late fall (Attachment Figure 26) and winter (Attachment Figure 29), respectively. As with 2D lines, the magnitude of the attraction effect for Dempster Highway and 3D seismic lines was small relative to base habitat selection. Additionally, considering the potential mechanisms of effects that 3D lines could have on caribou, the apparent attraction of caribou to the 3D seismic lines is likely a spurious result. Based on other studies examining the effects of 3D lines on caribou and their primary predators, wolves, it was expected that the PCH would exhibit a neutral or weak avoidance response to 3D lines due to the potential for facilitated predation to occur.

In addition to the weak effects exhibited by ZOIs relative to base habitat selection, there are other factors that warrant cautious interpretation and use of these analytic results. (1) ZOI estimates and their magnitude of effect can be sensitive to (a) sample sizes and (b) spatial and temporal coverage of the data. Though numerous overall, the data used in this analysis had relatively modest sample sizes near linear features and were unevenly distributed in relation to linear features in Eagle Plains. (2) Caribou can exhibit dramatically different ZOIs from year to year. Collared caribou were only present in modest numbers in 2012/13, 2014/15, 2017/18, and 2018/19, so the data had to be lumped across years to estimate a single ZOI. (3) ZOIs estimated for the PCH in this analysis are substantially smaller than those estimated by Johnson and Russell (2014). The issues associated with these factors are discussed below.

The spatial and temporal context of ZOI studies can influence outcomes. Estimates of ZOIs are a consequence of broad- and fine-scaled space use, and these patterns of distribution can emerge from population demography, biotic interactions (e.g., density-dependent competition or predator-prey interactions), abiotic conditions (e.g., snowfall, forage availability), habitat selection, and potential sources of disturbance (e.g., dust fall, sensory disturbance) (Messier et al. 1988, Johnson et al. 2001, Mahoney and Schaefer 2002, Hinkes et al. 2005, Bowyer et al. 2014, Chen et al. 2017, Boulanger et al. 2021, Pedersen et al. 2021). These sources of variation in space use do not negate the importance of quantifying indirect effects of anthropogenic development, but they do point to underlying issues with the ZOI framework and its utility for management and mitigation. For example, Boulanger et al. (2021) documented ZOI responses by Bathurst caribou to the Ekati-Diavik mine complex (Northwest Territories) that have varied dramatically from year-to-year, which the authors attribute to changes in drought conditions. Similarly, Johnson et al. (2020) found that ZOIs around energy infrastructure (North Slope of Alaska, USA) reduced during periods of high mosquito activity for the Central Arctic Herd (CAH). In these examples, fine-scale changes in caribou space use was primarily driven by selection for areas adjacent to large, open bodies of water: Lac de Gras by Bathurst caribou and the Arctic Ocean by CAH caribou.

Another issue regarding the interpretation of ZOIs is their sensitivity to the data and analytical methods used. For example, Boulanger et al. (2021) found that GPS-collared caribou exhibited 'avoidance' (a ZOI) in only four out of nine years at the Ekati-Diavik mine complex (range = 6–13 km). In five of those nine years, caribou exhibited either no relationship or attraction to mine infrastructure. Additionally, when comparing an overlapping year (2012) between GPS data and aerial survey data for Bathurst caribou, a ZOI was identified using GPS collar data (ZOI = 7.09 km, odds ratio not overlapping zero; see Table 3 in publication) but was not identified using aerial survey data (ZOI = 11.4 km, odds ratio overlapping zero; see Table 4 in

publication). During the data exploration phase of the current study, ZOI results also varied considerably based on different subsets of the PCH data. For example, the estimates of a ZOI around 2D seismic lines (including winter roads and trails) changed by several kilometres when assessing not only different years but different spatial extents (e.g., ecoregions).

The ZOI analysis conducted by Johnson and Russell (2014) for the PCH used a similar approach to the current analysis and other studies, but yielded very different results for seismic lines and major roads. Johnson and Russell (2014) also caution against interpreting their results based on several factors, including a large change in the PCH's population size over their study duration, variation in animal behaviour across the range of development types, and relatively small effect sizes for caribou-disturbance responses. The potential reason for differences between the results in this study and those of Johnson and Russell (2014) are not apparent and may reflect the sensitivity of results to the differences in sample sizes and spatiotemporal patterns in the data used between the two studies. Landscape conditions and land use activities were similar between the two study periods and likely included some of the same data (e.g., winter 2012). Both Johnson and Russell (2014) and the current study dealt with trade-offs in spatial and temporal coverage. Though Johnson and Russell (2014) had data with longer temporal coverage (27 years), these data suffered from poorer spatial resolution associated with larger interval collar fixes (on average, once every seven days), smaller sample sizes (N = 2,127), and coarser habitat variables (i.e., landcover classification). In contrast, the current study used data with shorter temporal coverage (8 years) but had higher spatial resolution associated with collar fixes (on average, one per day), larger sample sizes (N_{fall} = 8,323 and N_{winter} = 13,014), and high resolution habitat variables (i.e., 30 m x 30 m plant functional type percent and digital elevation model). The current study had the advantage of higher spatial resolution, which is especially important for ZOIs, which are, by nature, a spatial phenomenon. A limitation to both this study and Johnson and Russell (2014) is the lack of sufficient interaction between caribou and linear features each year, which prevented the estimation of annual ZOIs.

ZOI analyses, including the analyses in this study, often do not explicitly test specific mechanisms that could be causing caribou to avoid anthropogenic features. It is assumed, correctly or incorrectly, that caribou avoid these areas because they perceive elevated predation risk (Frid and Dill 2002, Semeniuk et al. 2012). This can include avoidance due to direct sensory disturbances associated with the features and learned behaviours that could result in avoidance beyond sensory perception distances (Boulanger et al. 2021). Assuming the ZOIs detected in this study are 'real', potential mechanisms that cause caribou to avoid 2D seismic lines, winter roads, and trails are perceived mortality risk associated with human hunting (Wolfe et al. 2000, Plante et al. 2017) and facilitated predation by wolves (James and Stuart-Smith 2000, Dickie et al. 2017).

Ultimately, the purpose of measuring and testing caribou responses to linear features is to inform management and mitigation. Given the weak effects associated with the ZOIs generated here, and the analytical issues discussed above, it is recommended that these results not be used solely to estimate the effects of linear features on the PCH. Rather, it is recommended that the results be used in conjunction with results from other studies, adapted to the Eagle Plains setting and the ecology of the PCH, to develop a set of ZOIs for assessment and management purposes.

[1] covariate transformation = $\log_e(x + 1)$.

[2] covariate estimates based on standardized covariate values = (x – mean[x])/std. deviation(x).

Note: the zone of influence estimate derived within the iteration zone was used to predict habitat selection across the winter range for the purpose of comparing habitat coefficients only.

6.8 SUMMARY

The PCH is known for large population aggregations, dramatic population fluctuations, lengthy migrations, and significant cultural and social value to northern Indigenous peoples. Within the NYLUP, the PCH is considered "…*the most significant and culturally important wildlife resource in the planning region.*" Habitat, food supply, predation, hunting, disease and climate range likely play interactive roles as limiting factors to the PCH population. Factors have limited potential to regulate the PCH, individually.

- The potential for food supply, especially lichen, to regulate the PCH is more limited than other barren ground caribou herds because of the PCH's very large annual and seasonal ranges and the diversity of habitats found within those ranges (e.g., including several ecoregions). Overall, the PCH winter range is relatively rich in lichen resources and is comparable to, or better than, those of other herds that winter in taiga regions.
- Predation does not seem to play a role in limiting PCH growth while the herd is at high numbers. One study suggested that the predation rate had to be near twice the observed level to cause the PCH to decline.
- The comprehensive measures within the Harvest Management Plan to monitor and respond to declines in the PCH (i.e., by reducing harvest) provide a solid system to minimize the potential effects that harvesting could have on the herd.

The portion of the PCH annual range that occurs within Yukon is protected by a network of parks, special management areas, conservation areas, wilderness areas, protected areas, ecological preserves, habitat protection areas, and IMA zones within the North Yukon Regional Land Use Plan and the Peel Watershed Regional Land Use Plan. In total, 54% of the annual range of the PCH within Yukon falls within some type of protected area where industrial activity is prohibited, 36% of the annual range occurs within Integrated Management Area zones where development is limited, and 9% of the annual range is not covered by any land management zonation. The Eagle Plains RSA occurs within IMA Zone IV, which permits the highest level of development.

The PCH have historically overlapped the Eagle Plains RSA in the rut/late fall and winter periods. However, the RSA constitutes only a small portion of those ranges — 6.0% of the late fall range and 6.5% of the winter range. The RSA does not overlap with the most frequently used portions of the late fall and winter ranges.

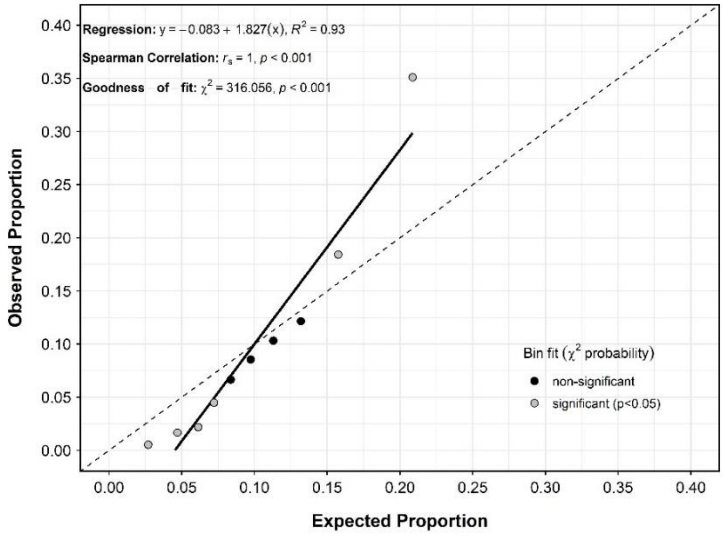
Habitat selection by the PCH in late fall and winter was estimated using resource selection functions. Selected habitats were dependent primarily on the distribution of macrolichen cover. Distance to linear features had a small effect on habitat model predictions. Overall, the strength of selection was greater in winter than late fall, which corresponds to broader movement patterns and use of more diverse habitats by the PCH in fall. In terms of regional habitat distribution, the RSA had similar proportions of selected habitat in fall as the full late fall range; however, the RSA had a much lower proportion of selected habitat in winter compared to the full winter range. Within the RSA, lichen distribution (and caribou use) was strongly affected by extensive recent burns, which had lower lichen cover than unburned areas.

The PCH typically exhibits movements of several kilometres per day in late fall and winter. Late fall daily movements (8.7 km/day in the RSA) were substantially greater than during winter (4.4 km/day). Caribou tended to occupy portions of the landscape for shorter periods during late fall than winter. Caribou residency times in both seasons were two-fold greater in the broader landscape than within the Project RSA, suggesting that, on average, the RSA is more of a transitory area than other portions of the seasonal ranges.

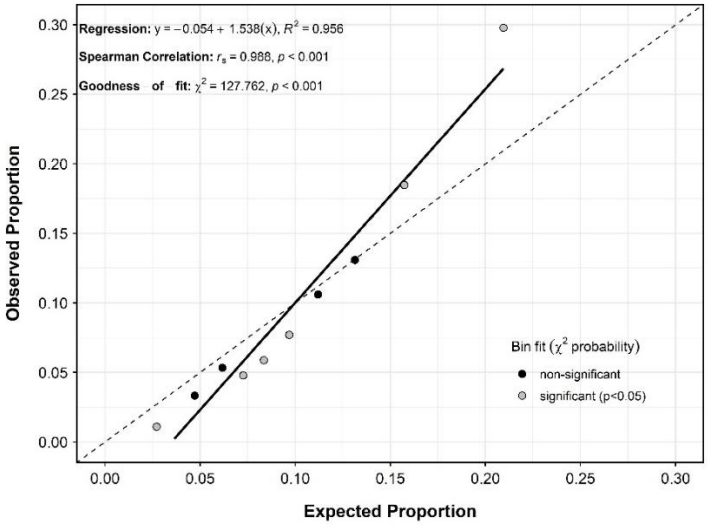
6.9 CARIBOU SECTION ATTACHMENTS

6.9.1 ATTACHMENT 6–A — 5-FOLD CROSS-VALIDATION

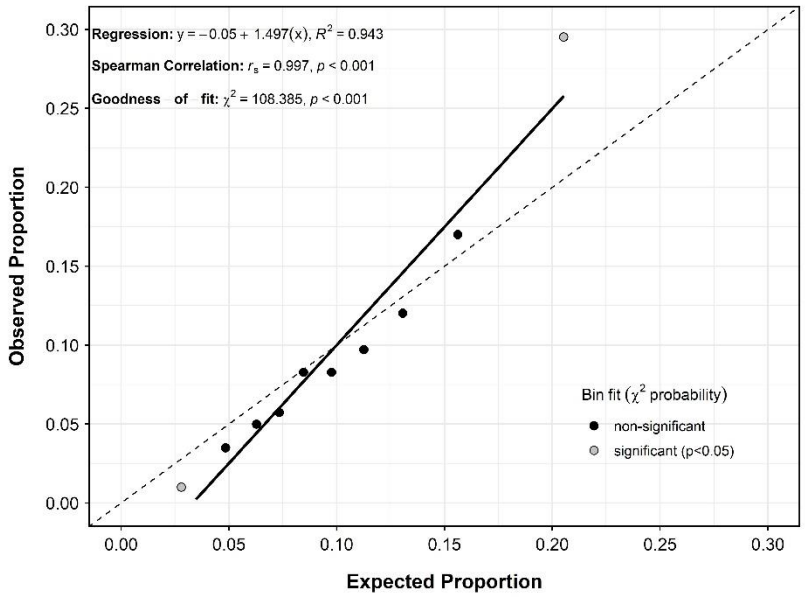
Late Fall



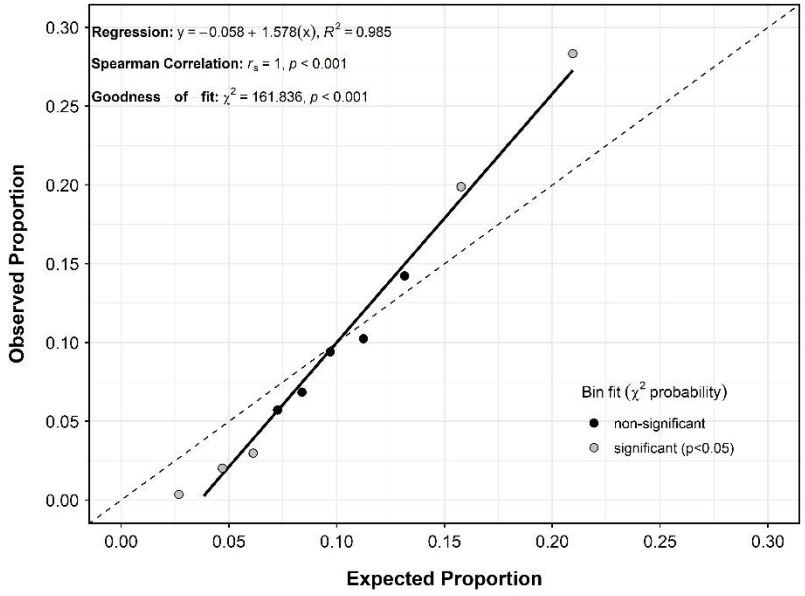
Attachment Figure 1. Cross-validation results comparing expected versus observed proportion of GPS telemetry observations (n = 18,310) of caribou during late fall across 10 quantile bins (Fold 1). Dashed line shows the line of unity (observed = expected). Black line shows the fitted regression; points are either black (not statistically different than expected) or grey (statistically different from expected) for each bin.



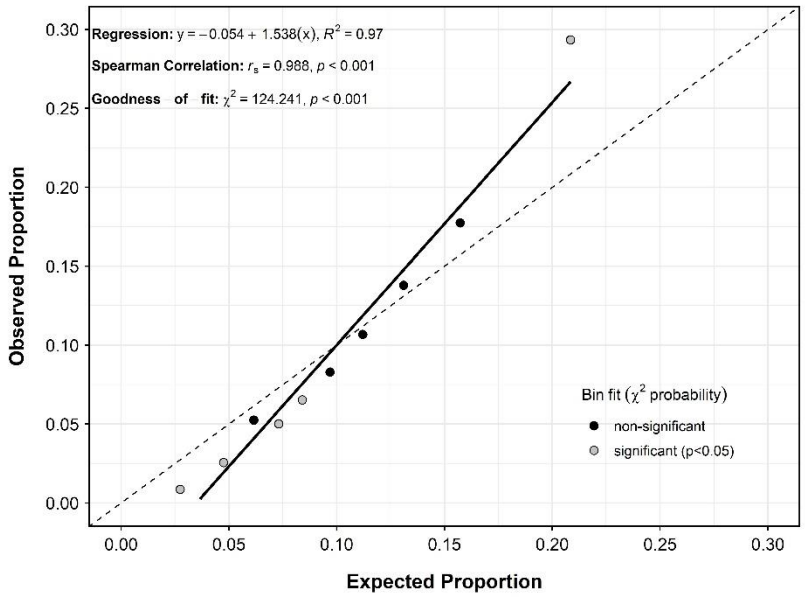
Attachment Figure 2. Cross-validation results comparing expected versus observed proportion of GPS telemetry observations (n = 18,310) of caribou during late fall across 10 quantile bins (Fold 2). Dashed line shows the line of unity (observed = expected). Black line shows the fitted regression; points are either black (not statistically different than expected) or grey (statistically different from expected) for each bin.



Attachment Figure 3. Cross-validation results comparing expected versus observed proportion of GPS telemetry observations (n = 18,310) of caribou during late fall across 10 quantile bins (Fold 3). Dashed line shows the line of unity (observed = expected). Black line shows the fitted regression; points are either black (not statistically different than expected) or grey (statistically different from expected) for each bin.

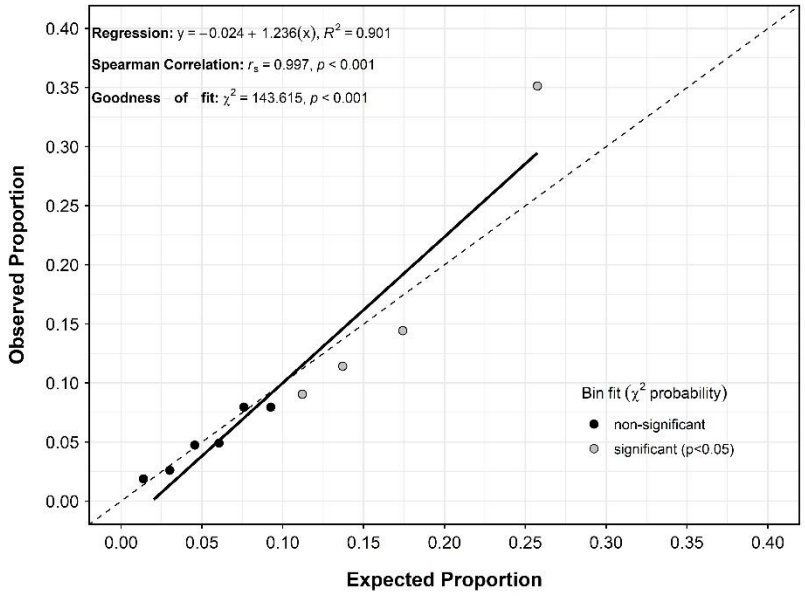


Attachment Figure 4. Cross-validation results comparing expected versus observed proportion of GPS telemetry observations (n = 18,310) of caribou during late fall across 10 quantile bins (Fold 4). Dashed line shows the line of unity (observed = expected). Black line shows the fitted regression; points are either black (not statistically different than expected) or grey (statistically different from expected) for each bin.

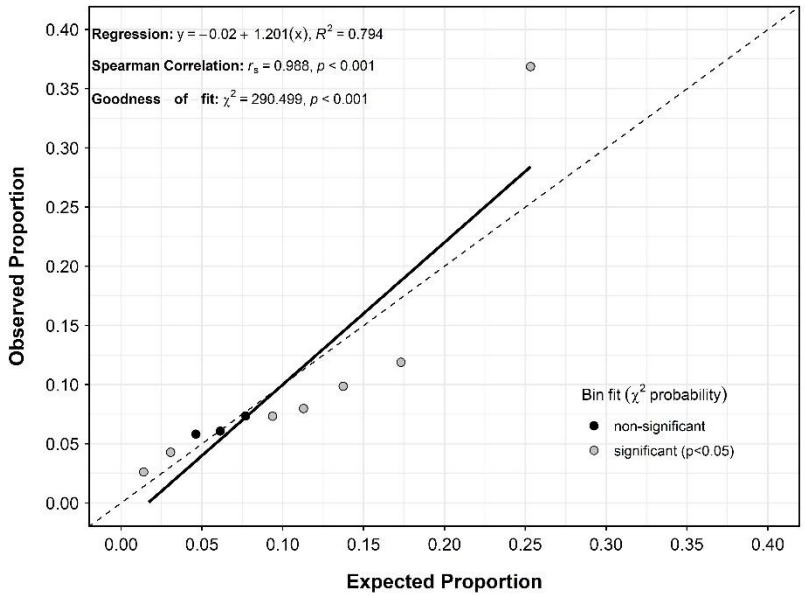


Attachment Figure 5. Cross-validation results comparing expected versus observed proportion of GPS telemetry observations (n = 18,310) of caribou during late fall across 10 quantile bins (Fold 5). Dashed line shows the line of unity (observed = expected). Black line shows the fitted regression; points are either black (not statistically different than expected) or grey (statistically different from expected) for each bin.

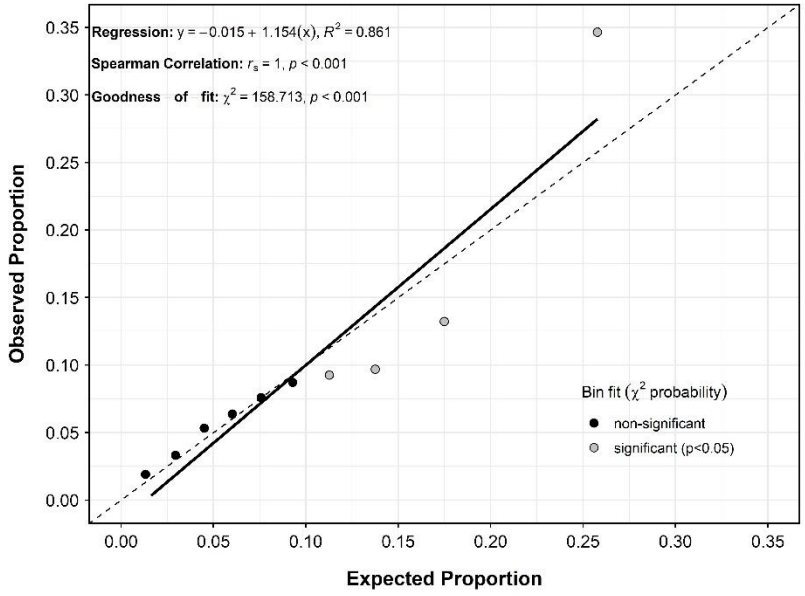
Winter



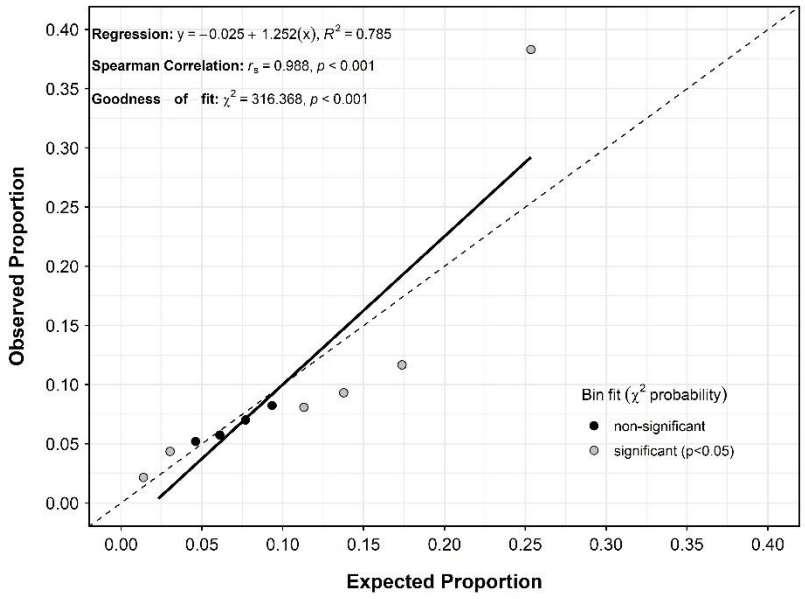
Attachment Figure 6. Cross-validation results comparing expected versus observed proportion of GPS telemetry observations (n = 28,630) of caribou during winter across 10 quantile bins (Fold 1). Dashed line shows the line of unity (observed = expected). Black line shows the fitted regression; points are either black (not statistically different than expected) or grey (statistically different from expected) for each bin.



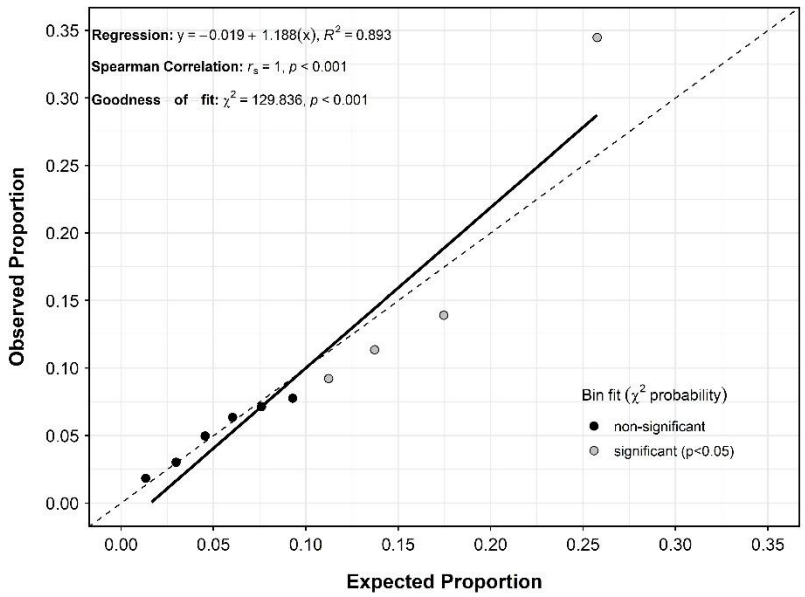
Attachment Figure 7. Cross-validation results comparing expected versus observed proportion of GPS telemetry observations (n = 28,630) of caribou during winter across 10 quantile bins (Fold 2). Dashed line shows the line of unity (observed = expected). Black line shows the fitted regression; points are either black (not statistically different than expected) or grey (statistically different from expected) for each bin.



Attachment Figure 8. Cross-validation results comparing expected versus observed proportion of GPS telemetry observations (n = 28,630) of caribou during winter across 10 quantile bins (Fold 3). Dashed line shows the line of unity (observed = expected). Black line shows the fitted regression; points are either black (not statistically different than expected) or grey (statistically different from expected) for each bin.



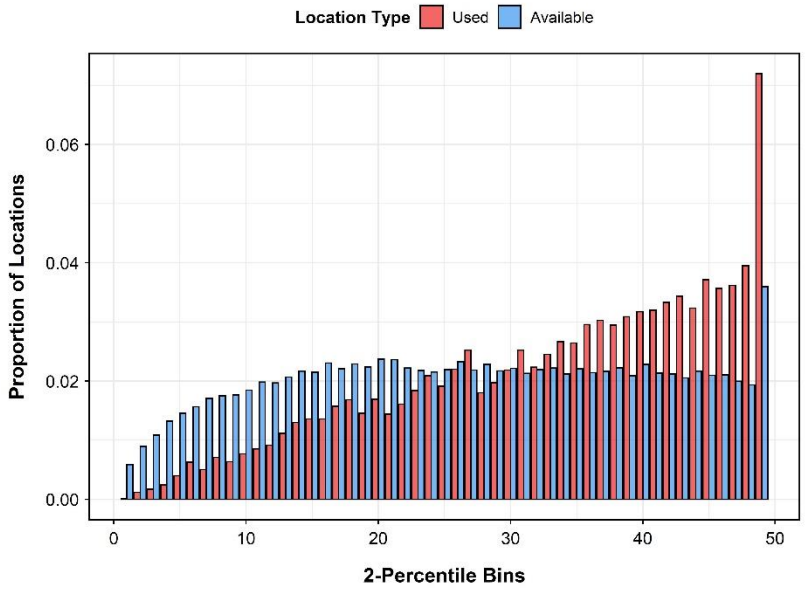
Attachment Figure 9. Cross-validation results comparing expected versus observed proportion of GPS telemetry observations (n = 28,630) of caribou during winter across 10 quantile bins (Fold 4). Dashed line shows the line of unity (observed = expected). Black line shows the fitted regression; points are either black (not statistically different than expected) or grey (statistically different from expected) for each bin.



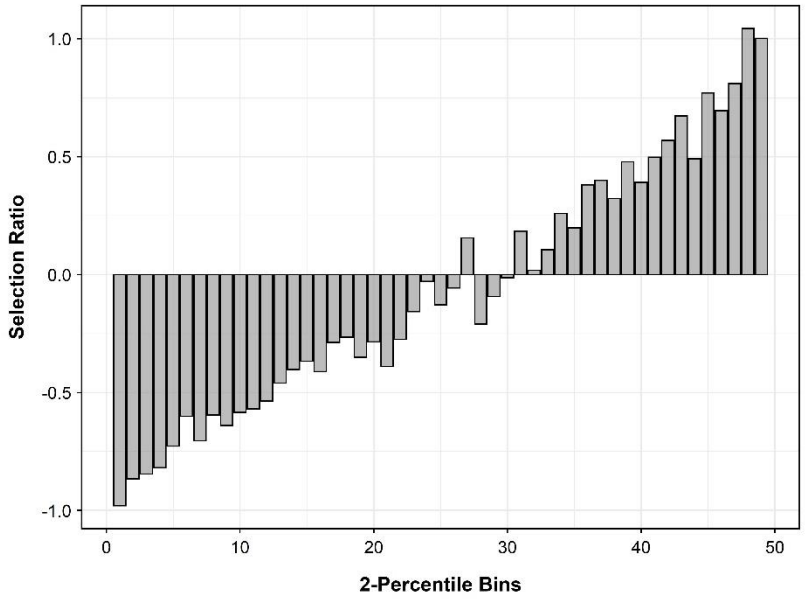
Attachment Figure 10. Cross-validation results comparing expected versus observed proportion of GPS telemetry observations (n = 28,630) of caribou during winter across 10 quantile bins (Fold 5). Dashed line shows the line of unity (observed = expected). Black line shows the fitted regression; points are either black (not statistically different than expected) or grey (statistically different from expected) for each bin.

6.9.2 ATTACHMENT 6–B — SELECTION RATIOS AND HABITAT RATINGS

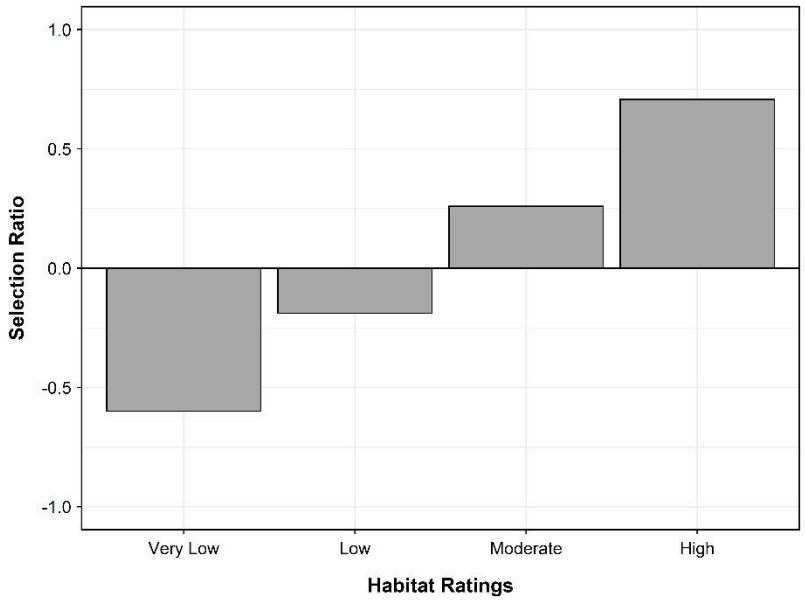
Late Fall



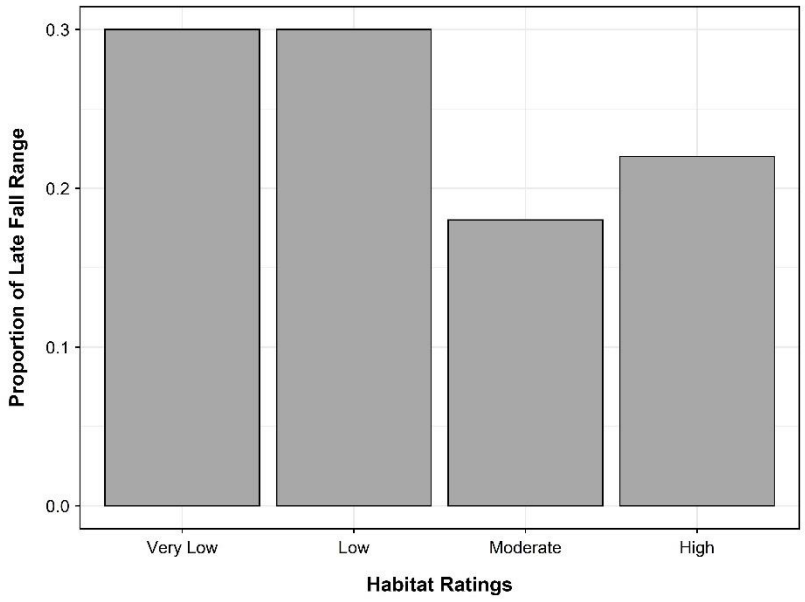
Attachment Figure 11. Proportions of used and available locations across 2-percentile (49 quantiles) interval bins of resource selection predictions during late fall, 2012–2021.



Attachment Figure 12. Selection ratios comparing the proportion of used to available locations across 2-percentile (49 quantiles) interval bins of resource selection predictions during late fall, 2012–2021.

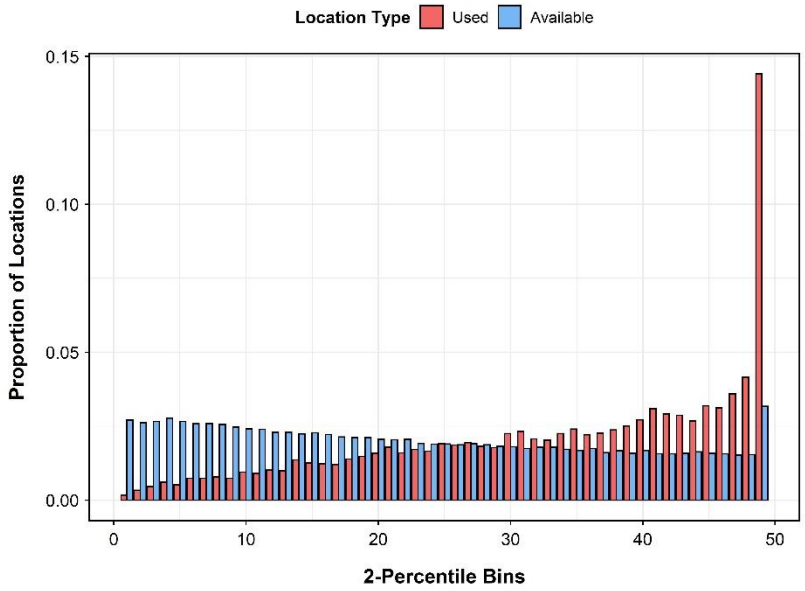


Attachment Figure 13. Selection ratios comparing the proportion of used to available locations across habitat rating classifications during late fall, 2012–2021.

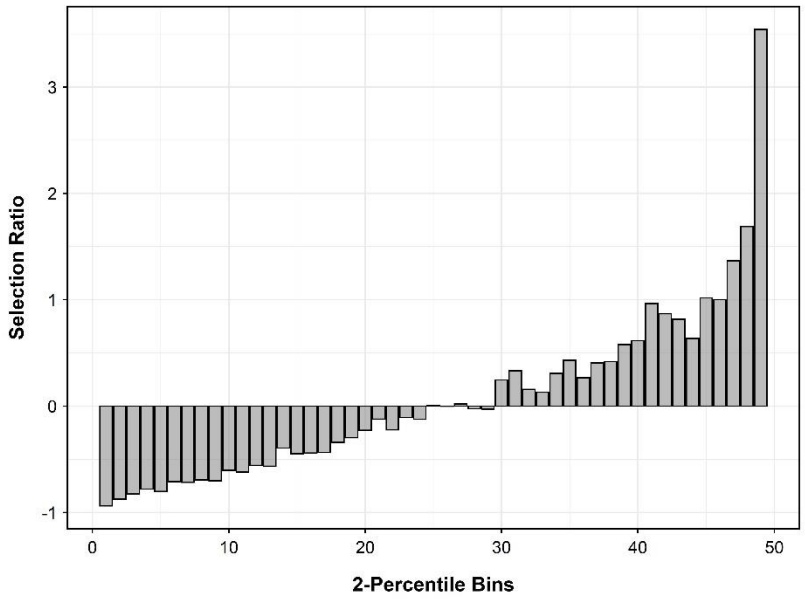


Attachment Figure 14. Proportion of the PCH late fall range composed by each habitat rating classification.

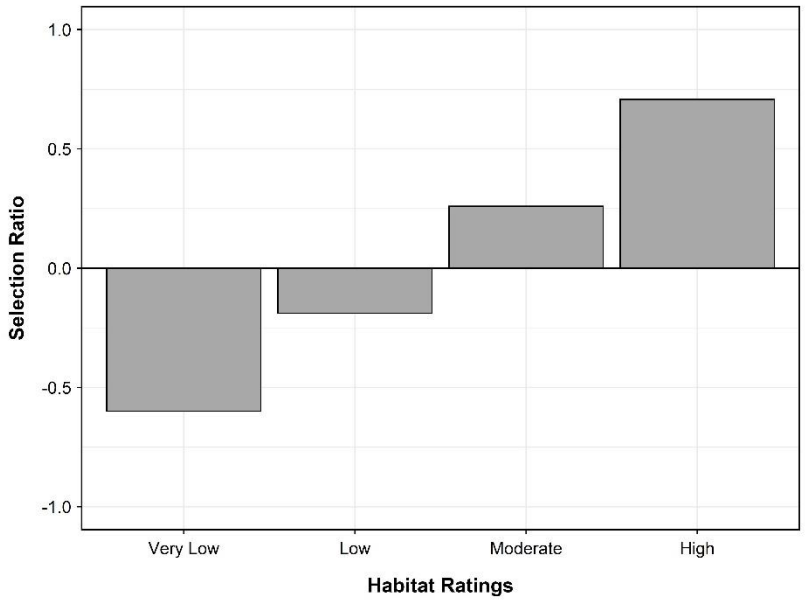
Winter



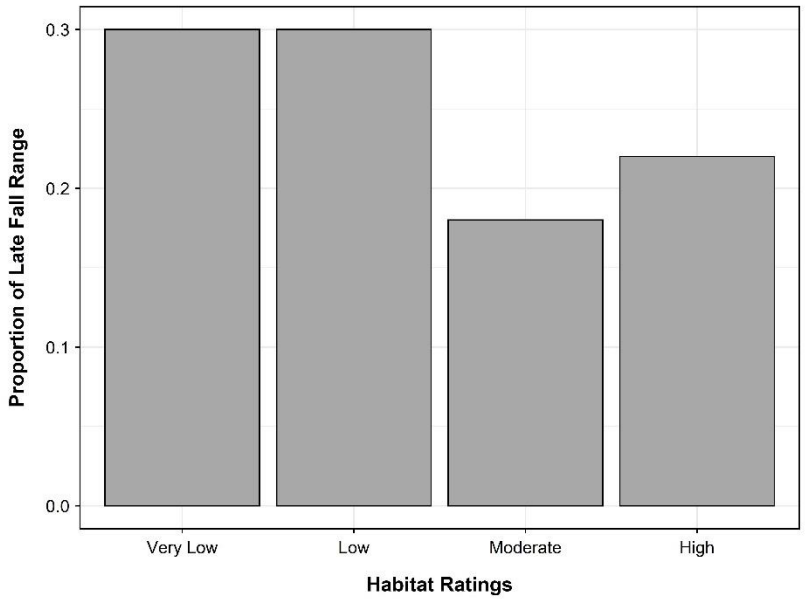
Attachment Figure 15. Proportions of used and available locations across 2-percentile (49 quantiles) interval bins of resource selection predictions during winter, 2012–2021.



Attachment Figure 16. Selection ratios comparing the proportion of used to available locations across 2-percentile (49 quantiles) interval bins of resource selection predictions during winter, 2012–2021.



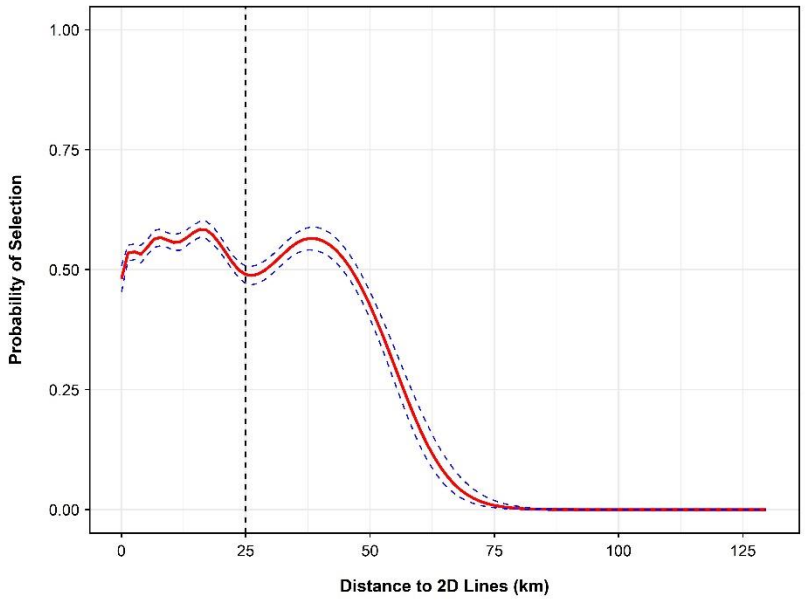
Attachment Figure 17. Selection ratios comparing the proportion of used to available locations across habitat rating classifications during winter, 2012–2021.



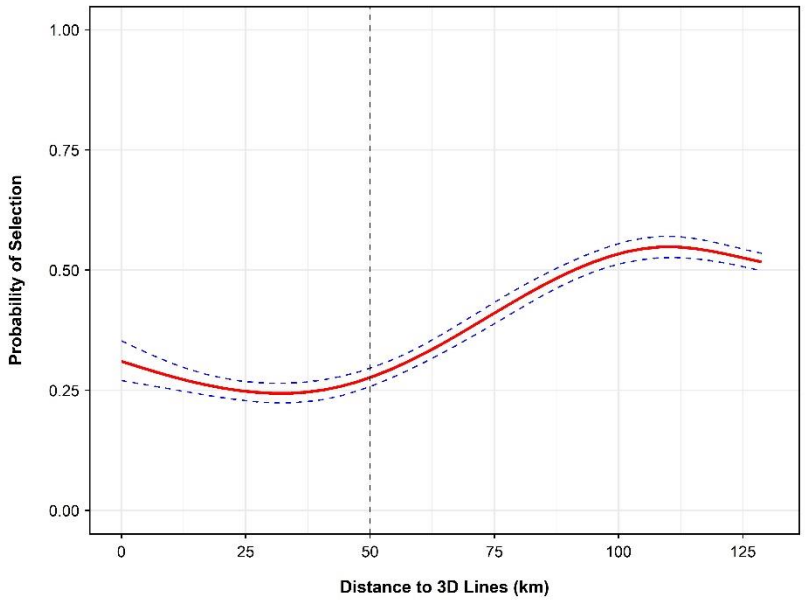
Attachment Figure 18. Proportion of the PCH winter range composed by each habitat rating classification.

6.9.3 ATTACHMENT 6–C — ZONE OF INFLUENCE ANALYSES

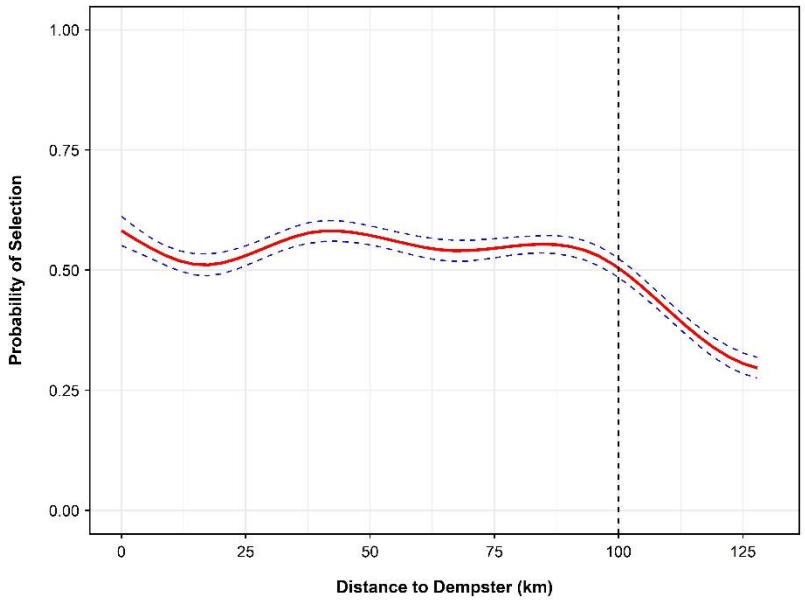
Late Fall



Attachment Figure 19. Marginal effect of distance to 2D seismic lines (including winter roads and trails) on the probability of selection by caribou during late fall (2012–2021) based on a generalized additive model with cubic regression splines. Solid red and dashed blue lines are the fitted mean and 95% confidence intervals, respectively. Vertical dashed line indicates iteration zone cut-off.

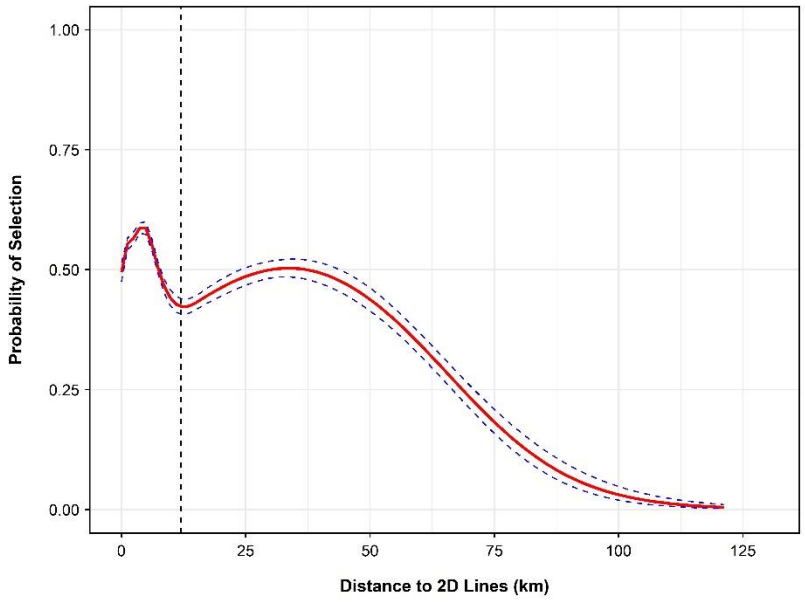


Attachment Figure 20. Marginal effect of distance to 3D seismic lines (single grid in Project RSA) on the probability of selection by caribou during late fall (2012–2021) based on a generalized additive model with cubic regression splines. Solid red and dashed blue lines are the fitted mean and 95% confidence intervals, respectively. Vertical dashed line indicates iteration zone cut-off.

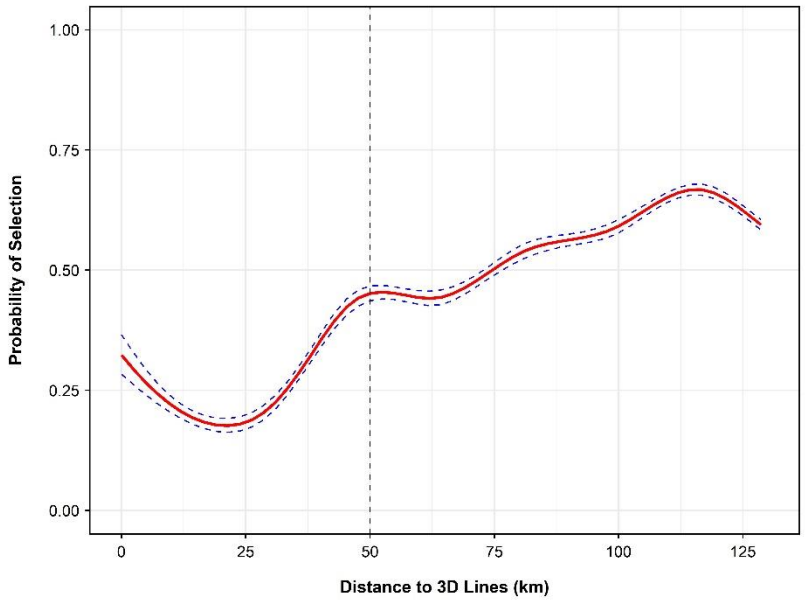


Attachment Figure 21. Marginal effect of distance to the Dempster Highway on the probability of selection by caribou during late fall (2012–2021) based on a generalized additive model with cubic regression splines. Solid red and dashed blue lines are the fitted mean and 95% confidence intervals, respectively. Vertical dashed line indicates iteration zone cut-off.

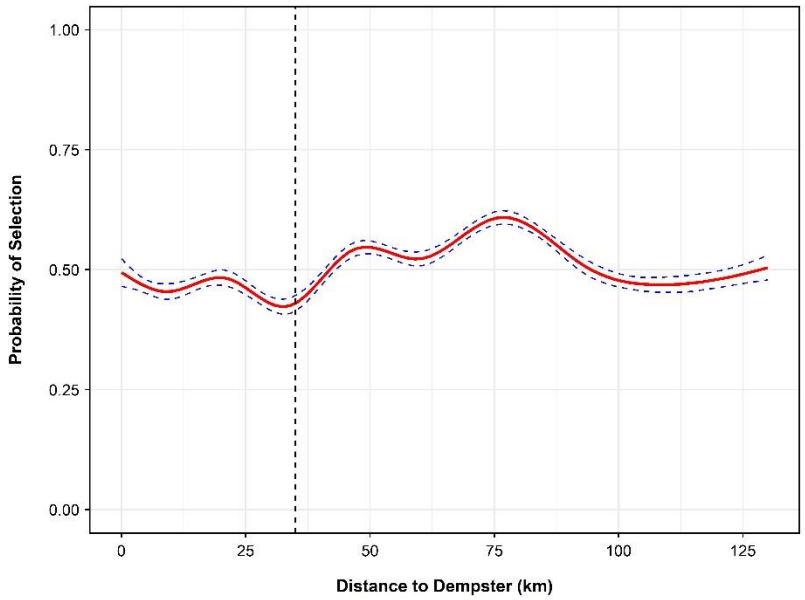
Winter



Attachment Figure 22. Marginal effect of distance to 2D seismic lines (including winter roads and trails) on the probability of selection by caribou during winter (2012–2021) based on a generalized additive model with cubic regression splines. Solid red and dashed blue lines are the fitted mean and 95% confidence intervals, respectively. Vertical dashed line indicates iteration zone cut-off.

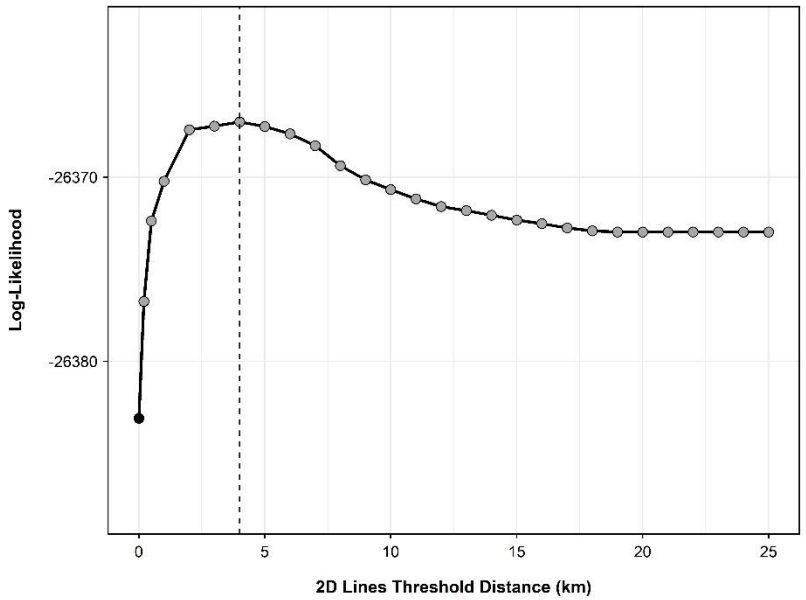


Attachment Figure 23. Marginal effect of distance to 3D seismic lines (single grid in Project RSA) on the probability of selection by caribou during winter (2012–2021) based on a generalized additive model with cubic regression splines. Solid red and dashed blue lines are the fitted mean and 95% confidence intervals, respectively. Vertical dashed line indicates iteration zone cut-off.

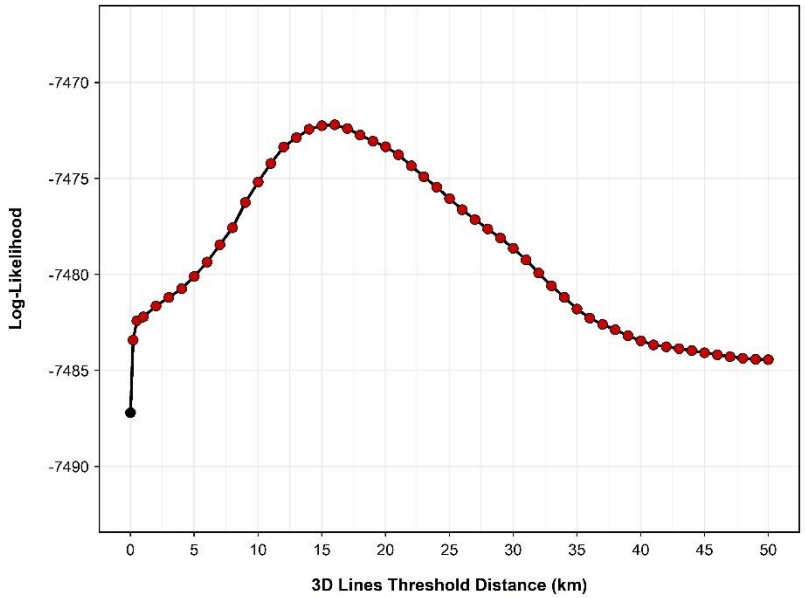


Attachment Figure 24. Marginal effect of distance to the Dempster Highway on the probability of selection by caribou during winter (2012–2021) based on a generalized additive model with cubic regression splines. Solid red and dashed blue lines are the fitted mean and 95% confidence intervals, respectively. Vertical dashed line indicates iteration zone cut-off.

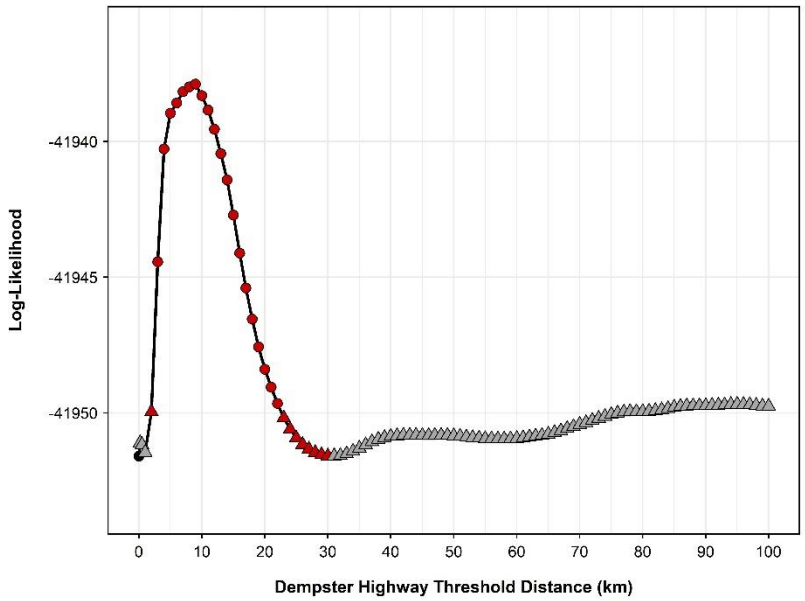
Late Fall



Attachment Figure 25. Segmented regression approach to estimating a zone of influence (ZOI) relative to 2D seismic lines (including winter roads and trails) using GPS collar data from PCH caribou during late fall, 2012–2021. The threshold distance with the highest log-likelihood corresponds with the most likely ZOI. Circles and triangles indicate statistically significant and non-significant ZOI distances, respectively. Grey and red fills indicate positive and negative coefficients, respectively. Vertical dashed line indicates ZOI at 4 km.

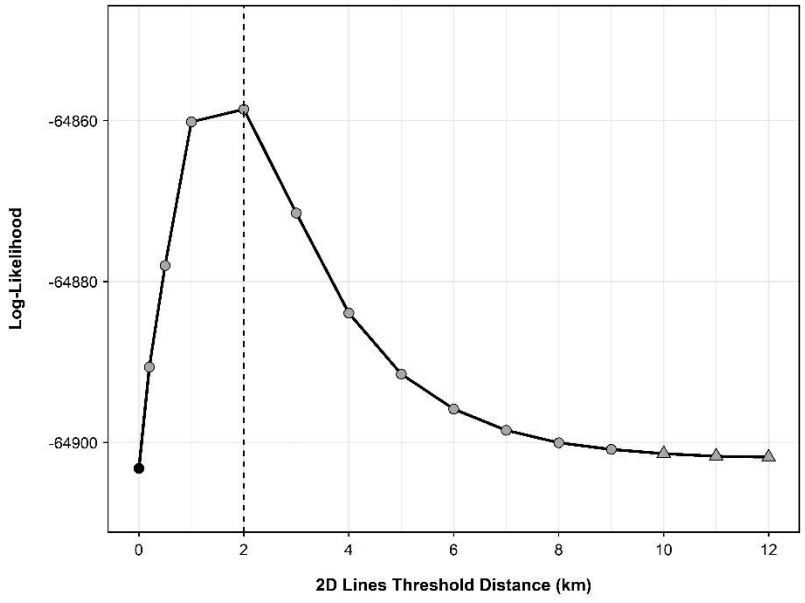


Attachment Figure 26. Segmented regression approach to estimating a zone of influence (ZOI) relative to the lone 3D seismic grid using GPS collar data from PCH caribou during late fall, 2012–2021. The threshold distance with the highest log-likelihood corresponds with the most likely ZOI. Circles and triangles indicate statistically significant and non-significant ZOI distances, respectively. Grey and red fills indicate positive and negative coefficients, respectively.

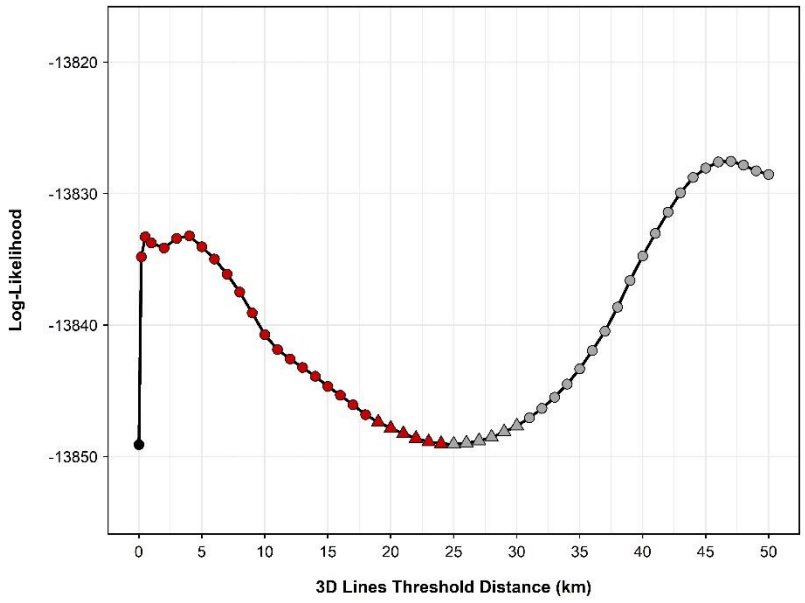


Attachment Figure 27. Segmented regression approach to estimating a zone of influence (ZOI) relative to the Dempster Highway using GPS collar data from PCH caribou during late fall, 2012–2021. The threshold distance with the highest log-likelihood corresponds with the most likely ZOI. Circles and triangles indicate statistically significant and non-significant ZOI distances, respectively. Grey and red fills indicate positive and negative coefficients, respectively.

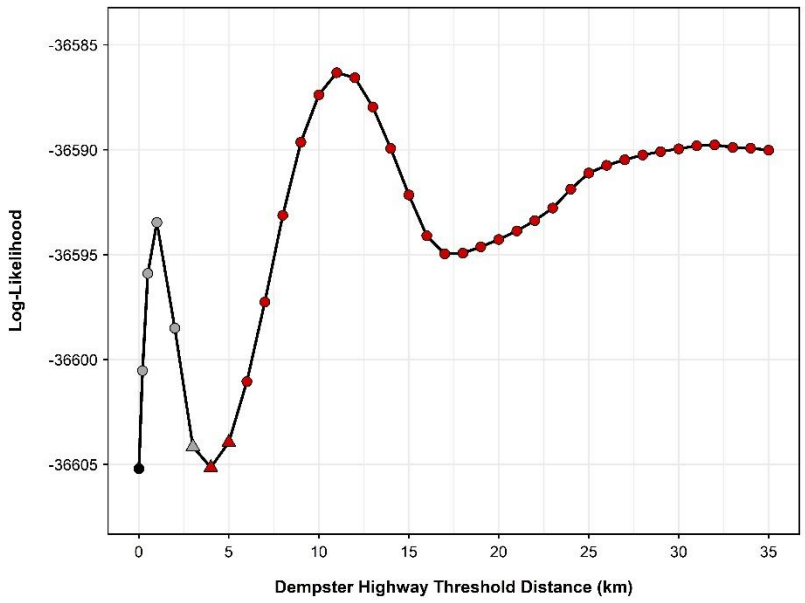
Winter



Attachment Figure 28. Segmented regression approach to estimating a zone of influence (ZOI) relative to 2D seismic lines (including winter roads and trails) using GPS collar data from PCH caribou during winter, 2012–2021. The threshold distance with the highest log-likelihood corresponds with the most likely ZOI. Circles and triangles indicate statistically significant and non-significant ZOI distances, respectively. Grey and red fills indicate positive and negative coefficients, respectively. Vertical dashed line indicates ZOI at 2 km.



Attachment Figure 29. Segmented regression approach to estimating a zone of influence (ZOI) relative to the lone 3D seismic grid using GPS collar data from PCH caribou during winter, 2012–2021. The threshold distance with the highest log-likelihood corresponds with the most likely ZOI. Circles and triangles indicate statistically significant and non-significant ZOI distances, respectively. Grey and red fills indicate positive and negative coefficients, respectively.



Attachment Figure 30. Segmented regression approach to estimating a zone of influence (ZOI) relative to the Dempster Highway using GPS collar data from PCH caribou during winter, 2012–2021. The threshold distance with the highest log-likelihood corresponds with the most likely ZOI. Circles and triangles indicate statistically significant and non-significant ZOI distances, respectively. Grey and red fills indicate positive and negative coefficients, respectively.

EXECUTIVE SUMMARY

The Eagle Plains Exploration Project (the Project) is an oil and gas exploration project located in north Yukon. Chance Oil and Gas Ltd. (Chance) intends to conduct exploratory activities to confirm the quality, quantity, and extent of hydrocarbons over ten years. Work will include seismic exploration and exploratory wells supported by an expanded winter road network. Oil and gas exploration activities create long, narrow clearings through natural vegetation, such as seismic lines and roads, collectively known as 'linear features.' Linear features can be a management challenge because they can affect how people and animals move and plants disperse within a landscape. For example, in southern parts of the boreal forest, linear features appear to affect predator-prey dynamics that can result in increased caribou mortality by wolves. The North Yukon and Peel Watershed Regional Land Use Plans identify mitigations to minimize the potential effects of linear features, including cautionary (0.75 km/km^2) and critical (1.0 km/km^2) indicator levels of linear disturbance.

Intermittent exploration activities in the Eagle Plains area from the 1950s to 2014 have created a network of winter roads, 2D seismic lines, and, most recently, 3D seismic lines in parts of the Regional Study Area (RSA). However, the extent of liner features that currently occur in the RSA, the structural, vegetation, and functional characteristics of different linear feature types, and their degree of regeneration are unknown. EDI Environmental Dynamics Inc. conducted a linear features study to characterize the structural, vegetation, and functional aspects of linear features in the RSA to address these information gaps. The study addressed three objectives: (1) comprehensive mapping and classification of existing linear feature footprints within the RSA; (2) quantification of structural aspects (e.g., widths) and functional aspects (ease of travel and sightlines) of linear features; and (3) quantification of regeneration pathways and structural stages of linear features. This combined information supports assessing potential effects of linear features in the Project application and refinement of mitigation measures for linear features to minimize possible effects.

The linear features inventory was compiled from multiple spatial datasets and was verified and supplemented using satellite imagery in a Geographic Information System. Linear feature densities were estimated for each linear feature type. Estimates were adjusted to account for (i) overlap with open habitats, such as recent burns, where vegetation heights were similar on and off the line, and (ii) for average rates of regeneration determined from field studies.

Site selection used a stratified random design to obtain a representative sample of different feature types across the RSA. Ground and aerial surveys measured specific structural, vegetation, and functional characteristics across the different line types. Measures included width, successional class, structural stage, vegetation composition and height, and sightline distances. A 'walk test' was used to index ease of movement for large mammals. A driving survey documented the visibility of seismic lines from the Dempster Highway (i.e., as an index of potential human access onto the seismic lines). An aerial winter track survey was conducted in March 2020 to assess ungulates' relative use of different linear feature types.

Four primary types of linear features occur in the RSA, totalling 4,269 km: 2D seismic (34%), 3D seismic (51%), winter roads (14%), and the Dempster Highway (1%). The unadjusted linear feature density for the RSA totalled 1.79 km/km^2. After accounting for burns, natural openings and regeneration, the adjusted linear

feature density for the RSA totalled 0.52 km/km², below the cautionary and critical indicator levels in the North Yukon and Peel Watershed Regional Land Use Plans.

Structural, vegetation, and functional characteristics differed substantially among linear feature types. 3D seismic accounts for the largest extent of linear features in the RSA and had the narrowest widths and limited functional effects (e.g., the proportion of features used by ungulates in the winter was less than a third of the rates of use on 2D and winter roads). Winter roads had the widest average widths and the greatest functional effects except for the Dempster Highway. However, a substantial portion (39%) had also regenerated into or past the Tall Shrub stage (which this study suggests may be the best criterion for functional recovery). Most 2D lines had substantial vegetation regeneration, resulting in the shortest average sightlines and slowest movement speeds. However, ungulates still appeared to select them to travel on during winter.

Except for the Dempster Highway, where walking speeds were near twice the rate of other linear feature types, there was relatively little difference in movement rates among linear feature types and control areas. The density of shrubs and trees primarily limited movement rates. 2D lines, which had the highest density of shrubby regeneration, had the slowest average movement rates. For other linear feature types, the combination of vegetation regeneration on linear features and the naturally open nature of most adjacent undisturbed areas did not convey a substantial increase in movement rates on linear features compared to undisturbed areas.

Sightline distances on 2D lines and winter roads were also affected mainly by the degree of vegetation regeneration. Where regeneration was limited, sightlines on 2D lines and winter roads regularly exceeded 150 m. On 3D lines, which have not had enough time since their creation for vegetation to regenerate to the height that restricts vision, sightlines were limited by meanders purposely constructed to reduce sightlines. The meanders employed on 3D lines were also effective in reducing the detectability of the lines from the Dempster Highway. In the blind test, where observers did not know the location of the 3D lines, only 5% (4 out of 74) crossings were spotted. With a map showing the crossing locations, only two additional 3D lines were detected.

These results provide information to assess the potential effects of linear features in the Project application and refine mitigation measures.

ACKNOWLEDGEMENTS

EDI Environmental Dynamics Inc. (EDI) completed the work within the traditional territories of the Vuntut Gwitchin First Nation (VGFN), First Nation of the Na-Cho Nyäk Dun, and the Tetlit Gwich'in Council (Secondary Use Area). Tyrel Kassi, a VGFN citizen, played an active role in the field components of the project. We thank him for his diligence and shared perspectives during the project.

AUTHORSHIP

Team members from EDI who contributed to preparing this report include:

1 INTRODUCTION

1.1 PROJECT OVERVIEW

The Eagle Plains Project (the Project) encompasses a 2,386 km² area in north-central Yukon, approximately 605 km north of Whitehorse and 40 km south and west of Eagle Plains hotel, along the Dempster Highway (Map 1-1). The Project occurs within the Eagle Plains petroleum basin, north of the Ogilvie River and west of the Richardson Mountains. The basin contains proven natural gas and oil reserves (Peel Watershed Planning Commission 2019), including 4.6 billion m³ of gas and 3.2 million m³ of oil (Hannigan 2014).

The Regional Study Area (RSA) has had intermittent periods of oil and gas exploration since the 1950s. That activity has developed winter roads, seismic lines, and exploratory wells across parts of the current RSA. Approximately 40 exploration wells have been drilled at Eagle Plains. Eight wells are maintained in suspended status, and the remaining wells have been plugged and abandoned. Seismic exploration has included approximately 10,000 km of two-dimensional (2D) lines (mainly before 1985), and about 325 km² of three-dimensional (3D) seismic was conducted in 2013–2014 (Northern Cross (Yukon) Ltd. 2014).

The current exploration program will build on past exploration to better define the extent, amount and quality of oil and gas deposits. Under the current program, Chance Oil and Gas Ltd. proposes conducting additional 3D seismic over large extents of the RSA and drilling up to 30 exploratory wells. Depending on the drilling program results, extended flow testing over several months may be conducted at a subset of the wells to determine the quantity and quality of the oil and gas deposit. The existing winter road network will be expanded to support the seismic and drilling programs. Most work is expected to be conducted in the winter (e.g., seismic line clearing and drilling); however, seismic recordings and extended flow testing may also occur during summer.

Oil and gas exploration activities create long, narrow clearings through natural vegetation, such as seismic lines and roads, collectively known as 'linear features.' Linear features can be a management challenge because they can affect how people and animals move and plants disperse within a landscape. For example, in southern parts of the boreal forest, linear features appear to affect predator-prey dynamics that can result in increased caribou mortality by wolves. The North Yukon and Peel Watershed Regional Land Use Plans identify mitigations to minimize the potential effects of linear features. The Plans also include cautionary (0.75 km/km²) and critical (1.0 km/km²) linear density indicator levels.

1.2 PURPOSE AND OBJECTIVES

Intermittent exploration activities in the Eagle Plains area from the 1950s to 2014 have created a network of winter roads, 2D seismic lines, and, most recently, 3D seismic lines in parts of the RSA. However, the extent of liner features that currently occur in the RSA, the physical and functional characteristics of different linear feature types, and their degree of regeneration are unknown.

EDI Environmental Dynamics Inc. (EDI) conducted a linear features study to characterize the physical and functional aspects of linear features in the RSA to address these information gaps. The three objectives of this study were to: (1) conduct comprehensive mapping and classification of existing linear feature footprints within the RSA; (2) determine physical aspects (e.g., widths) and functional aspects (ease of travel and sightlines) of linear features; and, (3) quantify regeneration pathways and stages of linear features. The combined information forms the basis for assessing the potential effects of linear features in the RSA and refining mitigation measures for linear features.

1.3 STUDY AREA

The RSA for the Eagle Plains Project is approximately 2,386 km² (238,566 ha), centred in the Eagle Plains Ecoregion in north Yukon (Map 1-1). The area consists of subdued topography of rolling hills and sloping plains. The RSA is centred on a major watershed divide (denoted by the location of the Dempster Highway), with the northwestern two-thirds of the RSA draining into the Porcupine River watershed to the north, via Chance Creek, and west, via McParlon Creek and the Whitestone River. The southeastern third of the RSA drains into the Peel River watershed via Dalglish Creek.

Development in the RSA and the surrounding Eagle Plains is low. The Dempster Highway is the primary vehicle access corridor, running from approximately Dawson City, Yukon in the south to Inuvik, Northwest Territories in the north, and transiting the RSA. The Eagle Plains settlement is on the Dempster Highway, approximately 40 km northeast of the RSA and includes the Eagle Plains Hotel and the Government of Yukon's Highway Maintenance camp. The Eagle Plains area has had intermittent periods of oil and gas exploration since the 1950s. That activity has created winter roads, seismic lines, and exploratory wells across parts of the RSA. Approximately 40 exploration wells have been drilled at Eagle Plains. Eight wells are maintained in suspended status, and the remaining wells have been plugged and abandoned. Approximately 10,000 km of 2D lines have been developed across the Eagle Plains Ecoregion, mostly between 1961 and 1984 (Access Consulting Group and EBA Engineering Consultants Ltd. 2001, GEOTIR 2014). More recently, approximately 2,200 km of 3D LIS exploration was conducted in a 325 km² area between November 2013 and April 2014 (GEOTIR 2014). This 3D exploration grid is near the centre of the RSA, spanning north and south of the Dempster Highway.

1.3.1 REGIONAL ECOLOGICAL SETTING

The Eagle Plains Ecoregion is a 20,400 km² portion of the Taiga Cordillera Ecozone in north Yukon between the Richardson and Ogilvie Mountains. Unlike much of the mountainous Taiga Cordillera, most of the Eagle Plains Ecoregion occurs as low altitude rolling topography between 300 m and 600 m above sea level (masl), with few scattered peaks above and around 1,000 masl (Ecological Stratification Working Group 1995). Most of the ecoregion is unglaciated terrain, with surficial features formed due to permafrost and frozen ground-related processes, including thermokarst subsidence, soil creeps, cryoturbation, solifluction, and active layer detachment slides on shale (Yukon Ecoregions Working Group 2004).

The Eagle Plains Ecoregion experiences moderate precipitation, with annual amounts around 400 mm. Most precipitation falls as rain throughout the summer, averaging 50 to 80 mm per month, June through August. Precipitation is lighter through September to April and falls as snow, with average winter snowpacks of 80 cm peaking in April. The climate is strongly affected by latitude, with extended winter conditions from October to early May. There is a substantial variation in seasonal temperatures in the Eagle Plains, with cool short summers and long cold winters. Average winter temperatures are between −30°C and −25°C, with extremes as low as −60°C. Average summer temperatures are around 13°C, with extremes as high as 30°C. Due to the northern latitude, this region experiences continuous sun above and below the horizon, in summer and winter, respectively.

Most of the Ecoregion, including the northeast portion of the RSA, drains north into the Yukon River via the Whitestone, Porcupine and Eagle rivers. That part of the RSA includes the headwaters of the Eagle River and several other tributaries of the Porcupine River, along with the Chance and McParlon Creek subdrainages of the Whitestone River. The southeast corner of the Ecoregion drains east to the Mackenzie River via the Peel, Wind and Ogilvie Rivers. Dalglish and Enterprise creeks flow directly into the Peel River. The few lakes in the Ecoregion are generally oxbow or thermokarst lakes (Yukon Ecoregions Working Group 2004). Several wetland complexes are associated with larger creeks in the RSA.

The Eagle Plains Ecoregion is within the continuous permafrost zone where permafrost can be found up to 200 m thick. The Eagle Plains Ecoregion is dominated by the Cryosolic soils that occupy much of the northern third of Canada, characterized by near-surface permafrost. Turbic Cryosols predominate, exhibiting patterned ground formations and hummocks, and are often associated with open stands of black spruce (*Picea mariana*), tamarack (*Larix laricina*) and birch (*Betula* spp.). The active permafrost layer in these ecosystems generally ranges between 20 cm and 90 cm below the surface. The active layer depth is generally deeper directly under hummocks and shallower under inter-hummock areas (Yukon Ecoregions Working Group 2004).

The RSA is entirely within the Subarctic Bioclimate Zone (Environment Yukon 2014). Vegetation in the RSA is characterized by open-canopy, spruce-dominated habitats where permafrost and short cool growing seasons limit tree growth and often result in stunted, disclimax vegetation communities (Environment Yukon 2016). Hummocky, black and white spruce (*Picea glauca*) woodlands with well-developed shrub communities are common in upland areas. White spruce and ground lichens increase in abundance in well-drained sites. Areas with low slope gradients and fine-textured soils often have ground cover dominated by cottongrass tussocks beneath a shrub layer of birch, black spruce, Labrador tea (*Rhododendron groenlandicum*), and occasionally tamarack (*Larix laricina*) (Yukon Ecoregions Working Group 2004).

Forest fires are a common disturbance agent in the region, and burns of various ages occur throughout the RSA. Fires increase the depth of the active permafrost layer and changes in soil moisture and productivity, affecting vegetation regeneration and resulting in terrain disturbances, such as slope failures and erosion. Regenerating burns are dominated by shrubs, such as scrub birch (*Betula glandulosa*), willows (*Salix spp.*) and alder (*Alnus spp.*), with Alaskan paper-birch (*Betula neoalaskana*) often the first tree species to colonize burn areas. As burns regenerate into young and mature forest, black and white spruce typically become the dominant forest species. Residual Alaskan birch in spruce-dominated stands often defines the extent of old burns (Yukon Ecoregions Working Group 2004).

Mammal diversity is relatively low in the Eagle Plains Ecoregion due to its northern location and low productivity. Voles (*Microtus* spp., *Myodes* spp., *Phenacomys* spp.), American marten (*Martes americana*), ermine (*Mustela erminea*), and red fox (*Vulpes vulpes*) are common smaller mammals. Wolves (*Canis lupus*), wolverines (*Gulo gulo*), and both black and grizzly bears (*Ursus americanus* and *U. arctos*.) are present at low densities. Moose (*Alces alces*) inhabit the region year-round. The RSA overlaps a small portion of the winter range of the Porcupine caribou herd (PCH), a subpopulation of the barren-ground caribou (*Rangifer tarandus granti*). The PCH is an iconic species in north Yukon, with high cultural, social, economic, and ecological values. The PCH's population has been increasing over the last several decades and is currently estimated to consist of 202,106 to 234,808 caribou (Caikoski 2017, Porcupine Caribou Technical Committee 2018). The PCH is known to occupy portions of the Eagle Plains Ecoregion in fall and winter when they tend to occur in smaller groups over a larger area than during other seasons.

1.3.2 REGIONAL LAND USE PLANNING

The RSA overlaps four First Nation Traditional Territories. Most of the RSA is within the Traditional Territory of the Vuntut Gwitchin First Nation. The southeastern portion is in an area of overlapping Traditional Territories of Vuntut Gwitchin First Nation, the Tetlit Gwich'in Council, the First Nation of Na-cho Nyäk Dun, and Tr'ondëk Hwëchin. Although the RSA is located outside of any First Nation Settlement Lands, it does abut Vuntut Gwitchin First Nations Settlement Lands on parts of its east and southwest borders. Each First Nations government has provided input to, and approved of, the Regional Land Use Plan(s) on their Traditional Territory under the respective First Nation Final Agreements.

1.3.2.1 North Yukon Regional Land Use Plan

The RSA lies mainly within the North Yukon Planning Region and is subject to the North Yukon Regional Land Use Plan (NYRLUP) (Map 1-1). The NYRLUP was created to protect the natural and cultural resources of the region while allowing sustainable economic development opportunities (Vuntut Gwitchin Government and Yukon Government 2009). It provides management direction for using public and settlement lands based on four principles: sustainable development, precautionary principle, conservation, and adaptive management. The NYRLUP divides the Planning Region into 23 land management units classified into three categories: protected area, integrated management area (IMA), and community area. IMAs are further classified into four zones: Zone 1 (lowest development), Zone II (low development), Zone III (moderate development), and Zone IV (highest development). IMA zones are classified based on the area's sensitivity to landscape disturbance, ecological and cultural values, risk of significant impacts, and level of acceptable change. The RSA is a Zone IV IMA with lower ecological and cultural values in a moderately sensitive biophysical setting. Subsequently, Zone IV IMAs allows for the highest development level to occur.

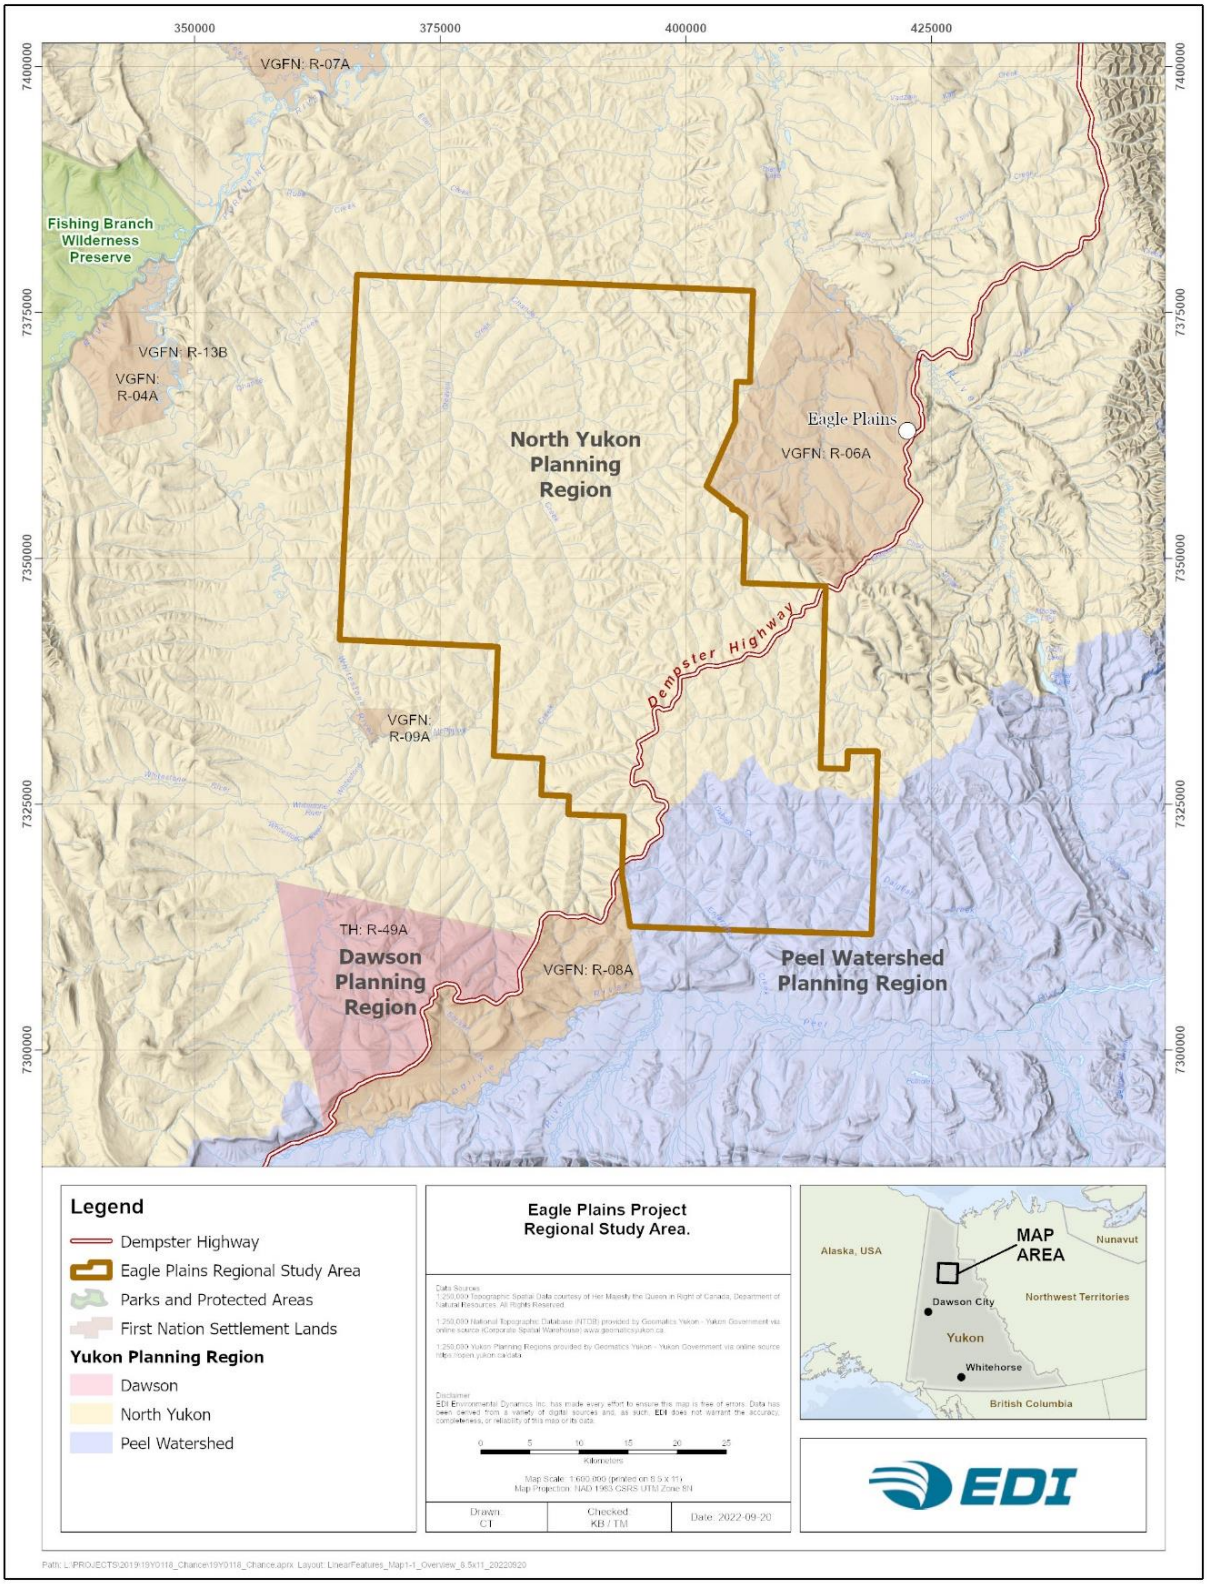
The NYRLUP encourages results-based management and uses cumulative effects indicators to determine if goals and objectives are met. Results-based management allows for innovation and creativity in land-use strategies and approaches. The two cumulative effects indicators included in the NYRLUP are direct surface disturbance and linear density. The NYRLUP guidelines for Zone IV IMAs are 0.75–1.0% surface disturbance and 0.75–1.0 km/km² linear density (Vuntut Gwitchin Government and Yukon Government 2009).

However, as surface disturbances and linear features reach a level of functional recovery and become part of the continuous landscape, they can be subtracted from the total amount of disturbed area (Vuntut Gwitchin Government and Yukon Government 2009). The NYRLUP suggests using a height of 1.5 m for woody vegetation in forested areas, as vegetation above this height would likely no longer allow for travel or access by humans or wildlife and is, therefore, considered functionally recovered. Activities considered exempt from functional disturbance restrictions are (1) new linear features less than 1.5 m wide; (2) land-use activities that occur on frozen water bodies; (3) winter work with no required clearing of trees; and (4) winter work that uses existing disturbances and linear features.

1.3.2.2 Peel Watershed Regional Land Use Plan

The southeastern corner of the RSA lies within the Peel Watershed Planning Region (PWPR) and is subject to the Peel Watershed Regional Land Use Plan (PWRLUP) (Peel Watershed Planning Commission 2019) (Map 1-1). Like the NYRLUP, the PWRLUP was established to provide management direction and ensure long-term sustainable development in the Planning Region. The PWRLUP was founded on three main themes: environmental protection, social considerations, and economic development. It follows a similar framework as the NYRLUP. The PWPR is divided into 16 Landscape Management Units (LMU), which each share similar ecological characteristics, planning issues, and management intent. Each LMU is categorized by a land-use designation system. Conservation Areas are managed to protect ecological and cultural resources, while IMAs are 'working' landscapes where new development and surface disturbance may be allowed. IMAs are further classified into Zones, which correspond to the level of allowable development with comparable justification as the NYRLUP. The RSA is part of LMU 7 (Dalglish Creek), classified as an IMA Zone IV, allowing for the highest level of development.

Like the NYRLUP, the PWRLUP encourages results-based management and uses the same cumulative effects indicators, surface disturbance and linear density to inform decisions. The PWRLUP cautionary and critical indicators are identical to those of the NYRLUP: 0.75–1.0% surface disturbance and 0.75–1.0 km/km² linear density. As surface disturbances reach a level of functional recovery and no longer enable travel or access by wildlife and people, they can be subtracted from the total amount of disturbed area. The PWRLUP suggests using a 1.5 m woody vegetation height as a threshold for functional recovery in forested or shrubland areas. In areas dominated by low-growing vegetation, a feature could be considered functionally recovered when covered by native species roughly the same height and composition as the surrounding vegetation. To be considered as "functionally recovered," features must have similar sediment and run-off compared to background levels, roughly match original contours, and have no human-brought materials on the site. Exceptions to the linear density calculation are identical to those outlined in the NYRLUP.



Map 1-1. Eagle Plains Project Regional Study Area.

2 BACKGROUND

The term "linear feature" refers to any narrow, linear clearings of vegetation on the landscape. They include roads, seismic lines, power lines, and pipelines. Seismic lines are the dominant linear feature class in northern Canada, accounting for approximately 46% of all linear features in the Canadian boreal region (Pasher et al. 2013). Seismic exploration detects underground oil and natural gas reservoirs by analyzing sound waves reflected from the underlying geology (Yukon Energy Mines and Resources 2006). Sound waves are emitted by detonating small charges in a series of drilled shot holes (up to 20 m deep) or by vibrating a heavy metal plate on the ground's surface using a truck-mounted vibrator (Yukon Energy Mines and Resources 2006). Both methods require cleared travel corridors for equipment transportation, which results in a network of seismic lines across the landscape where seismic exploration has occurred.

Until the late 1990s, conventional 2D was the primary form of seismic exploration used in North America. 2D seismic lines were created using bulldozers to clear all vegetation in straight swaths, approximately 5–10 m wide in their earliest form. These wide, straight lines were necessary to enable large, heavy equipment movement. This process resulted in significant physical disturbance, often removing most surface vegetation and roots and the top layer of soil (Bliss and Wein 1972). Progressive improvements in 2D seismic exploration methods reduced the environmental impact, such as clearing in winter instead of summer and raising and adding mushroom shoes to the bulldozer blade to reduce soil disturbance. Despite these improvements, many of the 2D seismic lines created in the 1960s and 1970s in northern Canada remain disturbed, with little evidence of ecological recovery (Lee and Boutin 2006, van Rensen et al. 2015).

3D seismic exploration provides more accurate subsurface geological structure data than 2D technology. 3D seismic exploration techniques were developed in the mid-1990s, and their use became widespread in the early 2000s (Dabros et al. 2018). At the same time as the transition to 3D, the seismic industry was transitioning to smaller and more specialized equipment that reduces cost, improves efficiency and reduces environmental impacts. Modern seismic equipment and methods typically use what is referred to as Low Impact Seismic (LIS) methods that minimize line widths and site disturbance and compaction. Typical 3D seismic lines are 2–3 m wide, constructed in 100–500 m spaced grids, and follow meandering rather than straight routes. There have been substantial improvements in the equipment used for 3D seismic line creation: low ground pressure mulchers, lighter equipment, ATV-mounted equipment, mushroom shoes and smear blades, and 'envirodrills' greatly reduce physical and vegetation disturbance (Dabros et al. 2018). These methods often leave the ground vegetation intact and only remove trees and tall shrubs, reducing overall disturbance and facilitating faster regeneration. The location of the seismic line can be adjusted on the fly in the field to minimize impacts, such as avoiding the cutting of large trees.

Continuous advancements in seismic exploration technology have improved geophysical accuracy while simultaneously reducing environmental impact. Numerous studies have examined the effects of linear disturbances on soil, hydrology, vegetation, regeneration, and wildlife responses (see Dabros et al. 2018 for a comprehensive review). Although the bulk of literature focuses on 2D seismic lines, as they have been part of the landscape for over 60 years, there have been several recent studies investigating the effects of LIS and 3D seismic lines (e.g., Kemper and Macdonald 2009a, Kansas et al. 2015, Golder Associates 2016).

Linear features have been associated with various environmental effects, including permafrost thaw, soil compaction and rutting, increased soil moisture and pooling, altered snow cover, temperature and wind patterns, and varied vegetation and wildlife responses (Dabros et al. 2018). In addition to the immediate loss of vegetation, linear features can create extensive edge effects, facilitate non-native or disturbance-induced species establishment, alter species composition, and positively and negatively affect wildlife (Dabros et al. 2018).

One of the most extensively studied effects of linear features in the southern boreal forest is the indirect effects that linear features can have on mortality risk to woodland caribou (*R. tarandus caribou*). Linear features can result in complex effects on populations dynamics that include (i) increases in secondary prey (moose and deer), which elevate wolf populations (apparent competition) and (ii) more efficient hunting by predators along linear features (facilitated predation) (Wittmer et al. 2007, Latham et al. 2011, Dickie et al. 2017a, Keim et al. 2019b, 2021). Research has also documented the responses of birds to linear features (Bayne et al. 2005, Machtans 2006, Lankau et al. 2013), bears (Tigner et al. 2014, Finnegan et al. 2018), and furbearers (Tigner et al. 2015).

Most studies investigating impacts and recovery of seismic lines and other linear features were conducted in southern boreal forest ecosystems (i.e., Boreal Plains Ecozone; e.g., Lee and Boutin 2006, Kansas et al. 2015, van Rensen et al. 2015, Dickie et al. 2017a). There are fundamental differences in the climate, vegetation communities, wildlife communities, and ecological processes in taiga ecosystems that may result in different patterns and responses to linear features. For example, regeneration patterns of linear features in taiga ecosystems over permafrost can follow different successional trajectories than those of southern boreal regions (Simpson 2008). The few studies that have examined linear features in taiga regions have found similarities and differences to southern studies revegetation (Kemper and Macdonald 2009, Dabros et al. 2018). One of the key objectives of this study was to collect local information from Eagle Plains that can be used to better contextualize or adapt the findings from other studies to the Eagle Plains Project.

3 METHODS

A GIS analyses and field surveys were conducted to characterize linear features within the RSA. The inventory of linear features in the RSA was developed in a GIS by compiling available spatial data and then verifying and updating that against satellite imagery. Field studies quantified the width, vegetation characteristics, ecological function (line-of-sight, large mammal ease of movement assessment), and visibility of lines from the Dempster Highway.

3.1 LINEAR FEATURES INVENTORY

The inventory of existing linear features in the RSA was developed in a GIS by compiling available spatial data and then verifying and updating that against satellite imagery. A preliminary linear feature database was first developed that was used to support field surveys (described below in this section). A second step linked the field data to the linear feature database and conducted a more thorough review and verification process using satellite imagery to produce a final linear feature dataset for the RSA (see details in section 3.5.1).

Linear feature spatial data were obtained from the following sources:

- Yukon Government Energy, Mines and Resources "Oil and Gas Seismic Lines" dataset (a combination of less detailed National Energy Board data pre-1999 and the more detailed company-submitted data post-1999) (Yukon Government 2019)
- Natural Resources Canada CanVec "Roads," "Trails," and "Cut Lines" 1:50,000 scale datasets (Natural Resources Canada 2019)

The two datasets were merged into one dataset of all linear features documented in Yukon and clipped to the RSA. Key attribute data included (if available) the linear feature type (i.e., 2D and 3D seismic lines, winter roads, trails, Dempster Highway), width, year of establishment, and data source. This preliminary linear feature dataset was compared against satellite imagery at a (minimum) 1:10,000 scale to verify its accuracy. Any linear features that did not correspond with features visible in satellite imagery were either corrected or deleted based on satellite imagery interpretation. In the case of duplicate features across datasets, the 'best' data were attributed to a single feature by considering the spatial accuracy and the amount and accuracy of attribute data, as assessed against satellite imagery. Where duplicate widths occurred in the two source datasets, the wider width was retained.

3.2 LINEAR FEATURE CHARACTERISTICS SURVEY

Field studies quantified the width, vegetation characteristics, line-of-sight, and large mammal ease of travel assessment across the linear feature types identified from the GIS inventory. One aspect of the field study was to compare vegetation, line-of-sight, and ease of movement on the linear features to undisturbed areas adjacent to the cleared lines. Three types of surveys collected data for the linear feature study: ground surveys

(finest level of detail), air surveys (medium level of detail), and air calls (coarsest level of detail). EDI crews collected field data between July 28 and August 8, 2019.

3.2.1 SITE SELECTION

All ground surveys and aerial surveys occurred at predetermined, random sites. Sample sites were selected using a clustered, random sampling approach. This approach balanced obtaining a random, representative sample across linear feature types with survey efficiency (i.e., without clustering sites, the travel time between points would have been substantially greater and resulted in smaller sample size). Survey sites were drawn from 5,000 points distributed randomly across the set of mapped linear features (minimum spacing of 200 m between points). Each point was randomly assigned a unique number.

Each survey cluster included options for both ground and air surveys. For ground surveys, the cluster used a 2 km radius designed to accommodate approximately four ground survey sites, intended to be surveyed within a half-day of work (and close enough so crews could walk between sites). The objective was that two ground clusters could be surveyed by a crew each day. For air surveys, a 4 km radius was used that generally provided at least ten random survey site options. The objective for air survey clusters was that they could be surveyed while transiting between ground survey clusters.

Survey sites were selected via a two-stage process. The first stage was randomly drawing 100 points from the 5,000-point dataset. These points defined the survey clusters and served as actual survey sites. In this first stage, site selection was stratified to obtain an approximately equal sample across 2D, 3D and winter roads. This overweighted sampling of 2D and winter roads, relative to their extents in the RSA, but those features had the highest uncertainty in terms of their widths, vegetation characteristics, and functional characteristics. Stratification was necessary to obtain sufficient sample sizes across these less-common features. The second site-selection stage selected additional random points from the 5,000-point dataset in proximity to the first point, using the 2 km radius for ground surveys and the 4 km radius for aerial surveys.

The RSA was divided into 10 work areas to implement the sample design, each corresponding to a day of surveys. Each day the survey crew selected clusters to survey using the ascending order of the random identification number of the first point used to define each cluster. Similarly, points within each cluster were prioritized in ascending order of the random identification number. Normally, at least two ground clusters and two air clusters were sampled each day. However, that varied somewhat depending on the number of sample sites available in each cluster and the availability of the helicopter.

3.2.2 LINEAR FEATURE CHARACTERISTICS AND SURVEY METHODS

3.2.2.1 Linear Feature Characteristics

A range of structural, vegetation, human use, and functional characteristics was assessed in the field. A list of the various characteristics examined, with a description of each, is provided in Table 3-1. Successional classes and structural stages of vegetation are defined in Table 3-2 and Table 3-3, respectively.

Table 3-1. Description of physical, ecological and function characteristics assessed in the Eagle Plains linear feature study.

Parameter	Description	Survey Measured [1]
Plot location	Latitude and longitude using WGS 1984, measured by Garmin GPS units to ~4 m accuracy.	G, AS, AC
Linear feature type	Dempster Highway, winter road, 2D, 3Dc (conductor lines), 3Dr (receiver lines), and 3D5 (3D lines used both for seismic and local equipment/vehicle travel.	G, AS, AC
Linear feature width	During ground surveys, measured to the nearest 0.05 m and replicated four times. During aerial surveys, they were visually estimated to the nearest 1 m.	G, AS
Percent mulch	Percent cover of mulch (wood chips) on the seismic line, estimated to the nearest 1% using visual estimates. In areas with dense trees or large shrubs, the thick mulch layer produced during line clearing can hinder vegetation regeneration.	G, AS
Successional class	Refers to the successional trajectory of vegetation regeneration on the linear feature. Includes normal, magnified, stagnated, retrogressive, no succession, or recent disturbance class following Simpson (2008)[1].	G, AS, AC
Burn status	Burnt or not burnt; based on visual assessment (i.e., burned trees, charred ground vegetation).	G, AS, AC
Structural stage	Categorical descriptor of the dominant vegetation life form in the plot following the *Field Manual for Describing Yukon Ecosystems* criteria (Environment Yukon 2017). Structural stage categories are defined in Table 3-3.	G, AS
Height and species of tallest vegetation	Measured to the nearest 0.1 m for the tallest vegetation layer, approximated by the 90th percentile height to exclude extreme heights of individual plants.	G
Cover and species of dominant trees	Percent cover was recorded to the nearest 1% if less than 10%, and to the nearest 5% if over 10%. One or two dominant tree species were recorded.	G, AS
Cover and species of dominant shrubs	Percent cover was recorded to the nearest 1% if less than 10%, and to the nearest 5% if over 10%. Up to five co-dominant shrub species were recorded. Ground shrubs were excluded.	G, AS
Ecosite	Ecosite was recorded using Predictive Ecosystem Mapping (PEM) Units, available at the time of the survey. However, separate vegetation surveys indicated that the accuracy of the PEM mapping was poor, and ecosites were not used in subsequent analyses.	G
Permafrost activity/degradation	Present or absent. Additional comments (i.e., type of activity, percent cover) were recorded if applicable.	G
Wildlife trails	Present or absent. If present, rated as poorly, moderately, or well defined.	G
Potential for Off-Highway Vehicle (OHV) passage	Present or absent. Based on professional judgment, a 4x4 side-by-side is summer, considering obstructing vegetation, ground conditions (e.g., wetlands, peatlands), and graminoid tussocks.	G, AS
Signs of human activity	Present or absent. If present, applicable comments were recorded.	G
Ground disturbance	Percent cover of visibly disturbed ground. If present, type and additional descriptive comments were recorded.	G

[1] G=Ground Survey, AS=Aerial Survey, AC=Air Call.

[2] Between 2006 and 2008, Yukon Government, Department of Energy, Mines, and Resources investigated the recovery status of linear features in the Eagle Plains, British Mountains, and Peel River Plateau Ecoregions (Simpson 2008). They found that linear features typically regenerated into one of six categories: normal succession, magnified succession, retrogressive succession, successional stagnation, no succession, and recent disturbance (Table 3-2).

Table 3-2. Descriptions of successional classes on linear features in the Eagle Plains area (following Simpson 2008).

Successional Class	Description
Normal succession	Vegetation is similar to the adjacent undisturbed area but often in an earlier seral stage. E.g., often young trees surrounded by early successional shrubs and forbs. The disturbance was likely limited to removing trees and shrubs, with little to no disturbance to soil or permafrost.
Magnified succession	Vegetation on the feature is taller than the adjacent undisturbed area. Deciduous species often dominate tree and shrub layers, but a similar pattern was also observed for coniferous trees on some sites. The response is likely due to increased site productivity (including increased soil moisture, nutrients, and temperature) due to soil disturbance or increased depth to permafrost. Most frequently, but not exclusively, observed in burns.
Retrogressive succession	Sites are typically moss or sedge-dominated (rarely forb or low shrub), with high moisture content, often including standing water (i.e., micro wetlands), that contrast to upland conditions in adjacent undisturbed areas. The condition appears to result from permafrost melting and water pooling associated with vegetation removal and removal/compaction of the peat layer and mostly associated with winter roads.
Successional stagnation	Vegetation is typically dominated by graminoids or shrubs and not progressing to more advanced successional stages. Disturbance to soil or permafrost is likely. The ground may have been compacted. Almost exclusively associated with winter roads.
No succession	No ecological differences between the linear feature and adjacent undisturbed areas except that there is no or very little tree or shrub regeneration on the line, other than what was left after creation of the feature. Disturbance appears to be limited to the removal of trees and shrubs, with little to no disturbance to ground vegetation, soil, or permafrost.
Recent disturbance	Newer seismic line where successional patterns could not be determined. Features in this class were most likely trending to 'normal succession' or 'no succession', but the degree of regeneration was too limited to classify confidently.

Table 3-3. Structural stage categories used in ground and air surveys for the Eagle Plains linear feature study.

Structural Stage Code	Structural Stage Name	Description
1	Non-vegetated	Very recent disturbance (e.g., fire or flood) and no vegetation or less than 5% vegetation.
2	Sparse/Cryptogram	Either the initial stages of primary succession or a cryptogram community maintained by environmental conditions (e.g., bedrock, talus). Sparse tree, shrub and herb cover. Either sparsely vegetated overall (low cover of vascular plants and cryptograms, if present) or dominated by cryptograms.
2a	Sparse	5–10% vegetation cover.
2b	Bryoid	Bryophyte-dominated.
2c	Lichen	Lichen-dominated.
3	Herb	Early successional stage (e.g., post-fire forest succession) or a herb community maintained by environmental conditions or disturbance. Vegetation is dominated by herbs, although if the site overall is sparsely vegetated, herb cover can be low as long as herbs characterize the vegetation. Trees and shrubs are usually sparse or absent; however, shrub cover and stature (compared to herb cover and stature) determine whether the site is considered herbaceous.
3a	Forb-dominated	Includes non-graminoid herbs and ferns.

Structural Stage Code	Structural Stage Name	Description
3b	Graminoid-dominated	Includes grasses, sedges, reeds, and rushes.
3c	Aquatic	Floating or submerged plants dominate.
3d	Ground shrub-dominated	Dominated by dwarf woody species such as kinnikinnick (*Arctostaphylos uva-ursi*) or dwarf willows.
4	Shrub	Early successional stage of a forest or a shrub community maintained by environmental conditions or disturbance. Dominated either by shrubby vegetation, including tree seedlings or saplings; or, if sparsely vegetated overall, dominated by shrubs, which characterize the community as a shrubland.
4a	Tall Shrub	Dominated by woody plants >2 m tall with diameter at breast height (dbh) ≤7 cm.
4b	Low Shrub	Dominated by woody plants <2 m tall.
5	Treed: Pole/Sapling	Trees >2 m tall and with dbh >7 cm, typically densely stocked. Self-thinning and vertical structure are not yet evident in the canopy. Younger stands are vigorous (usually >15 to 20 years old); older stagnated stands (up to 100 years old) are also included; time since disturbance usually <40 years; up to 100+ years for dense (5,000–15,000+ stems per ha) stagnant stands.
6	Treed: Young Forest	Self-thinning has become evident and the forest canopy has begun to differentiate into distinct layers. A more open stand than at the pole/sapling stage.
7	Treed: Mature Forest	Trees established after the last stand-replacing disturbance have matured; a second cycle of shade-tolerant trees may have become established; shrub and herb understoreys become well developed as the canopy opens up.
8	Treed: Old Forest	Stands of old age with complex structure; patchy shrub and herb understoreys are typical; regeneration is usually of shade-tolerant species with a composition similar to the overstorey. Fire-maintained stands may have a single-storey appearance.
9	Treed: Very Old Forest	Very old stands with complex structures, abundant large trees, snags and coarse woody debris (CWD); snags and CWD occurring in all stages of decomposition; stands are comprised entirely of shade-tolerant overstorey species, with well-established canopy gaps.

3.2.2.2 Survey Methods

Three types of surveys assessed linear feature characteristics: ground surveys (finest level of detail), air surveys (medium level of detail), and air calls (coarsest level of detail). The reason for using different survey types was to maximize the sample size obtained, recognizing that the ability to collect certain types of data, or the level of measurement precision, decreased from ground surveys to aerial surveys to air calls. The characteristics that were measured during each survey type are noted in Table 3-1. Surveys were conducted between July 28 and August 8, 2019.

Ground surveys collected the most information and had the highest measurement precision of the three survey methods. All parameters listed in Table 3-1 were recorded. Field measurements generally followed methods in *Field Manual for Describing Terrestrial Ecosystems* (BC MFLNRORD and BC MOE 2010) with parameter specific details noted in Table 3-1. Photographs were taken of representative on-line and off-line plots.

Air surveys collected moderate resolution data on linear features. Air surveys efficiently collected a larger quantity of more generalized data than ground surveys. The subset of parameters recorded for aerial surveys is noted in Table 3-1. The survey methods generally followed procedures outlined for helicopter-based 'visual checks' in *Standard for Terrestrial Ecosystem Mapping in British Columbia* (Resources Inventory Committee 1998). Data were collected by hovering in a helicopter approximately 30 m over the sample sites for approximately three minutes while field crews recorded data for the reduced set of variables. Like ground surveys, relevant data were collected for both on-line and off-line plots. Photographs were taken at representative air survey plots (Attachment A).

Air calls collected data at the coarsest resolution of the three survey types, and no off-line data were collected. The data collected during air calls were limited to linear feature type, successional class, and burn status. Air calls were opportunistically conducted when EDI crews were flying through the RSA and linear features were encountered.

A fundamental aspect of the field study was to compare linear feature characteristics to adjacent undisturbed areas. Hence, field surveys included paired on-line and off-line plots at each sample site (excluding sites assessed via air calls). Off-line plots were located 50 m off the linear feature, with the direction off the feature selected randomly at each site using a coin toss. Data collected for each sample site were recorded on tailored survey forms (Attachment B).

3.2.2.3 Line-of-Sight and Ease of Travel

In addition to the structural and vegetation measures noted above, line-of-site and ease-of-movement were assessed as functional characteristics of the linear features at each ground plot. The sightline, measured to the nearest metre, was calculated as the farthest line that could be sighted using a range finder at the height of 1.5 m off the ground. Two measurements were recorded, one in each direction along the linear feature. Sightline measurements were repeated using the same bearings in the off-line plot.

Ease of travel was assessed using a 'walk test,' as Keim et al. (2019a) described in a study assessing the functional recovery of linear features. They found that ease of travel, as measured by a walk test conducted by human researchers, positively correlated with the intensity of use by several wildlife species. One EDI crew member timed themselves to the nearest second for the walk test while walking an approximately 75 m transect, measured to the nearest metre using a hip chain. This walk test was repeated in both the on-line and off-line plots, the paired transects spaced in parallel, approximately 50 m apart. The same observer conducted both walk tests to minimize observer bias at each site.

3.3 VISIBILITY OF LINEAR FEATURES FROM THE DEMPSTER HIGHWAY

One of the management concerns associated with seismic exploration is that seismic lines create travel routes that humans use. The probability of human use of seismic lines to access the surrounding landscape likely increases if the seismic line is visible and accessible from roads. The intersections of seismic lines and winter roads with the Dempster Highway are the primary locations where this could originate. Driving surveys were conducted along the 47 km section of the Dempster Highway within the RSA to determine the number and

type of linear features that could be located and accessed by the public from the Dempster Highway. Two types of surveys were conducted: a blind search where the location of the linear features was unknown and a 'map search,' where the observers had a map of the linear features that showed where they occurred. Both surveys were conducted on August 8, 2019.

The blind search approximated the proportion and type of linear features that the public could locate and access without prior knowledge of their locations. An EDI field crew drove along Dempster Highway at 35 km/h and attempted to identify linear features by visual inspection alone, unaware of where they intersected the highway. When a linear feature was identified, the crew stopped to record the following parameters:

- linear feature type;
- sight line distance;
- evidence of human use;
- evidence of wildlife use; and
- potential for OHV passage.

Photographs were taken, and relevant comments were recorded for each linear feature intersection where applicable.

The map search was a targeted search designed to approximate the proportion and type of linear features the public could spot from the Dempster Highway with prior knowledge of their locations. Using a map of linear features present in the RSA, an EDI field crew drove along the Dempster Highway, slowing to 10 km/h and attempting to identify the linear features when passing a point where the map showed they intersected the highway. When a linear feature intersection was reached, the crew recorded whether the line was visible or not and the parameters listed above for the blind search where a line was detected.

3.4 WINTER TRACK SURVEY

An aerial survey was conducted to assess the relative frequency of use of different liner feature types by ungulates and humans in late winter (March 2020). The survey consisted of 11 transects spanning the width of the RSA. Three of the transects were established parallel to the Dempster Highway at 50 m, 1 km and 5 km off the highway. The remaining transects were spaced approximately 5 km apart across the remainder of the RSA.

Before the field survey, each transect was established in a GIS. Each intersection with a linear feature was given a unique identification point and used to generate a field form (i.e., with a row for each linear feature intersection). The field survey involved flying along each transect and recording the presence of ungulate tracks or human tracks (e.g., snowmobile tracks) at each linear feature that was traversed. Surveys were conducted via helicopter at approximately 70 km/h, 50 m above the ground, with one navigator/data recorder and one primary observer. The surveyors classified tracks to species and counted the number of unique tracks. However, overlapping tracks and dustings of new snow made track identification and counts uncertain in over

half the detections. Therefore, analyses defaulted to the simple presence/absence of ungulate tracks. The primary metric examined was the proportion of linear features with ungulate tracks.

The original survey plan was also to count tracks in undisturbed areas between linear features. However, tracks were so numerous that surveying the entire area between linear features would have required substantially reducing the aircraft speed. This would have reduced the number of transects that could have been surveyed. As a compromise, field crews subsampled the area between lines by surveying an approximate 200 m band of an undisturbed area adjacent to each linear feature.

In conjunction with winter fish habitat assessments, the transects were surveyed over six days (March 7–13, 2020). Each day, one or two transects were surveyed while transiting to/from the study area. No track-erasing snowfalls occurred during the survey period. Snow depths ranged from 65 to 80 cm.

3.5 DATA PREPARATION AND ANALYSIS

3.5.1 SPATIAL DATA

The project generated two primary spatial datasets — a point database corresponding to all field survey sites and the linear feature database. The Linear Feature Survey Point Database (ArcGIS point feature class) contains all location-specific (point coordinate) field data collected at sample sites in summer 2019. Several fields were added to this database based on calculations and spatial joins (e.g., year of linear feature establishment and most recent fire). Paired on-line and off-line plot data were recorded as part of the same sample site coordinate.

The Linear Feature Inventory (ArcGIS polyline feature class) is a compilation of all documented linear features within the RSA, verified by comparing the preliminary linear feature inventory to aerial and satellite imagery and ground-truthing results.

Several modifications were made to improve the accuracy and detail of the Linear Feature Inventory:

- Linear features were classified into the following categories:
  - 2D (historical seismic lines, typically >3m wide),
  - 3D5 (including 4–5 m wide 3D lines that were used for both seismic and local vehicle/equipment travel);
  - 3Dc (3 m wide 3D seismic conductor lines);
  - 3Dr (2 m wide 3D seismic receiver lines);
  - winter roads (any trails or limited use roads used by vehicle or equipment, generally wider than 5 m and often with an obviously curving path); and,
  - Dempster Highway.
- Overlapping features (within a 3 m tolerance) were addressed according to the following rules:

- If two linear features of the same or unknown age overlapped, the wider feature was saved and the narrower feature deleted.
- If two linear features of the same or unknown width overlapped, the more recent feature was saved and the older feature deleted.
- If a 3D line overlapped with a 2D line, both lines were saved. This is because the older 2D lines were often still evident on the landscape in some state of regeneration, as were the 3D lines. However, both were saved since it was unknown at what state each line was in (i.e., if the 2D line was still evident, or only the 3D line, or both in varying states of regeneration). This occurred for 33 km of linear features within the RSA.

The preliminary linear feature inventory within the RSA was compared against a recent high-resolution satellite or aerial imagery (generally, 0.5–1 m resolution) at a 1:10,000 (or finer) scale to verify the accuracy of the source data. Any features that were visibly offset from georeferenced imagery were corrected to match the imagery.

Some older (1960s and 1970s) 2D seismic lines included in the source databases did not appear in satellite imagery. These 2D lines were compared against the imagery along the length of the feature to search for any sign of linear disturbance and then cross-referenced with field surveys conducted along the line, if present. These unverified linear features were classified as 'not applicable' and excluded from analysis if there was no evidence of linear disturbance along the feature's length in the imagery, which could often be verified with associated surveys noting that the feature was 'not present,' 'not visible,' or 'completely regenerated.' Unverified linear features were retained if there was evidence of linear disturbance along any feature's length in the imagery or if associated surveys had noted that the feature was present and in some state of regeneration, even if the feature was not visible in the imagery. A total of 199,473 m of erroneous or regenerated linear features were deleted from the linear feature inventory within the RSA.

Some linear features were visible on the imagery that had not been included in any of the source databases. In these cases, the linear features were manually digitized and classified into linear feature types based on visual assessment and attributes of adjacent connecting features, if present. Digitized linear features were assigned a year if they were obviously a continuation of a documented feature or if they were surrounded by features of the same type and year. Otherwise, the year was not included. High-resolution imagery was not available for the southernmost portion of the RSA (approximately 25 km by 15 km). This area was compared against lower quality Google Earth imagery, but this was not detailed enough to detect undocumented linear features if any existed (Google Earth 2019). However, existing linear features were verified using this method. A total of 202,945 m of linear features were digitized within the RSA.

After the Linear Feature Inventory was verified and corrected to be consistent with imagery and field observations, it was spatially joined to the Linear Feature Survey Point Database. In cases where the survey point did not correspond with any nearby linear feature, or if a linear feature was deleted (following the methods described above), the data were retained in the survey point database, but the linear feature type was updated to 'not applicable' and excluded from data analysis. Ten survey plots were identified as 'not applicable' and excluded from analyses; thus, the corrected sample size for survey plots is n = 210.

3.5.2 FIELD DATA

After completing field sampling, data forms and field notes were reviewed for completeness and accuracy during an internal data quality-assurance process. All associated digital photographs and GPS coordinates were reviewed to correspond to the appropriate field plots. A summary of field plots by linear feature type and survey type is provided in Table 3-4. All recorded data were entered into MS Excel databases (Microsoft 2019). Spatial data were uploaded to the ArcGIS platform (ESRI 2019).

Field-collected data were summarized primarily using Excel spreadsheets (Microsoft 2019). More detailed statistical analyses were performed on select data using R Statistical Software (R Development Core Team 2020). For example, the variation in ease of travel and vegetation cover as a function of linear feature types, burn history, successional stage, or ecosite were explored. During formal analyses, standard assumptions of normality and homogeneity of variance were assessed, and variance-covariance structures were applied to model heterogeneity (of residuals) if required. For instance, the sightline distance (m) was fourth-root transformed to meet normality. In certain models, random effects were included to account for variance among different subjects. For example, observers were included as a random variable to account for observer bias (i.e., a random intercept model; package "nlme", Pinheiro et al. 2016). Corrected Akaike's Information Criteria (AICc) scores were used to compare sets of candidate models. Models with the lowest AICc score were selected because they yielded the best balance (parsimony) between explained variance and level of complexity.

Table 3-4. The number of sites surveyed using ground surveys, air surveys, and air calls for each linear feature type in the Eagle Plains RSA.

Linear Feature Type	Survey Type			
	Ground Survey	Air Survey	Air Call	Total
2D	31	32	44	107
3D-5m wide	5	0	0	5
3D-Conductor	26	3	0	29
3D-Receiver	23	1	0	24
Winter Road	18	17	8	43
Dempster Highway	2	0	0	2
Not Applicable	3	2	5	10
Total	108	55	57	220

3.5.3 LINEAR FEATURE DENSITY CALCULATION

Linear feature densities were calculated in two ways: (1) using the total linear feature extents, and (2) adjusting the extents to account for (a) lines through 'open' habitats, such as wetlands and recent burns, where the vegetation on the line did not differ from vegetation off the line, and (b) functionally recovered linear features such as 2D lines from the 1960s and 1970s that had advanced regenerated at least to the Tall Shrub structural stage. Adjustments were determined by intersecting the Linear Feature Inventory with a recently developed

Ecological Landscape Classification (ELC) map of the RSA (a companion Eagle Plains Project baseline report). The ELC map documented the type and structural stage of vegetation communities across the RSA. The extent of linear features in open habitats was determined by the lengths of linear features overlapping Low Shrub, Herb and Bryoid structural stages in the ELC maps. This includes seral habitats regenerating from burns and ecosystems that are maintained in those stages over time, such as wetlands and shrub-carrs. The extent of regenerated linear features was determined by integrating the proportion of regenerated lines observed from the field surveys (e.g., 61% for 2D lines) with the length of lines through non-open vegetation types in the ELC map. Adjustments were applied to generate functional linear feature densities for each linear feature type individually (i.e., to compare the relative extents of different feature types) and combined to provide an overall density for all linear feature types. For example, the linear feature density for 2D lines was calculated by starting with the total length of 2D lines in the RSA, reducing that by the length of lines through open vegetation types, then reducing the remaining extent by the average proportion of 2D lines that were observed to be regenerated, and then dividing the remaining total length of lines by the extent of the RSA.

4 RESULTS

4.1 LINEAR FEATURE INVENTORY AND DENSITIES

A total of 4,269 km of linear features were mapped and verified in the RSA (Map 4-1, Table 4-1). Winter roads and 2D seismic occur in varying densities across much of the RSA. The extent of 3D seismic is limited to the one area straddling the Dempster Highway in the centre of the RSA.

The total linear feature density in the RSA was 1.79 km/km², based on a total length of 4,269 km and the RSA area of 2,386 km². 3D seismic lines accounted for approximately half of the total length of linear features in the RSA, 2D seismic lines accounted for about one-third, followed by winter roads and the Dempster Highway (Table 4-1). Adjusting for open habitats (i.e., areas in structural stages Low Shrub, Herb, and Bryoid) and vegetation regeneration[1] resulted in substantially lower densities of 0.52 km/km² (Table 4-2). Relatively large extents of recent wildfires were the greatest factor reducing linear feature densities. The relative proportions of the different linear feature types were similar after adjustments, though the proportion of 3D increased and 2D decreased. This was mainly due to the greater degree of vegetation regeneration on 2D lines, consistent with their age since disturbance.

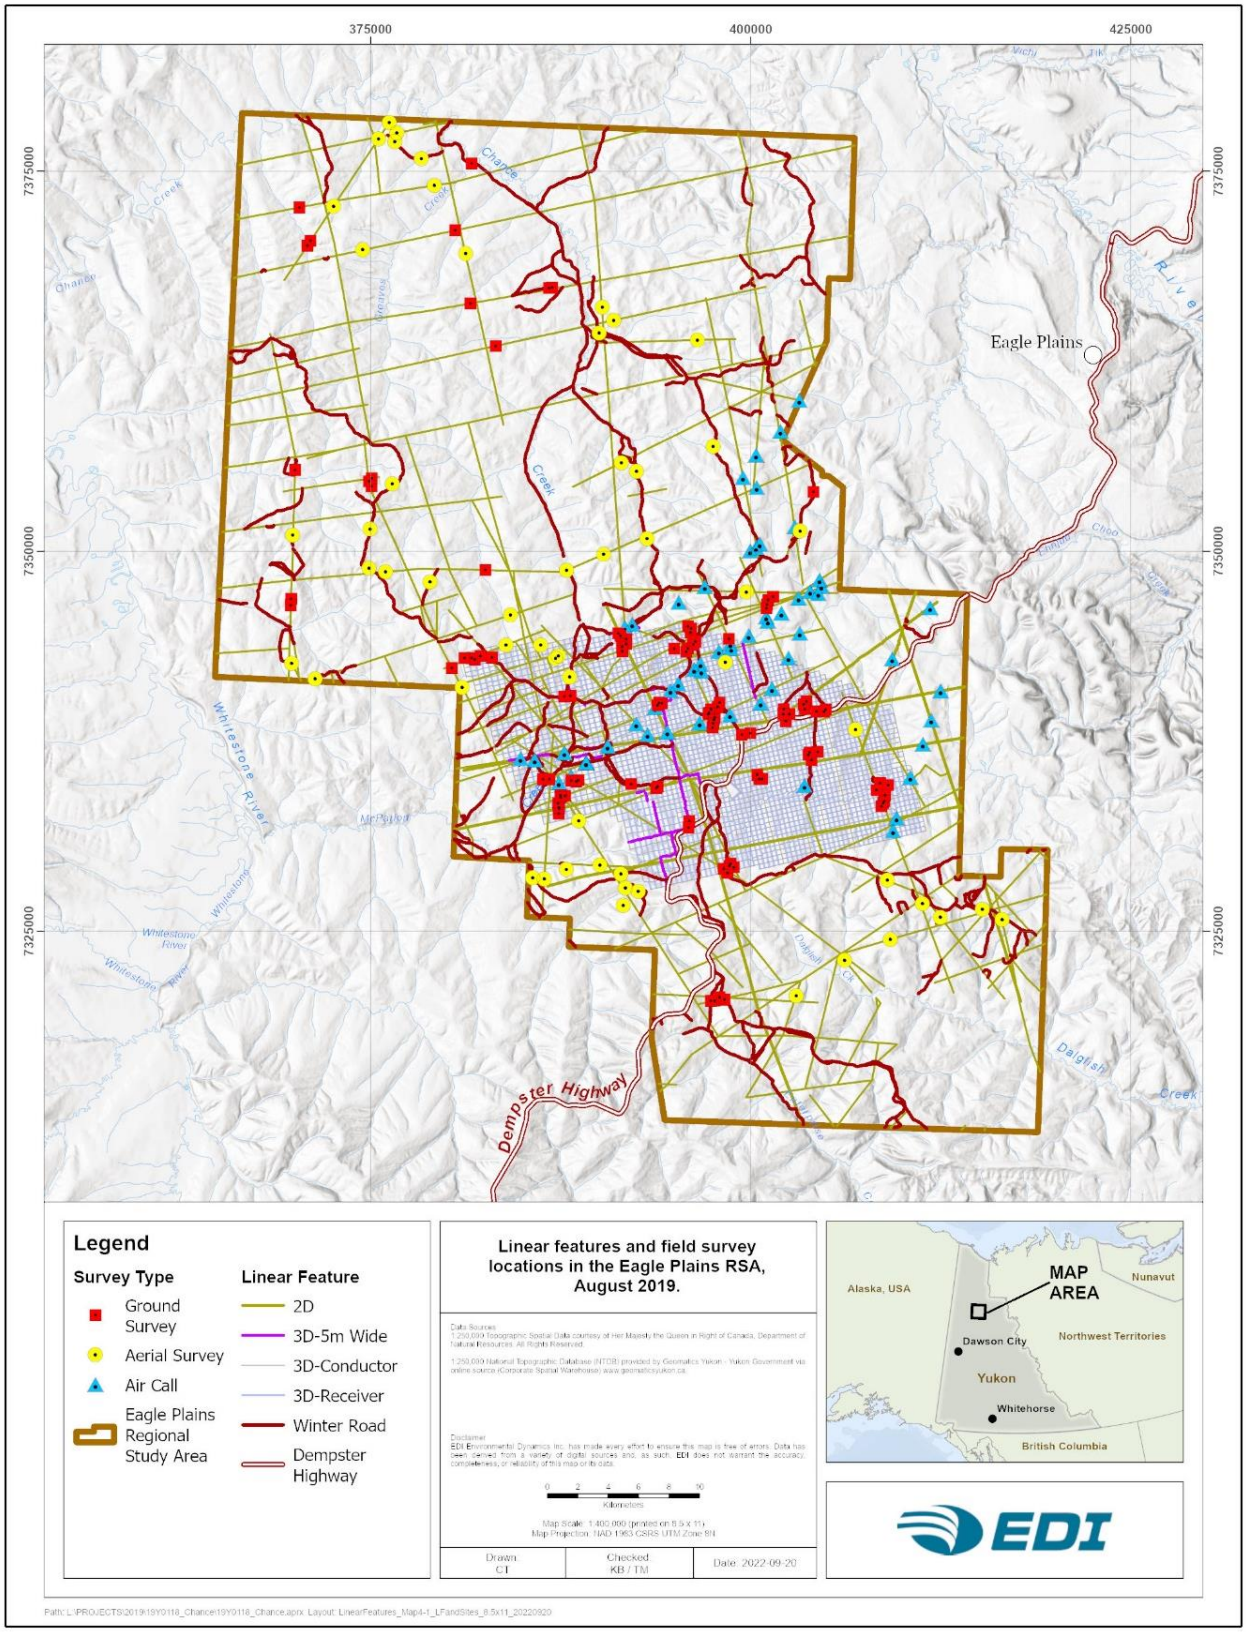
Table 4-1. Summary of total length and density of linear features documented in the Eagle Plains RSA.

Linear Feature Type	Total Length (km)	The Proportion of Total Length	Linear Feature Density (km/km²)
2D	1,452	34%	0.608
3D (combined)	2,165	51%	0.907
3D-5m wide	48	1%	0.020
3D-Conductor	1,189	28%	0.498
3D-Receiver	928	22%	0.389
Winter Road	596	14%	0.250
Dempster Highway	47	1%	0.020
Unknown	8	<1%	0.003
Total	**4,269**	**100%**	**1.788**

[1] See Section 5.5 Functional Recovery of Linear Features for details about vegetation regeneration criteria.

Table 4-2. Summary of total effective length and density of linear features in the Eagle Plains RSA adjusted for open habitat and vegetation regeneration.

Linear Feature Type	Total Length (km)	Proportion of Total Length	Linear Feature Density (km/km²)
2D	289	23%	0.121
3D (combined)	750	60%	0.314
3D-5m wide	21	<1%	0.009
3D-Conductor	401	32%	0.168
3D-Receiver	328	26%	0.138
Winter Road	171	14%	0.072
Dempster Highway	26	<1%	0.011
Unknown	8	<1%	0.003
Total	1,243	100%	0.521



Map 4-1. Linear features and field survey locations in the Eagle Plains RSA, August 2019.

4.2 LINEAR FEATURE CHARACTERISTICS

4.2.1 LINE WIDTHS

Line width varied by linear feature type. Mean line widths ranged from 1.96 m for the narrowest line type (3D receiver lines) to 33.75 m for the Dempster Highway (Table 4-3). Standard error around mean estimates were smallest for 3D seismic lines, which were cleared in the same season using the same equipment and methods, and greatest (by a large margin) for winter roads. The average difference in widths between 3D conductor (wider) and 3D receiver lines was 1.2 m.

Table 4-3. Widths of different linear feature types in the Eagle Plains RSA.

Linear Feature Type	n	Minimum mean width (m)	Maximum mean width (m)	Overall mean width (m)	Standard Error (m)
2D	107	3.97	8.5	5.42	0.11
3D-5m wide	5	5.30	6.40	5.68	0.22
3D-Conductor	29	2.50	4.80	3.17	0.13
3D-Receiver	24	1.63	2.53	1.96	0.04
Winter Road	43	2.53	17.97	7.42	0.66
Dempster Highway	2	33.00	34.50	33.75	0.75

4.2.2 MULCH COVER

Mulching of woody vegetation is common during seismic line clearing activities and was used in the 2013/14 3D program. In areas with thick tree or shrub cover, mulching can create a thick blanket of wood chips that inhibits vegetation regeneration (Golder Associates 2016). There was no evidence that this was an issue with any of the seismic lines within the RSA. On average, the percent cover of mulch was <1% on all line types.

4.2.3 HUMAN USE

No sign of human use was detected along linear features during the summer ground surveys (e.g., OHV tracks, ruts, water crossings, vegetation trampling/scarring, tree blazes, trap sets, garbage, and campsites), except for the two sites on the Dempster Highway.

On average, 42% of on-line sites were deemed passable to an OHV (a 4x4 side-by-side) during summer, considering obstructing vegetation, ground conditions (e.g., wetlands or peatlands), and the presence of graminoid tussocks (Table 4-4).

Table 4-4. Proportion of survey sites deemed passable to OHV in summer across different linear feature types in the Eagle Plains RSA.

Linear Feature Type	No. Survey Sites	% Passable
2D	55	9%
3D-5m wide	5	80%
3D-Conductor	29	59%
3D-Receiver	24	75%
Winter Road	29	55%
Dempster Highway	2	100%
Total	144	42%

4.2.4 SUCCESSIONAL CLASSES

Linear features surveys in the Eagle Plains RSA observed five of the six of the successional classes documented by Simpson (2008): normal succession, magnified succession, stagnated succession, no succession, and recent disturbance (Figure 4-1) (Attachment A). No retrogressive succession sites were observed at official survey sites. However, a small number of retrogressive sites were incidentally observed on winter roads while travelling through the RSA.

Most sites surveyed (79%) were undergoing normal succession. The next most common successional class was magnified succession, occurring in 11% of sites, followed by stagnated succession, occurring in 5% of sites. All 3D seismic lines surveyed followed a normal successional trajectory, except for one site that was classed as recently disturbed. Magnified succession was most common in 2D seismic lines (21%), while stagnated succession was most common in winter roads (19%). Successional classes were defined as 'not present' if the linear feature was not present in the field or had regenerated to a stage that was not discernable from the adjacent areas. The Dempster Highway was classified as recently disturbed due to the regular maintenance of the road.

Fire history appeared to influence some successional classes. Magnified succession was more common at burnt sites (19 burnt versus 5 unburnt). In contrast, stagnated succession was more common at unburnt sites (3 burnt versus 7 unburnt). Sites on a normal successional trajectory did not appear to have any relationship to burnt status. The remaining successional classes were too uncommon to draw any conclusions.

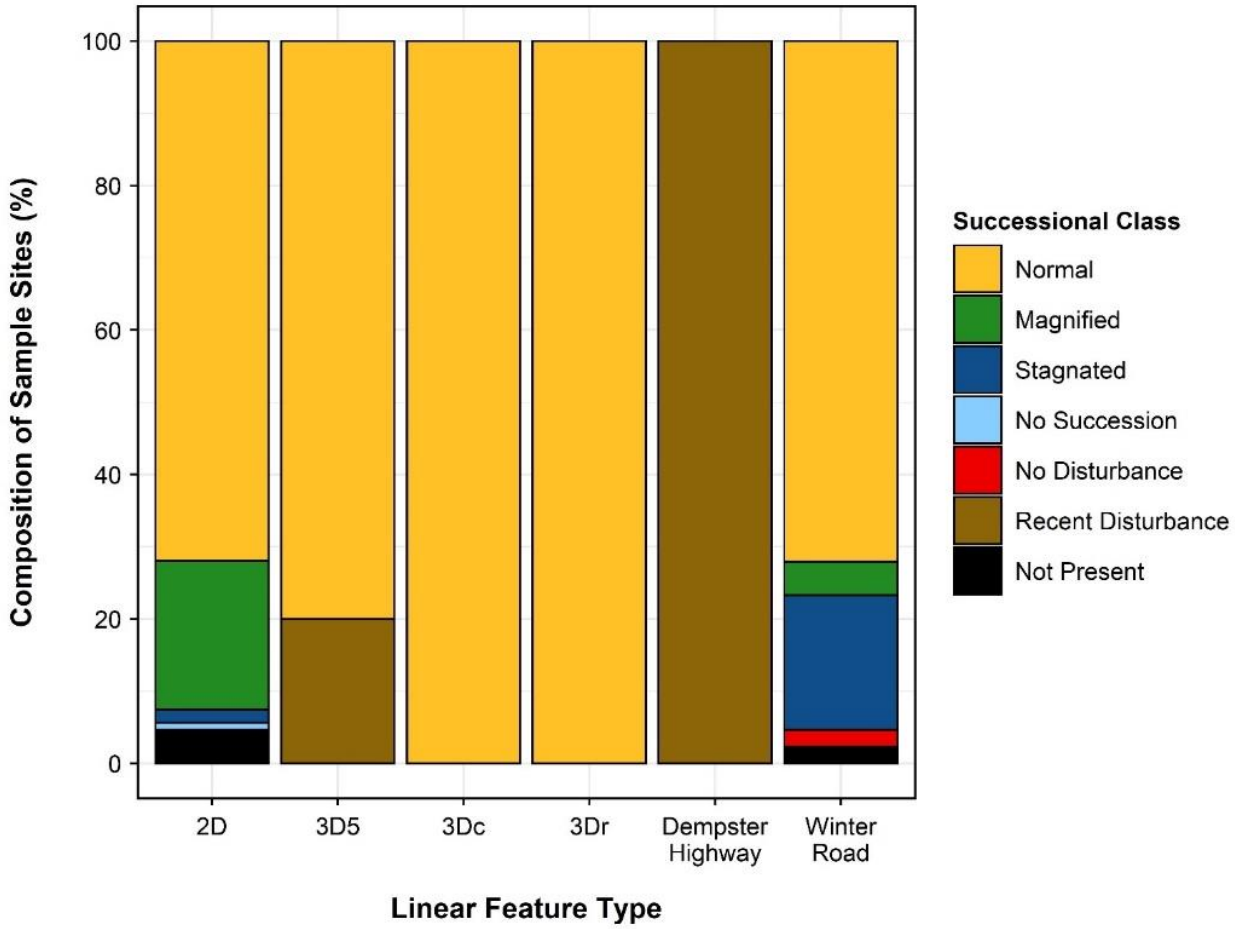


Figure 4-1. Summary of successional classes observed across different linear feature types in the Eagle Plains RSA.

4.2.5 STRUCTURAL STAGE

Most linear features were in a Low Shrub (56.1%) or Tall Shrub (29.0%) structural stage. However, the distribution of structural stages varied substantially across linear feature types (Table 4-5). Although herbaceous and forested stages occurred at some on-line plots, they were not common (less than 5%each). Nearly all forested structural stages were observed on 2D seismic lines and winter roads, reflecting the long time since they were created. Tall Shrub stages were almost twice as frequent in 2D seismic lines than any other linear feature type. Conversely, 83% of 3D linear features were in the Low Shrub structural stage, with most of the remaining in the Tall Shrub stage. The differences in structural stages between 2D and 3D lines appear to be primarily due to the time since disturbance. Winter roads were less consistent in their structural stages; herbaceous, shrubland and forested stages were all observed with moderate frequency. The two Dempster Highway plots were the only non-vegetated stages recorded.

Off-line plots were also mostly in Low Shrub and Tall Shrub stage, but they also included a higher proportion of Young Forest and Mature Forest compared to on-line plots (Table 4-5; Photos A-15 to A-20 in

Attachment A). For off-line plots, the Low Shrub sites were mostly burned areas, and the Tall Shrub sites were mostly stunted, open-canopy, black spruce forest 2–8 m tall.

Fire had a strong effect when comparing structural stages between paired on-line and off-line plots (Figure 4-2). The top two charts in Figure 4-2 show that the pattern of structural stages for burnt areas was very similar between on-line and offline plots. The bottom two charts show that the pattern of structural stages differs substantially between on-line and offline plots in unburnt areas. In unburnt areas, off-line plots had much lower numbers of sites in Low Shrub and much higher numbers of sites in Young Forest and Mature Forest than on-line plots. For burnt areas, the on-line and off-line plots at the same site were the same structural stage in 72% of cases, and within one structural stage of each other 91% of the time (e.g., Tall Shrub vs Pole Sapling). For areas that were not burnt, the on-line and off-line plots at the same site were the same structural stage in only 29% of cases. These results demonstrate that in the absence of fire, pronounced differences between linear disturbances and the surrounding community are evident in both recent (3D) and legacy (2D and winter road) linear feature types. But following a fire, the vegetation structure on-line and off-line are likely to be similar (Photos A-22 to A-24 in Attachment A).

Table 4-5. Vegetation structural stages observed on different linear feature types as a proportion of all plots sampled (n = 156) in the Eagle Plains RSA.

Linear Feature Type	No. Sites	Structural Stage[1]								
		Non-vegetated	Bryoid	Herb	Low Shrub	Tall Shrub	Pole-Sapling	Young forest	Mature forest	Old Forest

[1] See Table 3-3 for structural stage codes and descriptions.

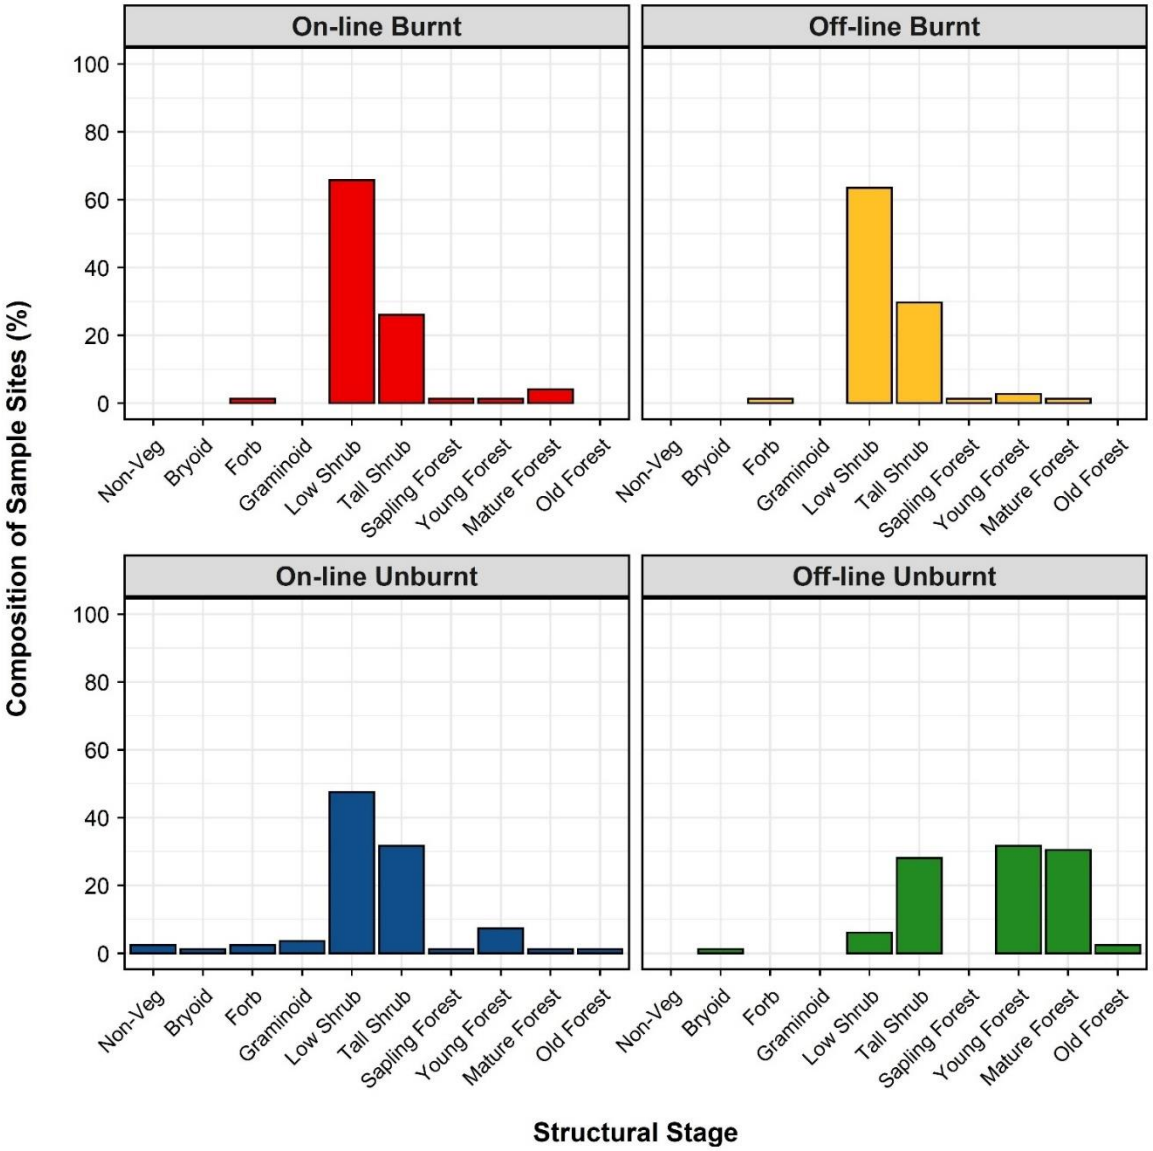

Figure 4-2. Comparison of structural stages on linear features to off-line plots in burnt and unburnt areas, in the Eagle Plains RSA.

4.2.6 VEGETATION HEIGHT

Based on the similarity of patterns in vegetation composition and structure, linear feature types were combined into two groups for assessment of patterns in height: (i) 2D and winter roads and (ii) 3D. A wide range of vegetation heights was recorded at both on-line and off-line plots in the RSA, from 0.3 m to 16 m. Collectively, off-line plots had a normal distribution of vegetation heights between 0 m and 4 m, and then a scattered distribution across heights up to 16 m (Figure 4-3). Plots with ≥4 m tall vegetation accounted for approximately 40% of all off-line reference plots.

In comparison, recovering 2D seismic lines and winter roads shared a relatively uniform distribution between 0 m and 4 m but with a peak occurring at vegetation heights measuring 1.5–2 m tall (Figure 4-4). Only 21% of 2D and winter roads contained dominant vegetation ≥4 m, and only 5% were ≥8 m tall. 3D seismic lines were rarely composed of vegetation ≥2 m, and most of the vegetation (67%) recovering on 3D lines was less than 1 m (Figure 4-5). This is very different from the off-line undisturbed height distribution. However, 3D lines were all only five years old at sampling, and shorter vegetation was expected.

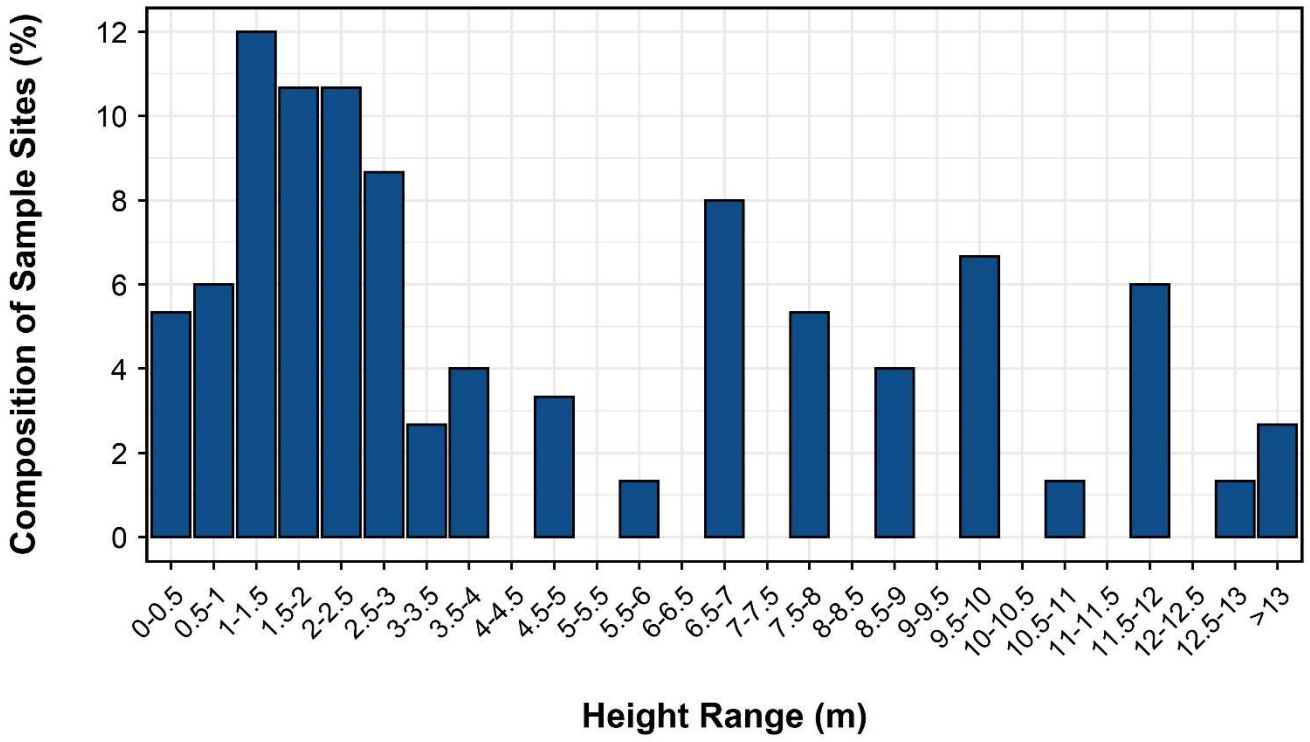

Figure 4-3. Vegetation height distribution of off-line reference plots in the Eagle Plains RSA.

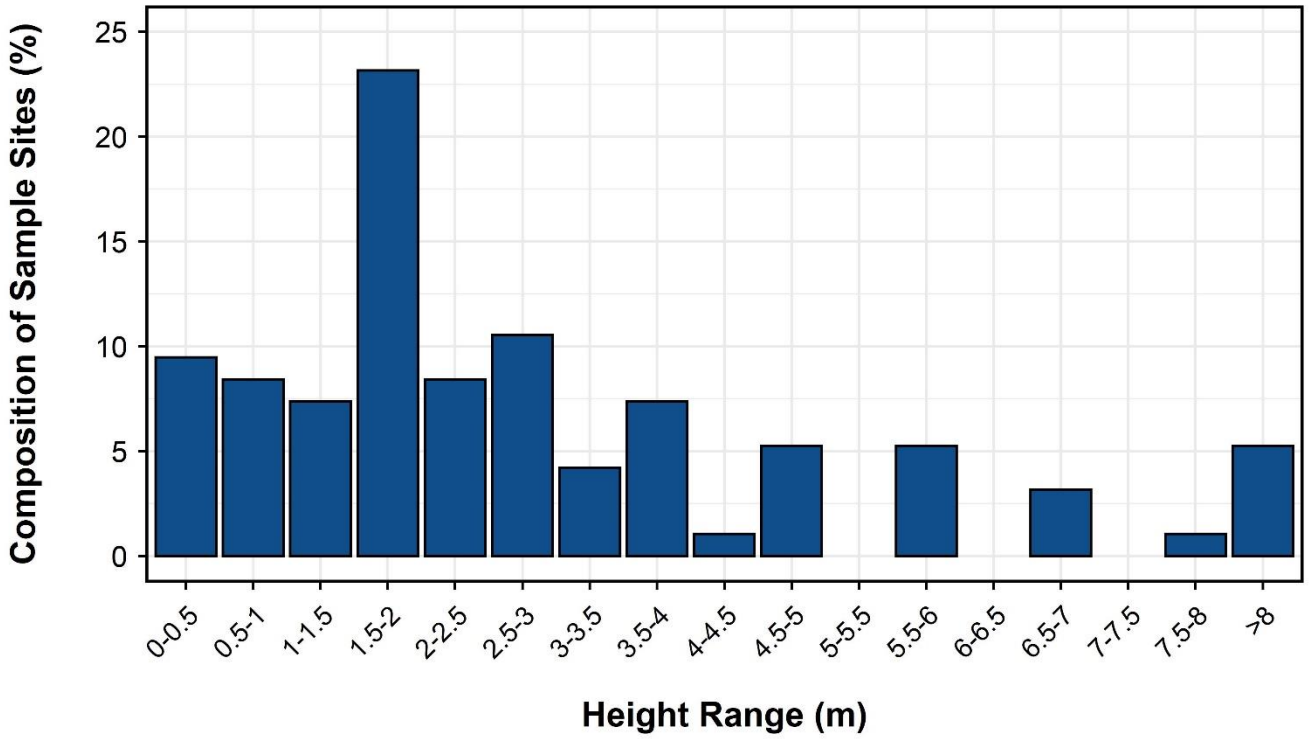

Figure 4-4. Vegetation height distribution of on-line 2D and winter road plots in the Eagle Plains RSA.

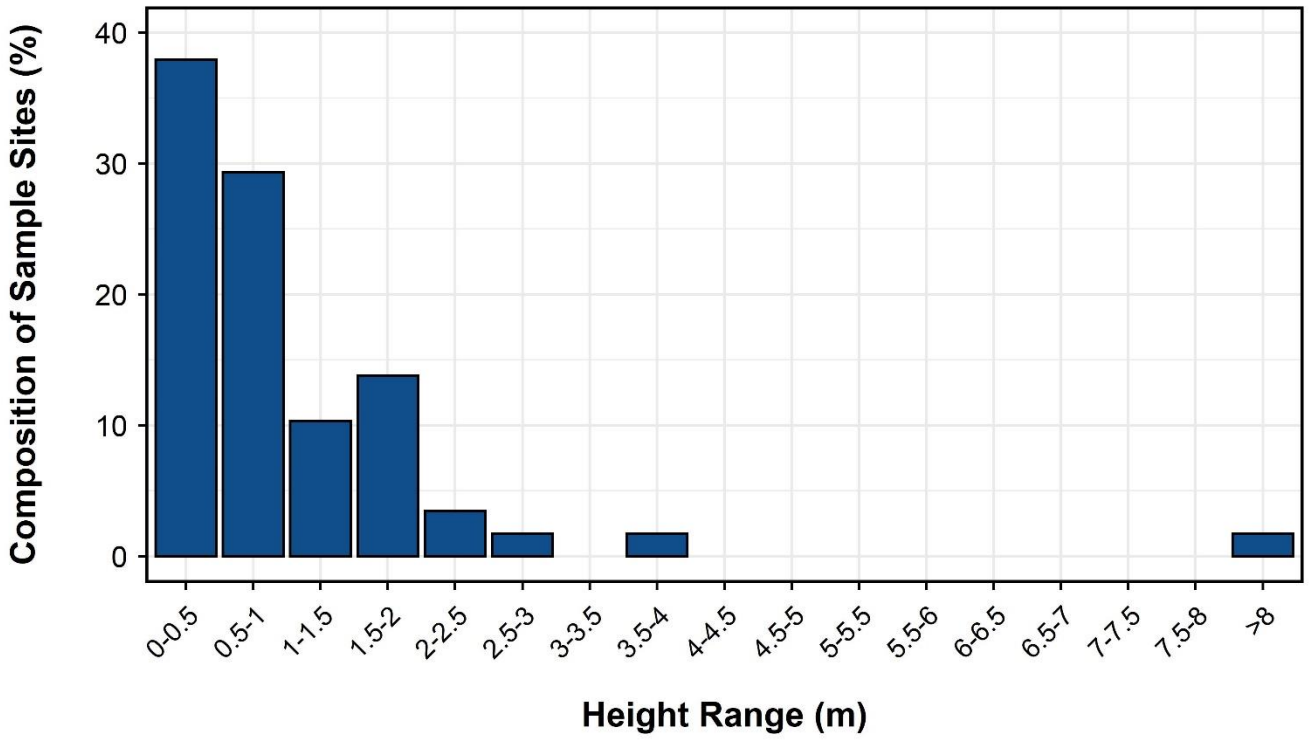

Figure 4-5. Vegetation height distribution of on-line 3D plots in the Eagle Plains RSA.

4.2.7 VEGETATION COVER

Tree and shrub cover varied between linear feature types and burn status (Table 4-6). Generally, tree cover was low on undisturbed reference plots (mean tree cover of 8% on unburnt and 2% on burnt sites). This is typical of the taiga cordillera landscape — forests are generally stunted and sparse due to poor nutrient regime and continuous permafrost conditions (Smith et al. 2004). Of the on-line plots, tree cover was greatest on 2D seismic lines and burnt winter roads (5% to 8%) and lowest on 3D seismic lines and the Dempster Highway (0%), regardless of burn status. This is likely due to the recently disturbed 3D seismic lines that are too young for trees to have re-established. Burnt 2D seismic lines and winter roads had greater tree cover than unburnt lines.

Shrub cover was much greater than tree cover overall. Shrub cover was typically 30–40% on unburnt off-line plots and 40–50% on burnt off-line plots. Shrub cover was highest on 2D seismic lines (~54%), regardless of burn status. Shrub cover was moderate on winter roads (38–45%) and lowest on unburnt 3D seismic lines (8–22%). Burnt 3D seismic lines had approximately twice as much shrub cover as unburnt 3D lines.

Table 4-6. Summary of the mean tree and shrub cover (%) between on-line and off-line, and burnt and unburnt plots surveyed in the Eagle Plains RSA.

Linear Feature Type	Burn Status	Mean Tree Cover (%)		Mean Shrub Cover (%)	
		On-line	Off-line	On-line	Off-line
2D	Burnt	7.0	3.5	54.0	36.0
	Unburnt	5.5	13.4	53.2	32.8
3D5	Burnt	0.0	0.3	41.7	60.0
	Unburnt	0.0	0.5	7.5	42.5
3Dc	Burnt	0.0	0.2	40.4	46.1
	Unburnt	0.4	6.0	21.5	34.3
3Dr	Burnt	0.0	0.7	35.0	51.9
	Unburnt	0.0	5.5	20.6	32.5
Winter Road	Burnt	7.7	1.0	45.0	43.8
	Unburnt	1.3	4.0	37.5	32.3
Dempster Highway	Unburnt	0.0	1.0	0.0	37.5

4.2.8 LINE-OF-SIGHT AND EASE OF TRAVEL

Line-of-sight (sightline) distance was examined primarily as a function of line type; however, vegetation height (the primary factor affecting sightlines) was also examined for on-line and off-line plots for each linear feature type using multiple linear regression. Mean sightlines varied significantly by linear feature type (Table 4-7, $F_{4,187} = 3.3$, $P = 0.01$). For reference, the average sightline distance for offline controls was 46.7 m. This relatively far distance reflects the open stand structure on most sites in the region. Burn status had little influence on sightlines (e.g., burnt off-line=50.2 m, unburnt offline=43.6 m). 2D lines had the shortest average sightline distances at 41.2 m. This was mainly due to the advanced stage of regenerating vegetation on the lines. Where regenerating vegetation was limited, sightline distances on 2D lines frequently exceeded 150 m.

On 3D lines, the time since clearing was too recent for regenerating vegetation to obscure sightlines. Instead, sightline distances on 3D lines were generally controlled by bends in the lines, which were specifically designed as mitigation measures to reduce sightlines. For 3D lines, sightline distances decreased from 3D5 to 3Dc to 3Dr lines. The reduction in sightline distances resulted from differences in line width and the average distance between bends across the feature types.

The regression analysis also found a significant interaction between on-line versus off-line occurrence and vegetation height ($F_{1,187}$ = 13.0, P = 0.0004), whereby on-line plots had, on average, more negative slopes than off-line plots. In other words, sightlines at on-line plots decreased more drastically than off-line plots with each incremental increase in vegetation height. This is consistent with the qualitative observations of field crews that the regenerating vegetation on lines was thicker than the vegetation off lines.

Similar to sightline distances, determining differences in ease of travel among line type the primary factor of interest for the walking speed tests. However, burn status, and the percent cover of trees and shrubs were expected to be the most important explanatory variables related to walk speeds, so they were included as secondary variables using a mixed-effects linear regression. Walking speeds across linear feature types and the differences between on- and off-line plots within linear feature types varied significantly (Table 4-8, $F_{5,170}$ = 3.4, P = 0.006). However, the magnitude of the difference between on-line and off-line plots was modest. Even the Dempster Highway only conveyed a 35% increase in walking speed over off-line plots. Other researchers, in other areas, often observed walk speeds on linear features were often at least twice as fast as off-line transects (Keim et al. 2019a).

Notwithstanding the modest magnitude of faster walking speeds on-lines, there were clear patterns in walking speed differences across linear feature types. 2D lines were the one feature type where walking speeds were slower on lines than off lines. This reflected the thick, shrub stage vegetation that had regenerated on most 2D lines, which impeded travel (similar to the effect that regenerating vegetation had on sightline distances in the previous section). Walk speeds decreased across the other feature types in relation to line width and the degree to which ground cover was levelled or compacted.

Statistical analyses indicated that both burn status ($F_{1,170}$ = 17.85, P < 0.0001) and percent cover of shrubs and trees (hereafter woody vegetation; $F_{5,170}$ = 5.29, P = 0.0002) affected walking speeds, both on and off lines. On average, walk speeds in burns were approximately 10% slower than in unburnt areas. This is partly related to thicker woody cover in most burns, which hinders walking speed because of the time it takes to push through or walk around it. Walking speeds significantly decreased, on average, by 0.04 (CI = 0.02–0.06) km/h and with every 10% increase in the percent of woody cover off-line and 0. 11 (0.07–0. 15) km/h on 2D lines.

Table 4-7. Average sightline distances along different linear feature types in the Eagle Plains RSA.

Linear Feature Type	n	Average Sightline Distance (m)	Comments
2D	30	41.2	Sightlines are frequently reduced by regenerating vegetation >1.5m tall
3D-5m	5	105.6	Has fewer bends than 3Dc and 3Dr
3D-Conductor	26	75.9	Sightlines limited by bends in lines; too recent for regenerating vegetation to impede sightlines
3D-Receiver	23	60.2	Sightlines limited by bends in lines; too recent for regenerating vegetation to impede sightlines
Dempster Highway	2	814.8	
Winter Road	17	106.2	
Off-Line Controls	103	46.7

Winter Road	16	3.6	3.1	17%
Off-Line Controls	97	n/a	2.9	

4.3 VISIBILITY OF LINEAR FEATURES FROM THE DEMPSTER HIGHWAY

Overall, the blind search identified 11 of 100 possible linear feature intersections with the Dempster Highway (Table 4-9). Five of the features were roads that were classified as winter roads in the GIS inventory, but most (four) were actually short, all-season roads leading to gravel pits or well sites. Two of the observed features were human truck/OHV trails that led to camp sites 100–200 m off the Dempster Highway, and four were 3D seismic lines. The map search detected two more 3D lines, one 2D line, and one old winter road. The 2D line and the old winter road had regenerated into Young Forest structural stages. Excluding the four short secondary roads into gravel pits and well sites, and the two human trails, only 8% of linear features that intersected the Dempster Highway were visible during the two driving surveys.

Only 6 of the 74 3D lines that crossed the Dempster were detected. The combination of construction design (i.e., creating a bend in the 3D line adjacent to the highway) and regenerating vegetation in the right-of-way made it difficult to detect the 3D lines. Evidence of human use (e.g., packed vegetation, tire tracks, rutting, garbage, campfire remnants, tree stumps, or tree blazes) was observed on four of the short, all-season roads

and the two trails. No evidence of human use was noted on any of the 2D or 3D seismic lines, or the three winter roads (including the Chance and Blackie winter roads). However, some types of human use do not leave sign during the snow-free season (e.g., snowmobile use in the winter).

Table 4-9. Summary of linear features identified and intersecting the Dempster Highway during a blind search test.

Linear Feature Type	No. Features Intersecting the Dempster	No. (%) Observed Blind Search	No. (%) Observed Map Search	Total No. (%) Observed	OHV Accessible	Sign of Human Use
2D	18	0 (0%)	1 (6%)	1 (6%)	0	0
3D	74	4 (5%)	2 (5%)	6 (8%)	4	0
Secondary Roads	8	5 (63%)	1 (13%)	6 (75%)	5	4
Trail	n/a	2 (n/a)		2	2	2
Total	100	11 (11%)	4 (4%)	15 (15%)	11	6

4.4 WINTER TRACKS

In total, 462 linear features were surveyed for winter tracks over 358 km along the 11 transects. No human sign was observed on any linear features, except the Dempster Highway. Ungulate tracks were frequently observed travelling along linear features. The proportion of linear features with tracks decreased with decreasing linear feature widths, from 29% on winter roads, 24% on 2D lines, 8% on 3D conductor lines, and 6% on 3D receiver lines (Figure 4-6).

The frequency of use in adjacent undisturbed areas, corrected to account for different survey extents between the linear features and the undisturbed areas, was 1%. As discussed in the methods, it was difficult to compare the frequency of use along linear features to use in undisturbed areas. The issue is that for the comparison to be relevant, the survey design needs to account for the size of the sample units (i.e., the extent of the undisturbed area needs to be comparable to the width of the linear features), and the two samples should be independent. These conditions were not achieved under the current survey design (i.e., the extent of the survey area in the undisturbed area was much larger than the width of the linear feature, and the location of the undisturbed area was spatially correlated to the linear feature). The estimated relative use rate of 1% in undisturbed areas adjusts the total counts within the 200 m survey area to 5 m (i.e., the average linear feature width); however, the adjustment fails to account for spatial correlation between the two samples. Therefore, the estimate of use in undisturbed areas could be biased. Notwithstanding this limitation in the estimate of travel rates in undisturbed areas, it is supported by qualitative observations of the survey crew that travel rates on even the least used linear features (i.e., 3D lines) are higher than undisturbed areas.

The relative use of linear features by ungulates also appeared to vary with distance from the Dempster Highway, with features within 1 km of the highway receiving lower use than features equal to or greater than 5 km from the highway (Figure 4-7). It is worth noting that the Highway and 1 km transects were completed on the first and second day of surveys, respectively, and the other transects were surveyed one to six days later, providing more time for tracks to accumulate. Snowfall data prior to the crew's arrival on site was not

available; however, road crews at Eagle Plains reported that there had not been a major snowfall in the area for at least a week. Based on this information, the issue of time since last snow has less potential to bias results than if a track-erasing snow event had recently occurred.

[1] as characterized by reaching a tall shrub stage, or greater.
[2] including stagnated and disturbed successional patterns.
[3] accounting for burns, natural openings, and regeneration.
[4] percent of lines with ungulate tracks during March 2020.

2D Seismic — 2D lines are, on average, the oldest features in the area and have had the longest time to regenerate. Most features were cleared before 1985, but some were developed in the early 2000s. Historical 2D lines were generally long and straight, with moderate widths of 4–8 m. Lines were typically constructed with bulldozers that cut into the moss layer and often included some patches of soil disturbance. The combination of site disturbance and wider widths generally resulted in a successional reset to pioneering vegetation (including early seral graminoids, forbs, and shrubs). Most sites were following a normal successional pathway (73%). However, 27% of sites exhibited atypical pathways, dominated by magnified succession (21%, mostly in burns), stagnated succession (3%) or no succession (1%). Sixty-one percent of the 2D sites had regenerated to a Tall Shrub or more advanced structural stage. 2D lines had the shortest sightlines and slowest walk test speeds of all feature types (including off-line controls), reflecting the regenerating vegetation's effect on these functional metrics. During winter, ungulates regularly used 2D lines to travel along.

3D Seismic — All 3D lines were created during the last exploration period, during the winter of 2013/14. 3D lines constitute the most extensive combined lengths of the different linear feature types, but their areal extent is limited to a relatively small portion of the RSA along the Dempster Highway. Due to their basic design, as well as specific mitigations, 3D lines minimize environmental effects compared to other linear feature types. They are narrow (averaging 3.2 m and 2.0 m for conductor and receiver, respectively), often

narrower than average tree spacing in the region. They were constructed during winter, over snow, using low-ground pressure equipment, which avoids ground disturbance and maintains vegetation in the moss, herb and low shrub layers. The lines were constructed with a meandering path, and strategically placed sharp angle dogleg bends to reduce the visibility of the lines from roads, reduce sightlines along them, and hamper travel by OHVs. All 3D lines that were surveyed were undergoing a normal successional pathway and were dominated by the same vegetation as in adjacent undisturbed areas. Regenerating vegetation was mostly in a Low Shrub structural stage, consistent with the relatively short six-year period since they were cleared. Sightlines and movement speeds were intermediate compared to other linear feature types, with sightlines primarily controlled by dogleg bends purposely designed to reduce sightline distances. Ungulates occasionally used 3D lines to travel on in winter, but at less than a third of the rate as 2D lines and winter roads.

Winter Roads — A network of winter roads across much of the RSA results from the historical exploration programs that have occurred. Although many of the winter roads were initially developed during the earliest exploration programs, vegetation has not had the same opportunity to regenerate as on 2D lines because the vegetation was re-cleared on several roads during subsequent exploration programs. The average width of winter roads was 7.4 m, but major roads, like the Chance road, were often 10–12 m wide. Historical winter roads were typically cleared with a bulldozer, and then snow was packed and graded to create a road surface. Similar to historical 2D seismic, the combination of site disturbance and wider widths (i.e., that increases solar exposure) generally resulted in a successional reset to pioneering vegetation (including early seral graminoids, forbs, and shrubs). Most sites were following a normal successional pathway (72%), but 26% of sites exhibited atypical pathways, dominated by stagnated succession (19%), magnified succession (6%) and no succession (1%); 2% of the sites were classified as no disturbance (indistinguishable from vegetation community off the road). Thirty-nine percent of the winter road sites had regenerated to a Tall Shrub or older structural stages. Winter roads had the longest sightlines and fastest walk test speeds of all feature types, other than the Dempster Highway, reflecting the variable levels of regenerating vegetation that occurred on winter roads. During winter, ungulates regularly used 2D lines for travel.

Dempster Highway — The Dempster Highway is the only all-season road in the RSA (except for short spurs off the Dempster to well sites and gravel pits). It is fundamentally different from all other linear features in the area in terms of wide width, surface material and maintenance, long sightlines, regular traffic, and base of access for human land use activities such as hunting, camping, and trapping.

5.2 LINEAR FEATURE CHARACTERISTICS

5.2.1 FIRE

The presence or absence of recent forest fires affected several linear feature characteristics, including linear feature width, successional class, structural stage, and vegetation height and cover. Mean measured linear features widths were 0.2–0.6 m wider at burnt sites than at unburnt sites. This may be due to the already shorter vegetation at burnt sites, which would reduce overgrowth occurring from forest edges and decrease the measured width between driplines (branches extending into the linear feature from either side of the line).

Magnified succession was nearly four times more common in burnt plots than unburnt plots, and stagnated succession was half as common. Fire likely facilitates magnified succession by increasing soil temperatures, accelerating decomposition, and releasing stored water and nutrients to promote vegetation growth (Seccombe-Hett and Walker-Larsen 2004, Simpson 2008). Stagnated succession is likely less common at burnt sites because the associated nutrient and water increase allows woody plant species to colonize more easily and advance through successional stages.

Overall structural stage distribution was very similar between burnt on-line and off-line plots, but was markedly different between unburnt on-line and off-line plots. Furthermore, when the structural stages were compared between paired on-line and off-line plots, they matched two to four times more frequently at burnt sites than at unburnt sites and were mismatched two to six more frequently at unburnt sites than at burnt sites. Nearly all burnt plots were in a low shrub, or tall shrub structural stage, which is expected as fires tend to remove overstory trees, and shrubs generally colonize rapidly post-fire (Seccombe-Hett and Walker-Larsen 2004).

Vegetation height was 4.4 m shorter in burnt than unburnt reference plots, and tree cover was approximately 6% less. These modest differences reflect the stunted and open nature of the taiga forest. There was little change in vegetation height between burnt and unburnt linear features, likely because there were very few linear disturbances in a forested structural stage; most of them, even in unburnt conditions, were already in a shrub-dominated stage due to the clearing of trees. For shrub cover, except for 2D seismic lines, the mean was approximately 10% to 20% greater at burnt plots than at unburnt plots. The increase in shrub cover at burnt sites was most prominent in 3D seismic lines due to their comparatively lower pre-fire shrub cover.

Post-burn vegetation was, on average, shorter and shrubbier than unburnt off-line plots, but taller and shrubbier than unburnt on-line plots. Furthermore, burnt paired plots were more similar in vegetation characteristics than unburnt paired plots. This evidence supports the theory that forest fires in taiga ecosystems resets the landscape to some extent and effectively erase signs of anthropogenic disturbance (Seccombe-Hett and Walker-Larsen 2004, Simpson 2008). Forest fire in the taiga returns ecosystems to an early successional stage (i.e., low shrub) and synchronizes baseline biophysical conditions on a landscape scale, allowing previously disturbed and undisturbed areas to recover at equal rates, as has been documented by Seccombe-Hett and Walker-Larsen (2004). Thus, most linear features that have experienced forest fires no longer create different ecological conditions or functional disturbances than the surrounding landscape.

5.2.2 SUCCESSIONAL CLASS

The idea that vegetation regeneration on linear features could follow different successional trajectories came out of work by the Yukon Government in the early 2000s (Simpson 2008). That work described six successional trajectory classes observed in the Eagle Plains area. However, that study did not quantify the relative extents of linear features that followed the different trajectories. This study used the classes that the Yukon Government work developed and quantified the proportion of linear features in each successional class across a random sample of linear features.

Successional classes in the Eagle Plains RSA varied according to linear feature type and burn status. However, one of the key findings was that normal succession was the dominant trajectory observed for all linear features except the Dempster Highway. All 3D seismic lines followed a normal successional trajectory, except for one recently disturbed site. This was likely attributable to the low impact methods used in 3D line creation that minimize ground and vegetation disturbance, creating conditions more likely to result in a normal successional trajectory (Yukon Energy Mines and Resources 2006, Golder Associates 2016). Magnified and stagnated succession were only observed in 2D seismic lines and winter roads. These linear features were generally wider and were created using methods that cause greater disturbance to soils, hydrology, and vegetation, leading to these alternative successional trajectories (Simpson 2008, Jorgenson et al. 2010, Dabros et al. 2018). Magnified succession is unique among the classes in that it results in accelerated vegetation regeneration. Magnified succession was most common on burned 2D seismic lines where the combination of site disturbance associated with the 2D lines and fire is suspected of causing accelerated soil warming, moisture availability, and nutrient flush, which increase on-line vegetation growth (Simpson 2008). Successional stagnation was most common on unburnt winter roads. Stagnation tends to occur on features that have experienced ground disturbance or have been seeded to agronomic species, which may have happened on winter roads in the RSA (Simpson 2008). Repeated disturbance associated with multiple exploration programs over time may also limit successional advancement and contribute to successional stagnation (Lee and Boutin 2006, Jorgenson et al. 2010).

Although some alternative successional pathways were observed in this study, most linear features in the Eagle Plains RSA are following a normal successional trajectory. This implies that most of these disturbances will recover to an ecological condition like that of the surrounding community with adequate time.

5.2.3 STRUCTURAL STAGE

The taiga forest in Eagle Plains presents a unique situation where the Tall Shrub stage is applied to two very different stand conditions. One condition, the more traditional, is of regenerating stands following a natural or anthropogenic disturbance. In this setting, the vegetation consists of deciduous shrubs and 2–8 m tall, 10–30 years old trees. The stage is transitional, with the vegetation expected to advance to the Pole-Sapling stage over time. The second condition where the Tall Shrub stage is applied is to stunted, old, black spruce stands in a disclimax state. In this setting, the vegetation consists of open, stunted, black spruce stands that are typically ≥50 years old and 2–8 m tall. Stands in this condition are expected to remain in the same condition over time(i.e., a disclimax state). Structurally, the stunted black spruce trees function more like shrubs than trees. Both Tall Shrub conditions (referred to as disturbance and disclimax forms hereafter) are widespread across the RSA in off-line sites. Only the disturbance form was observed on linear features.

The structural stage on linear features was predominantly Low Shrub or Tall Shrub, determined mainly by the time since line clearing and burn status. Less than 4% of surveyed features were in forested stages (Pole-Sapling or greater). Off-line plots had a higher proportion of forested structural stages (37%). However, they were still predominantly Low Shrub and Tall Shrub, resulting from extensive burns across the RSA and large extents in the disclimax form for Tall Shrub in un-burned areas.

The structural stage of on-line plots was also influenced by successional class. The small number of forested structural stages observed on features only occurred on sites undergoing normal succession. Stagnated succession was associated with only the Herb structural stage, which was expected as stagnation is defined by its high herbaceous species cover (among other factors) that limits the establishment of other structural groups. Magnified succession was the one atypical successional class with accelerated vegetation growth. Most structural stages on sites with magnified succession were in Tall Shrub and, occasionally, Pole/Sapling. Often the structural stage on magnified succession sites was one stage greater than the off-line plot.

5.2.4 VEGETATION HEIGHT

This study observed a range of vegetation heights across different feature types. Except for the 3D lines, the linear features' age was unknown, so it was impossible to estimate growth rates. Although some regenerating vegetation on 2D seismic lines and winter roads reached 8 m high, most were between 1.5 m and 2 m. Though the ages of specific features were mostly unknown, the minimum age for most was at least 35 years. Having most vegetation heights at only 1.5–2.0 m after this long period suggests regeneration growth rates on linear features may be quite slow. This pattern of slow vegetation growth on linear features may partly reflect the generally poor growing conditions in the taiga region. Still, it is also a pattern that has been observed on linear features in other studies in the southern boreal forest.

Interestingly, the vegetation heights on linear features in Eagle Plains are greater than reported in several other studies. For example, approximately 65% of sites on linear features in northeast Alberta had not advanced beyond a cover low forbs after 35 years (Lee and Boutin 2006). Key factors that have been linked to slow vegetation regeneration on linear features were continued human disturbance (e.g., OHV travel), ecosystem type (bogs and fens regenerated much slower than upland sites), competition from early seral and invasive graminoids and forbs, and soil or site degradation associated with feature construction (Lee and Boutin 2006, van Rensen et al. 2015, Finnegan et al. 2018).

There is limited data on vegetation regeneration in the taiga. A study from NWT found that vegetation regeneration on conventional seismic lines was affected by both a time lag for seedling establishment (as long as 17 years for black spruce) and slow growth rates (83 years to reach 5 m) (Seccombe-Hett and Walker-Larsen 2004). In burned areas, the seedling establishment delay was reduced to five years.

Although the 3D lines in Eagle Plains were only six years old when they were surveyed, a combination of field survey results and information from other studies suggests that vegetation recovery on 3D lines could be much faster than the previous examples for conventional 2D lines. This is because the undisturbed ground conditions and maintenance of the vegetation community in the moss, forb and low shrub layer provide both plants and growing conditions that support faster shrub and tree growth compared to sites beginning primary succession. In northeast British Columbia, Golder Associates (2016) found that in the first year following 3D seismic line creation, there were already black spruce seedlings exceeding 0.5 m in height. These seedlings were plants that were initially present on the site and that had survived line clearing. This is consistent with the results of this study, where nearly all of the 3D plots contained black spruce seedlings. Despite their relatively young age, most 3D seismic lines in Eagle Plains included shrubs and trees between 0.5 m and 1 m

tall. Although growth rates in Eagle Plains are not known, similar species that occur in Eagle Plains were observed to grow 5–10 cm per year on 3D lines in the boreal forest in northeastern British Columbia (Golder Associates 2016). If similar growth rates occur in Eagle Plains, regeneration on the 3D lines can be 2 m over the next 5–20 years.

5.3 HUMAN USE AND ACCESS ALONG LINEAR FEATURES

The NYRLUP and the PWRLUP indicate that one of the primary concerns about linear features is that they can increase human access into remote areas. This has been demonstrated in southern regions, and that access can have secondary effects of inhibiting vegetation regeneration (Lee and Boutin 2006) and, in winter, packing snow that can affect predator-prey dynamics (Latham et al. 2011, McKenzie et al. 2012, Keim et al. 2019a). In the boreal forest in northern Alberta, OHV travel was common on most conventional 2D seismic lines. After 35 years, approximately 20% of the lines were considered to have been converted to tracked access routes (Lee and Boutin 2006). In the same study, about 65% of the lines remained cleared after 35 years, and OHV use along the lines was identified as one factor contributing to the lack of vegetation regeneration. In contrast, there is little evidence of human use along linear features in the Eagle Plains RSA. No sign of human use was detected along linear features during the summer ground surveys (e.g., OHV tracks, ruts, water crossings, vegetation trampling/scarring, tree blazes, trap sets, garbage, campsites, etc.) or the winter track survey (e.g., snowmobile tracks). Although these surveys provided limited snapshots in time, and that some types of human activity leave little sign (e.g., evidence of snowmobile tracks have limited persistence during winter and leave no sign behind after snow melt), the results suggest that human use of the area is very limited outside of the Dempster Highway corridor. This is consistent with general comments from highway workers, staff at the Eagle Plains Hotel, pilots, and some First Nation residents that most areas beyond the Dempster Highway corridor receive very little human use. Specific instances of use of the area outside the Dempster Highway corridor include intermittent activity on the community trapline that occurs in Eagle Plains and occasional forays by hunters (First Nation and non-First Nation), mostly in winter.

People's limited use of the Eagle Plains area is likely due to its far distance from any human settlements and the difficulty of travel off the Dempster Highway. The network of winter roads in the area does provide access via specific types of OHVs in summer and snowmobiles in winter. However, there was no evidence observed that this occurs regularly. Travel along seismic lines, though possible in specific locations, would be hampered over any substantial distance by vegetation regeneration along the historical 2D lines, the narrow widths of and frequent dogleg bends in 3D lines and, during summer, difficult terrain (extensive peatlands and graminoid tussocks).

5.3.1 EFFECTIVENESS OF MITIGATION MEASURES FOR 3D SEISMIC LINES

In addition to the narrow widths of 3D lines, which hampers OHV travel, the 3D lines included regular bends in the lines, which were designed to limit the visibility of the lines at intersections with roads and other seismic lines, and to hamper OHV along the lines further. The driving survey along the Dempster found that this mitigation was very effective in reducing the visibility of the 3D lines from the road (i.e., only 6 of the 74 3D

lines intersecting the Dempster Highway were visible). Incidental observations during ground surveys observed similarly reduced visibility of 3D lines crossing winter roads. Regular bends in the 3D lines away from roads were also designed to limit human access by reducing sightlines and making travel more difficult along the line (i.e., needing to reduce speed to navigate the tight turns of a dogleg bend approximately every 70 m).

5.4 FUNCTIONAL CHARACTERISTICS OF LINEAR FEATURES

In addition to human travel, linear features can also affect how wildlife move within a landscape. Several studies in western Canada have documented the effects of linear features on the movements and population dynamics of large mammals, such as caribou, moose, deer, wolves and bears (Latham et al. 2011, McKenzie et al. 2012, Dickie et al. 2017b, Keim et al. 2019a). EDI focused on two established indicators of human and wildlife access and travel on linear features: sightline distance and ease of travel. These measurements act as a proxy for the functional recovery of disturbed areas. They are mainly dependent on vegetation height, cover, and terrain.

5.4.1 LINE-OF-SIGHT

Line-of-sight or sightline distance is how far one can see under normal conditions and was compared between linear features and paired reference plots. It has been proposed that humans and predators select linear disturbances because it is easier to travel and detect prey using those features (Finnegan et al. 2018). As vegetation grows taller and denser, sightlines diminish, and the use of linear features decreases (e.g., for wolves, Dickie et al. 2017a). This study found that average sightlines were farther on-line versus off-line for most linear feature types, but that sightlines varied substantially across line types. Sightlines were shorter on seismic lines than on roads, especially 2D lines which had more advanced vegetation regeneration than other feature types. On 3D lines, sightlines averaged approximately 30 m farther on lines than off lines. However, this difference probably provides little advantage to predators or human hunters because the increase is still within the olfactory and auditory detection zone for most large prey species. Average sightlines were 60 m farther on winter roads than surrounding forest, which may begin to confer more advantage to predators and hunters.

The range of sightlines observed on most linear features probably do not provide an advantage to detect prey species visually. For 2D lines and winter roads, sightline distances were primarily driven by the height and density of regenerating vegetation. The recovery period for 2D seismic lines appears to be sufficient to support vegetation that reduces visibility to a similar level as the surrounding habitats. The reason for longer sightlines on winter roads is that they are subject to intermittent re-activation, where the vegetation is cleared once again, which resets vegetation recovery and maintains longer sightlines. In contrast to 2D lines and winter roads, where sightlines were largely determined by vegetation regeneration, the sightlines on 3D lines were presently limited by the bends purposely constructed into the lines. Sightlines along all feature types will continue to diminish over time as vegetation regeneration continues.

5.4.2 EASE OF TRAVEL

Ease of travel is a fundamental indicator of functional recovery of linear features. Wolves, bears, and humans have been documented to select linear features with greater ease of travel, which is generally associated with lower and more sparse vegetation and stable, even terrain (Dickie et al. 2017b, Keim et al. 2019a). Access and travel resistance are the main determinants of predator and human use of linear features and the key concern of linear disturbances in the RSA (Vuntut Gwitchin Government and Yukon Government 2009, Peel Watershed Planning Commission 2019).

The walk test used in this study, as an index of ease of travel, found differences among linear feature types and between linear features and controls. However, the magnitude of the differences for both comparisons was modest. Even the Dempster Highway only conveyed a 35% increase in walking speed over off-line plots. Other researchers, in other areas, often observed walk speeds on linear features were often at least twice as fast as off-line transects (Keim et al. 2019a). Two conditions associated with the Eagle Plains area appear to limit the advantage of travelling on linear features. One is that the vegetation in most ecosites and structural stages is relatively open and has a limited effect on impeding movement. The second factor is that ground conditions limiting movement, including soft, thick peat and graminoid tussocks, were similar on both on-line and off-line plots for most linear feature types.

Notwithstanding the modest magnitude of faster walking speeds on-lines, there were clear patterns in walking speed differences across linear feature types. 2D lines were the one feature type where walking speeds were slower on lines than off lines. This reflected the thick, shrub stage vegetation that had regenerated on most 2D lines, which impeded travel (similar to the effect that regenerating vegetation had on sightline distances in the previous section). Walk speeds decreased across the other feature types in relation to line width and the degree to which ground cover was levelled or compacted. 3D seismic lines allowed slightly easier travel than paired off-line plots. They usually had lower vegetation cover and clearer route selection. As linear feature width decreased in 3D lines, walking speed also decreased. This implies that width may be related to functional recovery, with narrower lines having smaller impacts than wider lines, even within an already narrow linear feature type. Although ease of travel was greater in 3D seismic lines than surrounding community, it is expected that this will decrease in future years as vegetation increases in height and density.

5.5 FUNCTIONAL RECOVERY OF LINEAR FEATURES

Functional disturbance is defined in the NYRLUP and PWRLUP as "*physical land use disturbance that results in disruption of soil or hydrology, or that requires the cutting of trees*." One of the main concerns with linear disturbances under these land use plans is that such features can technically allow increased access to previously remote areas, potentially leading to a greater harvest of wildlife and fish, higher predation rates, and a change in how people and wildlife use the land (Vuntut Gwitchin Government and Yukon Government 2009). A disturbance can be considered functionally recovered and subtracted from the overall linear density when it no longer facilitates access or travel by humans or wildlife (Vuntut Gwitchin Government and Yukon Government 2009), or otherwise no longer functions as a surface disturbance (Peel Watershed Planning Commission 2019). Both plans use 1.5 m vegetation height as a threshold for functional recovery in forested communities. The

PWRLUP includes the following additional criterion for recovery "*in non-forested areas (dominated by vegetation under 1.5 m), when the disturbed area is covered by native species roughly the same height and composition as the surrounding dominant vegetation*" (Peel Watershed Planning Commission 2019):

One limitation of using height alone as a functional recovery criterion is that it does not consider vegetation density. Although regeneration may meet the recommended height criteria, if it is very sparse (as is often the case in the Eagle Plains Ecoregion), it may still facilitate access and travel by humans and wildlife. Attachment Photo A-25 provides an example in the Eagle Plains RSA where tall but sparse regeneration meets the 1.5 m criteria but does not inhibit access or travel.

The combined results of this study indicate that using regeneration to the Tall Shrub structural stage may be a more appropriate criterion for functional recovery. Attachment Photo A-3 and Attachment Photo A-10 provide examples of linear features that have regenerated to a tall shrub structural stage. Using the Tall Shrub criterion, 38% of all linear features in the RSA would be considered functionally recovered compared to 53% using the 1.5 m height criterion. For this study, the more conservative criterion of reaching the Tall Shrub structural stage was used to adjust (reduce) linear feature densities.

5.6 LINEAR FEATURE INVENTORY AND DENSITY

This study was successful in mapping all linear features within the RSA. The combined results of the mapping exercise and the field studies found that the extent of open habitats (burns and naturally open habitats like wetlands and shrublands), and the degree of vegetation regeneration, played a significant role in the effective density of linear features across the RSA. Before accounting for open areas and regeneration, the total linear feature density was 1.79 km/km². After accounting for open areas and vegetation regeneration (to the Tall Shrub structural stage), the effective linear feature density was 0.52 km/km². The NYRLUP and PWRLUP suggest cautionary levels for linear density of 0.75 km/km² and critical levels of 1.0 km/km² (Vuntut Gwitchin Government and Yukon Government 2009, Peel Watershed Planning Commission 2019).

The Yukon Land Use Planning Council (YLUPC) was conducting a pilot study of surface disturbance across the broader Eagle Plains Ecoregion (Skinner 2021) at the same time as this study. The methods they used consisted of mapping and attributing human-caused disturbances solely using high-resolution satellite imagery. The YLUPC classified vegetation into eight broad classes based on whether the surrounding area was forested or non-forested, the similarity of vegetation on-line to off-line, and the presence or absence of woody cover (i.e., shrubs or trees). The features were then classified as recovered or not-recovered based on the presence of woody cover (recovered) or, if woody cover was not present, the similarity to surrounding vegetation (i.e., if similar then recovered, if not similar, then not-recovered). Historical field data and photographs from the area (Simpson 2008) were used to verify interpretations.

The spatial data from the YLUPC work was not available to compare in detail to the linear feature inventory compiled in this study. However, the mapping linework is expected to be very similar because satellite imagery was used to verify and supplement the linear feature geospatial data compiled in this study (presumably the same satellite imagery that YLUPC used because the imagery was obtained from Yukon Geomatics). One

difference between the two products is that the YLUPC completed the inventory for the entire Eagle Plains Ecoregion, while this study was restricted to the RSA. Another difference is that the attribute data in this study is expected to be more detailed and more precise than the YLUPC data because (i) the original geospatial data includes some information, like date of creation, that would be impossible to estimate from imagery, and (ii) because this study linked field surveys to the mapping exercise to determine line widths and other characteristics more precisely.

Although it is impossible to directly compare the linear feature density estimates between the two studies, due to the different study extents, the general pattern of results is similar. The YLUPC estimated the linear density (accounting for recovery) to be 0.38 km/km² across the entire Eagle Plains Ecoregion. This is consistent with the estimate from this study for the RSA of 0.52 km/km² because the portion of the Ecoregion outside the RSA has lower linear feature density than the RSA.

6 CONCLUSION

This study successfully mapped all linear features within the RSA and measured a suite of structural, vegetation, and functional characteristics across different feature types. Generally, the effects associated with linear features (i.e., differences between conditions on-line and adjacent off-line areas) correlated to feature width and the degree of ground disturbance. In terms of combined effects across the range of feature types that occur in the Eagle Plains RSA, the ranks were:

Dempster Highway >>> Winter Roads > 2D Seismic > 3D-5m >> 3D Conductor > 3D Receiver[2]

The effects of 3D lines (both conductor and receiver lines) appear to be substantially lower than other feature types. This reduced magnitude of effects is important because 3D lines have the longest combined length of exiting linear features. They are also the predominant feature planned for the next exploration program. Important findings for 3D lines include:

- Relatively narrow line widths of 2–3 m are often smaller than natural tree spacing and minimize the potential for changes to microsite conditions (e.g., solar radiation, air and ground moisture) reported in other studies.
- Minimal ground disturbance and maintenance of the moss, herb, and low shrub layers, which retains the natural vegetation community and accelerates vegetation regeneration.
- Successful application of mitigations, notably dogleg bends that minimize sightlines, ease of human travel, and visibility of lines from roads.
- Ungulate use of 3D lines in winter was less than a third of the rate observed on 2D lines and winter roads.

The adverse effects of linear features in other areas are often caused or exacerbated by human use after the lines are initially constructed, including effects on vegetation regeneration and predator-prey dynamics. Human use does not appear to be a significant factor in Eagle Plains. No sign of human use was observed outside the Dempster Highway corridor.

Substantial vegetation regeneration has occurred on existing features in the Eagle Plains RSA. Previous work by the Yukon Government identified the potential for atypical successional trajectories to occur on linear features in the region. Although atypical succession occurred to a limited extent, this study determined that 81% of the sites exhibited a normal succession (100% on 3D lines). Only 5% exhibited inhibited regeneration trajectories (mostly stagnated succession on winter roads). Regarding functional recovery, 53% of sites met the NYRLUP and PWRLUP criterion of vegetation reaching 1.5 m, and 38% of sites met the criterion of attaining a Tall Shrub structural stage. Using the Tall Shrub structural stage as a criterion of functional recovery may be a more ecologically appropriate criterion to meet LUP objectives.

The extent of open habitats (e.g., burns, wetlands and shrublands) and the degree of regeneration on existing linear features (mostly the older 2D lines and winter roads) play an important role in calculating effective linear

[2] Relative magnitudes of effects: >>> large effect, >> moderate effect, > small effect.

feature density in the RSA. Before accounting for open areas and regeneration, the total linear feature density was 1.79 km/km². After accounting for open areas and vegetation regeneration (to the Tall Shrub structural stage), the effective linear feature density was 0.52 km/km².

EXECUTIVE SUMMARY

The Eagle Plains Project (the Project) is an oil and gas exploration program in north-central Yukon, approximately 605 km north of Whitehorse along the Dempster Highway. Chance Oil and Gas Ltd. intends to conduct exploratory activities over a 10-year period to confirm the quality, quantity, and areal extent of hydrocarbons. Project activities will include seismic exploration and exploratory wells supported by an expanded winter road network.

The Project's Regional Study Area (RSA) is approximately 2,400 km² and is spatially bounded by the Peel River and Ogilvie River to the south and the northern reaches of Chance Creek to the north. The Project is within the Eagle Plains ecoregion, an intermontane basin underlain by sedimentary rock. The regional land cover comprises subarctic coniferous forest with mixed forest and arctic/alpine tundra while also lying within a continuous permafrost zone.

For the Project to proceed, it must be evaluated under the *Yukon Environment and Socio-Economic Assessment Act*, which requires baseline wildlife information. As such, wildlife baseline studies were conducted to provide information about birds, American marten, grizzly bear, moose, and caribou to meet the information requirements to support a project proposal to the Yukon Environmental and Socio-economic Assessment Board. The following subsections provide an executive summary of each baseline study completed for the Project.

Birds

The purpose of the birds baseline study was to document the potential occurrence, relative abundance, and habitat associations of birds across the Project's RSA. This study consisted of a combination of a desktop assessment and field surveys. The desktop assessment included identifying ecosystem units across the RSA using predictive ecosystem mapping, collecting, and cleaning historic bird survey data in the broader area, and developing a comprehensive list of bird species with the potential for occurrence based on range and habitat requirements. Two types of field surveys were conducted, each targeted at broad habitat associations in the Project area: point count surveys (transects for terrestrial habitats) and wetland/pond surveys. The survey design followed a targeted, stratified habitat design to provide representative survey coverage across the range of habitat types that occur in the RSA. Point count stations were established along walking transects for efficient survey implementation, and sites were selected using a targeted, stratified habitat design. Ecosystem units for predictive ecosystem mapping were reclassified with field data to produce 32 ecosystem units that captured site-specific differences in vegetation. An average of 23 survey stations were located in each ecosystem unit, with a minimum of eight stations in uncommon habitats. Field surveys were conducted during the 2019 breeding season (June 25 to 30) by two experienced biologists.

To better explain broad patterns of habitat occupation by species of birds in the RSA, the initial 32 ecosystem units were consolidated into ten broad avian habitat types: Herb, Deciduous/Mixed Shrub, Tall Shrub – Black Spruce, Deciduous/Mixed Forest, Spruce Forest, Riparian/Wetland Deciduous Shrub, Riparian Coniferous Shrub, Riparian Spruce Forest, Open Water, and a classification ("Unknown") for distant (>100 m) or flyover observations that prevented associating birds with habitat.

Based on range and habitat, 128 bird species potentially occur in or adjacent to the RSA. Forty-eight bird species were recorded in adjacent areas during North American Breeding Bird Surveys. Possible species include eight listed either under the federal *Species at Risk Act* or identified in the Yukon *Wildlife Act*, and 67 are considered a priority and management concern under the federal *Bird Conservation Region 4 Plan*. Species listed in the *Species at Risk Act* include (with those in bold observed in the RSA): Horned Grebe (*Podiceps auritus*), Peregrine Falcon (*Falco peregrinus*), Short-eared Owl (*Asio flammeus*), **Red-necked Phalarope** (*Phalaropus lobatus*), **Common Nighthawk** (*Chordeiles minor*), **Olive-sided Flycatcher** (*Contopus cooperi*), Bank Swallow (*Riparia riparia*), and **Rusty Blackbird** (*Euphagus carolinus*).

During field surveys, nine hundred and seventy-nine birds from 53 species were observed in the RSA. Point counts identified 743 birds of 42 species, and wetland surveys identified 231 birds of 37 species. Five Swainson's Hawk (*Buteo swainsoni*) were also identified as incidental observations. Patterns of species relative abundance and richness (number of species) varied among the different habitat types. These patterns were consistent with regional habitat and known bird range-use and habitat requirements. Average relative abundance and species richness were greatest in Spruce Forest, Deciduous and Mixed Shrub, and Riparian/Wetland Deciduous Shrub habitats; and lowest in Herb and Tall Shrub – Black Spruce habitats. These patterns were generally related to the structural complexity and productivity of these different habitat types. However, the number of unique species in a given habitat did not depend on structural complexity. Many unique species were found in the Herb and Open Water habitats.

The general patterns of bird occurrence and habitat associations observed in this study are consistent with the limited information available for birds in the area.

Marten

Marten were selected as a Valued Component for the Project due to their value as a furbearer to the Vuntut Gwitchin First Nation and as an indicator species for mature and old forest values. Marten are a good species for assessing potential effects on habitat because they are more closely associated with habitat (mature forest) than many other species of medium-sized carnivore. However, little is known about basic marten ecology in northern boreal forest and taiga ecosystems. The RSA is located entirely within the Eagle Plains Ecoregion, where tree growth is limited by the presence of permafrost and short cool summers that limit the structural development of forests. The most common climax forest community is black spruce woodlands with open canopies and relatively small trees. The size and number of mature forest structures that marten use, such as large trees, snags, and coarse woody debris is much smaller than in forests used by marten in more southern latitudes. Therefore, indices of marten habitat suitability were evaluated in a relative context in this northern setting.

A habitat suitability index model was developed for marten to examine the amount, quality, and habitat distribution for the species in the RSA. Habitat was assigned a suitability ranking of High, Moderate, Low, or Nil/Very Low, relative to the range of habitat quality across the RSA. The rating categories correspond to qualitative predictions of the relative suitability of the habitat for supporting five life requisites of marten: reproduction, thermal cover, escape cover, foraging, and dispersal. High-quality habitat supports all five life requisites. Moderate-quality habitat supports escape cover, foraging, and dispersal. Low-quality habitat only

supports limited foraging and dispersal. Nil/Very Low-quality habitat does not contribute significantly to any life requisites; however, herb/shrub structural stages and stunted disclimax forest areas likely function as permeable barriers and allow intra-territorial movements within marten home ranges. Key habitat associations include selection for mature/old conifer structural stages and avoidance of herb/shrub structural stages (mostly resulting from fire), natural openings, wetlands, and stunted black spruce stands. The model also accounts for avoiding anthropogenic linear features, with greater rating reductions for wider linear features. The model uses two types of source information to provide a spatially explicit quantification of marten habitat across the RSA: vegetation mapping (Ecological and Landscape Classification mapping) and human disturbance, including the Dempster Highway, winter roads, and two types of seismic lines.

The model indicates a patchwork of High (16%), Moderate (23%), and Low (60%) quality marten habitats across the RSA. High-quality marten habitat is associated with mesic, spruce-dominant ecosites in mature to old structural stages. Concentrations of High-quality habitat include the southern portion of the study area, in the Enterprise and Dalglish Creeks watersheds, a band running east-west, north of the Dempster Highway, and the western portion of the northern half of the RSA. Moderate-quality habitat is associated with wetter and/or younger ecosystem units than High-quality habitat and is widespread across the RSA. High and Moderate quality habitat is also concentrated in narrow strips of mature/old riparian forests along some of the major watercourses in the RSA, including Chance and Greaves Creeks in the northwest and McParlon Creek west of the Dempster Highway. Low-quality habitat is associated with regenerating burns, wetlands, and stunted, open, black spruce areas. Concentrations of Low-quality habitat include recent burns on both sides of the Dempster Highway and wetlands and open, stunted spruce areas in valley bottoms in the lower reaches of the Chance watershed in the northwestern portion of the RSA. Nil/Very Low habitat constitutes only 1% of the RSA.

Linear features had a relatively minor effect on overall quality, amount, and distribution of potential habitat for marten in the RSA. This was due to the narrow width of linear features and small overall extent they comprise relative to the overall RSA. Though existing linear features result in reduced habitat quality at the site-level, their effects on habitat supply for marten at the home range scale are very limited.

Grizzly Bear

Grizzly bears (*Ursus arctos horribilis*) were selected as a Valued Component for the Project due to their conservation status and social, cultural, and economic value. Grizzly bears are Special Concern on Schedule 1 of the federal *Species at Risk Act*. The grizzly bear section provides baseline information about population trends, distribution, sources of mortality, diet, and habitat selection within the RSA. This section draws from multiple sources, including published and unpublished literature, personal communications with biologists, and traditional knowledge where available. Few studies on grizzly bears have been conducted in the Project area. Literature from surrounding regions was consulted when local information was not available.

Grizzly bear densities are thought to be low throughout the RSA. The most current grizzly bear population estimate for the broader Eagle Plains Ecoregion (which encompasses the RSA) is 184 individuals, based on expert opinion of grizzly bear habitat capacity from the 1980s. Little is known about seasonal grizzly bear distribution and movements within the RSA and surrounding areas. However, the Richardson and Ogilvie

Mountains (north and south of the RSA, respectively) are thought to have higher grizzly bear densities than the comparatively flat Eagle Plains Ecoregion. Grizzly bears congregate at the Fishing Branch River (20 km west of the RSA) in the fall to feed on spawning salmon. Grizzly bears may also follow the spring and fall migration of the Porcupine caribou herd to take advantage of the seasonal abundance of caribou as a food source.

Key threats to grizzly bear populations in the Yukon are human-wildlife conflict and harvest mortality. Licenced grizzly bear harvest rates are low in the RSA relative to other parts of the Yukon. Annual grizzly bear harvest in Game Management Zone 1 (which encompasses the RSA) has historically varied from zero to three bears per year. Other potential sources of grizzly bear mortality in the RSA include the defence of life and property kills, collisions with vehicles, and predation from other bears or large carnivores.

Seasonal grizzly bear diets reflect the phenological progression of key food resources such as herbaceous plants, roots, ungulate calves, berries, and fish. Terrestrial wildlife are likely an important food source for grizzly bears in northern Yukon, particularly barren-ground caribou (*Rangifer tarandus groenlandicus*) and arctic ground squirrels (*Spermophilus parryii*). The distribution of available food strongly influences habitat selection by grizzly bears during spring, summer, and fall seasons and the supply of suitable den sites in winter. Grizzly bears in the RSA may select habitats with abundant herbaceous vegetation, roots, or berries, such as riparian valleys and slopes. Grizzly bears may also travel to nearby mountain ranges to feed on ground squirrels, particularly in fall, as berry availability declines. Grizzly bears may follow caribou during spring and fall as they migrate to and from their calving grounds, targeting calves or opportunistically preying on adults.

Grizzly bears in northern Yukon hibernate in winter from approximately October to May. They prefer to den in mountainous regions; however, in areas with relatively flat topography (such as the RSA), grizzly bars will select small topographic features such as hills, steep riparian banks, or lakesides to excavate their dens. Grizzly bears in the taiga of northern Yukon have large home range sizes (females: 442–750 km^2, males: 760–1,250 km^2). They travel long distances to find suitable winter denning habitats in the mountains.

Moose

Moose (*Alces alces*) were selected as a Valued Component for the project's environmental assessment due to their value as a game species and their cultural values to local First Nations. The purpose of the moose study was to summarize existing baseline information for moose and develop a habitat model for the species within the Eagle Plains RSA. The habitat model quantifies the suitability, amount, and distribution of potential habitat for moose in the RSA. This information can be used to assess the Project's potential effects on moose and develop measures to mitigate effects if required.

There is limited incidental knowledge about moose population levels, distribution and habitat use within the Eagle Plain RSA. Formal population surveys of moose have not been conducted, but local knowledge suggests that, while moose densities in Eagle Plains are relatively low compared to areas in southern Yukon, they are relatively high compared to other areas in North Yukon. Information from two historical aerial surveys examining the distribution of moose (and other large mammals) indicates that moose occur across the RSA throughout the year, consistent with the relatively low elevation, subdued topography, and moderate

snowpacks that occur in the area. Several large, regenerating burns and smaller extents of riparian and wetland shrublands offer shrubby browse that moose depend on during winter.

The habitat model was developed specifically for the winter season because winter is the most limiting season for moose — forage is most limited, and energetic demands are greatest due to cold temperatures and the extra effort required to travel through snow. The model explicitly focussed on forage availability, which was believed to be the most significant factor affecting habitat selection in winter. During winter, moose feed almost exclusively on the stems and branches of certain shrubs. Vegetation surveys in the area found that several species of willows (*Salix spp.*) were the most abundant potential forage species and the species with the most frequent evidence of browsing by moose.

The habitat model included three variables, ecosystem type, structural stage, and fire disturbance status, all from recent vegetation mapping (Ecological and Landscape Classification mapping) conducted in the RSA. Habitat suitability ratings were developed for each combination of ecosystem type, structural stage, and fire disturbance based on the observed or potential abundance of willow. The highest-rated areas included natural shrublands, regenerating burns in riparian areas, and small extents of deciduous and mixed-wood ecosystems on mesic and moist sites. Moderate-rated areas were predominantly regenerating burns on mesic to wet sites. Low-rated sites were mostly undisturbed stands of open, stunted spruce on mesic to wet sites, ranging from tall shrub to old forest structural stages. Differentiating ratings between Moderate and Low areas was often difficult. Many burned and unburned sites had an average willow cover less than 15%, with high variation in cover among sites in the same ecosystem units. Generally, 7% willow cover was used as the threshold to differentiate between Moderate and Low sites. This is a relatively low value of willow cover but using a higher threshold would have resulted in large areas of regenerating burn being classified the same (Low) as undisturbed areas.

The habitat model indicates that High-suitability moose winter habitat is quite limited across the RSA, and Moderate habitat is widespread: High (12%), Moderate (43%), Low (44%), and Nil/Very Low (1%). Due to the scattered occurrence of High-suitability habitat across the RSA, some moose are expected to occur across the RSA in winter. However, local densities are likely to vary with the portions of Low and Moderate suitability habitats that form the matrix of habitat at a larger scale. This pattern of having extensive areas in Moderate suitability winter habitat is different than occurs in other parts of Yukon, especially in more mountainous regions, where suitable winter habitat (i.e., High and Moderate) are often constrained by elevation and broad vegetation patterns to a relatively small proportion of the landscape (e.g., <25%). In Eagle Plains, a substantial amount of winter forage occurs within large areas with relatively low willow cover (i.e., the Moderate suitability areas).

Caribou

The Porcupine Caribou Herd (PCH) is a subpopulation of barren-ground caribou (*Rangifer tarandus*), known for large population aggregations, dramatic population fluctuations, lengthy migrations, and significant cultural and social value to northern Indigenous peoples. Within the North Yukon Land Use Plan, the PCH is considered "the most significant and culturally important wildlife resource in the planning region." The PCH has been assessed as Threatened by the Committee on the Status of Endangered Wildlife in Canada, but the

subspecies is not listed on Schedule 1 of the federal *Species at Risk Act*. Within Yukon, barren-ground caribou are considered Vulnerable/Apparently Secure.

The specific objectives of this study were to:

- summarize existing information about the ecology of the PCH,

and, use telemetry data and analysis outputs from the Porcupine Caribou Technical Committee to:

- quantify the degree of seasonal range overlap by the PCH with the Eagle Plains Oil and Gas Exploration Project RSA during late fall and winter, when seasonal range use overlaps the RSA.
- quantify habitat use patterns and selection by the PCH during late fall and winter.
- quantify movement rates and residency periods of the PCH during late fall and winter.
- quantify potential effects of exiting linear features on the occurrence and movements of the PCH.

There is a long history of co-management of the PCH among indigenous, state, territorial and federal governments in Canada and the United States. In Canada, management initiatives are led by the Porcupine Caribou Management Board with technical support from the Porcupine Caribou Technical Committee. The Porcupine Caribou Technical Committee leads most monitoring and research work on the PCH, including population and demographic monitoring, seasonal movement monitoring (via GPS telemetry tracking), caribou body condition monitoring, habitat and human disturbance assessments, and annual snow surveys. The portion of the PCH annual range that occurs within Yukon is protected by a network of parks, special management areas, conservation areas, wilderness areas, protected areas, ecological preserves, habitat protection areas, and Integrated Management Area zones within the North Yukon Regional Land Use Plan and the Peel Watershed Regional Land Use Plan. In total, 54% of the annual range of the PCH within Yukon falls within some type of protected area where industrial activity is prohibited, 36% of the annual range occurs within regional land use plan Integrated Management Area zones where development is limited, and 9% of the annual range is not covered by any land management zonation.

Although most barren-ground caribou subpopulations are declining, the PCH numbers have increased over the last two decades. Since the first survey in 1972, the PCH has had two periods of population growth, with an interceding decline. The last successful population survey in 2017 estimated a record high of 218,457 caribou.

Like most barren-ground caribou subpopulations, the PCH has a large annual range and makes long-distance migrations, hundreds or thousands of kilometres, among different seasonal ranges. After calving on the north slope and Arctic coastal plains, the PCH typically splits in two, with portions of the herd moving southwest in Alaska and southeast in Yukon. Animals in the Yukon typically follow a clockwise movement through the seasonal ranges from the calving grounds on the north slope, to the British Mountains in summer, to the Richardson Mountains in late summer, dispersing widely and variably across northern Yukon (as far south as the Ogilvie Mountains) in fall and winter, before returning north to the coastal plains in spring. The PCH has historically overlapped the RSA in the rut/late fall and winter periods. However, the RSA overlaps a small

portion of those ranges — 6.0% of the late fall range and 6.5% of the winter range, and the RSA does not overlap with the most frequently used portions of those ranges.

Habitat selection by the PCH for late fall and winter was estimated using resource selection functions using GPS collar data from 2012 to 2021 for 164 caribou in late fall and 172 caribou in winter. Spatial habitat data included a set of plant functional type layers (light macrolichens, graminoids, forbs, evergreen shrubs, deciduous shrubs, and conifer trees), elevation, aspect, slope, terrain ruggedness, and distance to waterbodies >1 ha. PCH caribou tended to select and avoid similar resources in both late fall and winter. Key covariates in models for both seasons that were statistically significant (i.e., $P < 0.05$) included macrolichen cover (positive coefficient), conifer tree cover (negative coefficient), slope percent (negative coefficient), elevation (variable in fall and winter), and aspect (greater selection for south- and west-facing). Coefficients associated with lichen cover were of the greatest magnitude, suggesting that the selection of lichen is the primary driver of habitat selection in late fall, especially in winter. The resource selection function models were used to derive habitat quality maps with four ratings (Very Low, Low, Moderate, and High), which were determined by assessing selection ratios across resource selection function predictions. The distribution and proportion of selected habitat (Moderate and High) was then examined within the RSA and broader seasonal ranges. The proportion of selected habitat was equivalent between the RSA (0.404) and the broader range during late fall (0.415 ± 0.025) but was less in the RSA (0.265) than the broader range during winter (0.411 ± 0.026). Selected habitat, especially areas of High quality, were mostly dependent on the amount and distribution of macrolichen cover.

The potential for linear features (i.e., the Dempster Highway, winter roads, 2D seismic and 3D seismic) to mediate the base habitat model via avoidance of those features was assessed using a zone of influence (ZOI) framework. Although ZOIs were determined for some features, confidence in the outcomes was low because (i) the magnitude of the ZOI effects were weak (i.e., including the ZOI effects in the habitat models had little effects on the habitat predictions); (ii) the ZOI distance estimates were sensitive to the data and analytical methods used; (iii) the pattern of ZOI effects were not consistent with other studies and basic understanding of the PCH ecology. Developing ZOIs for assessment and management purposes will integrate results from other studies adapted to the Eagle Plains setting and the ecology of the PCH.

To better understand factors affecting PCH caribou movement, two analyses were conducted: (1) a comparison of daily movement rates and residency times of caribou in the Project RSA relative to the broader landscape, and (2) a delineation of movement paths to assess broad-scale movement patterns and the potential for caribou to interact with the Project. The PCH typically exhibits movements of several kilometres per day in late fall and winter. Late fall daily movements (8.7 km/day in the RSA) were substantially greater than during winter (4.4 km/day), and caribou tended to occupy portions of the landscape for shorter periods during late fall than during winter. Caribou residency times in both seasons were two-fold greater in the broader landscape than within the Project RSA, suggesting that, on average, the RSA is used as more of a transitory area than other portions of the seasonal ranges. There were relatively few collared caribou that travelled through the RSA during late fall. However, in the fall of 2015, 14 collared caribou made clear, directed movements along the height of land parallel to the Dempster Highway, from the northeast to the southwest. Most caribou appeared to avoid crossing the Dempster Highway while travelling through the Eagle Plains

region, but all animals eventually crossed the highway farther south, in the Ogilvie Mountains. The movements through Eagle Plains crossed numerous 2D seismic lines, winter roads and a large 3D seismic grid within the RSA.

1 INTRODUCTION

Baseline wildlife information and data are required for proposed oil and gas projects submitted to the Yukon Environmental and Socio-economic Assessment Board (YESAB) Executive Committee for screening under the *Yukon Environment and Socio-Economic Assessment Act* (YESAA), as well as applications submitted for an Industrial Licence and Type A Water Licence from the Yukon Water Board, among other permits and licences. To receive authorization for the Eagle Plains Project to proceed, the Project must be evaluated under YESAA. Specific wildlife objectives, as identified in YESAB's Proponent's Guide to Information Requirements for Executive Committee Project Proposal Submissions (2005), are to:

- describe the abundance and distribution characteristics of major wildlife species within the project area and vicinity;
- describe the habitat classifications used in the project area and any implications concerning the distribution and abundance of habitat types that may influence the project;
- provide a map showing the spatial arrangement of habitats of special interest, if applicable;
- identify and describe the transportation corridor and critical, key, and sensitive habitats;
- identify any species listed on the Committee on the Status of Endangered Wildlife in Canada (COSEWIC) and Species at Risk lists;
- describe any special management requirements due to vulnerability, threatened, or endangered status; and,
- identify and describe any ongoing studies and monitoring programs concerning wildlife in the project area and vicinity.

1.1 PROJECT OVERVIEW

The Eagle Plains Project (the Project) encompasses a 2,386 km² area in north-central Yukon, centred approximately 605 km north of Whitehorse and 40 km south and west of Eagle Plains hotel, along the Dempster Highway. The Project occurs within the Eagle Plains sedimentary basin, north of the Ogilvie River and west of the Richardson Mountains. The basin contains proven natural gas and oil reserves (Peel Watershed Planning Commission 2019), including 4.6 billion m³ of gas and 3.2 million m³ of oil (Hannigan 2014).

The Regional Study Area (RSA) has had intermittent periods of oil and gas exploration since the 1950s. That activity has established winter roads, seismic lines, and exploratory well sites across parts of the current RSA. Approximately 40 exploration wells have been drilled in the Eagle Plains sedimentary basin. Eight (8) wells are currently being maintained in suspended status, and the remaining wells have been plugged and abandoned. Seismic exploration has included approximately 10,000 km of two-dimensional (2D) lines (mostly before 1985), and about 325 km² of three-dimensional (3D) seismic was conducted in 2013/2014 (Northern Cross (Yukon) Ltd. 2014).

The current exploration program will build on past exploration to better define the extent, amount and quality of oil and gas deposits in the area. Under the current program, Chance Oil and Gas Ltd. proposes conducting additional 2D and 3D seismic data acquisition programs over large extents of the RSA and drilling up to 30 exploratory wells. Depending on the drilling program results, extended flow testing lasting up to two years may be conducted at wells where crude oil and/or natural gas are discovered to determine the quantity, quality and extent of the oil and gas deposit(s). The existing winter road network will be expanded to support the seismic, drilling, and flow testing programs. Most work is expected to be conducted in the winter (e.g., seismic line clearing and drilling); however, seismic recordings and extended flow testing may also occur during summer or year-round.

1.2 STUDY AREA

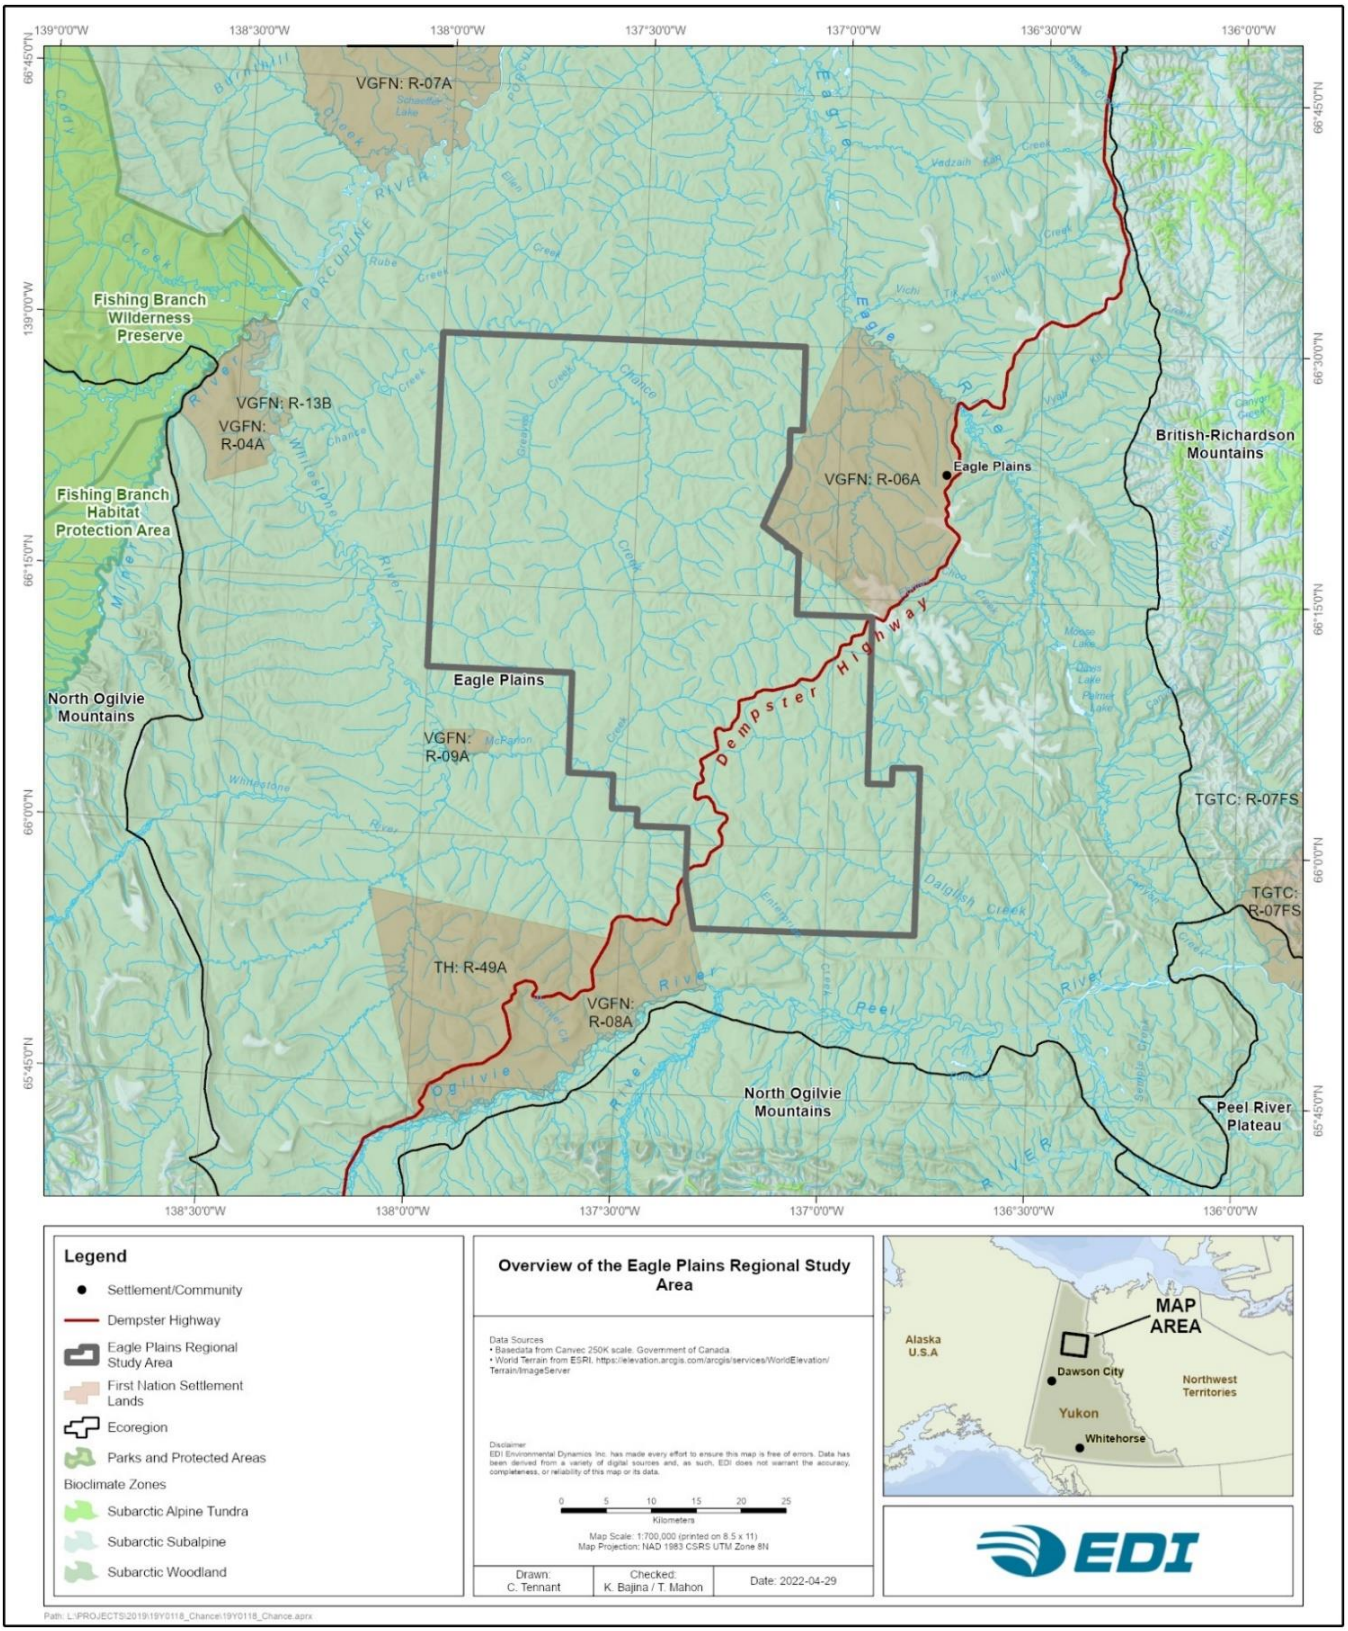
The Eagle Plains Project Regional Study Area (RSA; Map 1-1) is 2,386 km² (238,566 ha), centred in the Eagle Plains Ecoregion in north Yukon. The area consists of subdued topography of rolling hills and sloping plains. The Dempster Highway crosses the RSA along the local height of land. From there, the area drains into the Porcupine River watershed to the north (via Chance Creek) and west (via McParlon Creek and the Whitestone River) and into the Peel River watershed to the southeast (via Dalglish Creek).

The RSA overlaps four First Nation Traditional Territories. Most of the RSA is within the Vuntut Gwitchin First Nation (VGFN) Traditional Territory. The southeastern portion is in an area of overlapping Traditional Territories of VGFN, the Tetlit Gwich'in Council (TGC), the First Nation of Na-cho Nyäk Dun (NND), and Tr'ondëk Hwëchin First Nation (THFN). Although the RSA is outside any First Nation Settlement Lands, it adjoins VGFN Settlement Lands on parts of its east and southwest borders.

Development in the RSA and the surrounding Eagle Plains is low. The Dempster Highway is the main vehicle access corridor, running from approximately Dawson City, Yukon in the southwest to Inuvik, Northwest Territories (NWT) to the northeast and transiting the RSA along the way. Several winter access roads also branch off the Dempster Highway. A network of seismic lines (Photo 1-1) from historical exploration are found in the RSA. The Eagle Plains settlement is located on the Dempster Highway, approximately 30 km east of the RSA boundary and consists of the Eagle Plains Hotel and the Government of Yukon's Highway Maintenance camp.

The Project is within the North Yukon Planning Region and Peel Watershed Planning Region. Therefore, it is subject to the North Yukon Land Use Plan (NYLUP) and Peel Watershed Land Use Plan (PWLUP). The project falls within the Integrated Management Area (IMA) Zone IV of both plans, a zone with lower ecological and cultural values and the highest permissible development of the four IMA zones.

Photo 1-1. Seismic lines from historical exploration activities within the Regional Study Area.



Map 1-1. Overview of the Eagle Plains Regional Study Area.

1.3 ECOLOGICAL OVERVIEW

The Project falls within the Eagle Plains Ecoregion (Map 1-1), a 20,400 km² region in north Yukon between the Richardson and Ogilvie Mountains. The ecoregion consists of low-altitude rolling topography between 300 m and 600 m above sea level (masl), with few scattered peaks above and around 1,000 masl (Ecological Stratification Working Group 1995).

The Eagle Plains Ecoregion experiences moderate precipitation, with annual amounts around 400 mm. Most precipitation falls as rain throughout the summer, averaging 50 to 80 mm per month, from June through August. Precipitation is lighter through September to April and falls as snow, with average winter snowpacks of 80 cm peaking in April. The climate in this region is strongly affected by its latitude, with extended winter conditions that usually last from October through to early May. There is a substantial variation in seasonal temperatures in the Eagle Plains, with cool short summers and long cold winters. Average winter temperatures are between −30°C and −25°C, with extremes as low as −60°C. Average summer temperatures are around 13°C, with extremes as high as 30°C. Due to the northern latitude, this region experiences brief periods of continuous sun above and below the horizon in summer and winter, respectively.

Most of the Ecoregion, including the northeast portion of the RSA, drains north into the Yukon River via the Whitestone, Porcupine and Eagle rivers. That part of the RSA includes the headwaters of the Eagle River and several other tributaries of the Porcupine River, along with the Chance and McParlon Creek subdrainages of the Whitestone River. The southeast corner of the Ecoregion drains east to the Mackenzie River via the Peel, Wind and Ogilvie Rivers. Dalglish and Enterprise creeks flow directly into the Peel River. The few lakes in the Ecoregion are generally oxbow or thermokarst lakes (Yukon Ecoregions Working Group 2004a). Several wetland complexes are found to be associated with larger creeks in the RSA.

The Eagle Plains Ecoregion is dominated by the Crysolic soils that occupy much of the northern third of Canada, characterized by near-surface permafrost. Turbic Cryosols predominate, exhibiting patterned ground formations and hummocks, and are often associated with open stands of black spruce (*Picea mariana*), tamarack (*Larix laricina*) and birch (*Betula* spp.). The active permafrost layer in these ecosystems generally ranges between 20 cm and 90 cm below the surface. The active layer depth is generally deeper under hummocks and shallower under inter-hummock areas (Yukon Ecoregions Working Group 2004a).

The RSA is entirely within the Subarctic Bioclimate Zone (Environment Yukon 2014a). Vegetation in the RSA is characterized by open-canopy, spruce-dominated habitats where permafrost generally limits tree growth and results in stunted, disclimax vegetation communities (Environment Yukon 2016a). Hummocky, black spruce and white spruce (*Picea glauca*) woodlands with well-developed shrub communities are common in upland areas, with white spruce and ground lichens increasing in abundance in well-drained sites. Areas with low slope gradients and fine-textured soils often have ground cover dominated by cottongrass tussocks beneath a shrub layer of birch, black spruce, Labrador tea (*Rhododendron groenlandicum*), and occasionally tamarack (Yukon Ecoregions Working Group 2004a).

Evidence of forest fires can be observed throughout the RSA (Photo 1-2 and Photo 1-3). Alaskan paper-birch (*Betula neoalaskana*) is often the first tree species to colonize burn areas, and the extent of old burns is generally

correlated with young black spruce – Alaskan paper birch woodlands (Yukon Ecoregions Working Group 2004a). Fires increase the depth of the active permafrost layer, causing slope failures and changes in ecosystem moisture regimes.

Photo 1-2. Example of a regenerating moist forest stand after a fire within the RSA.

Photo 1-3. Example of a recently burnt area of the RSA.

2 BIRDS

2.1 PURPOSE AND OBJECTIVES

This section documents the occurrence, relative abundance, and habitat associations of birds occurring or likely occurring in the RSA. It includes a desktop assessment to collect and summarize existing information about birds; and field surveys to document the occurrence, relative abundance, and habitat associations of birds within the RSA. Field surveys were recommended by the regulator responsible for migratory birds (Environment and Climate Change Canada — Canadian Wildlife Service [CWS]) because no systematic bird surveys have been previously conducted in the Project area. Surveys in adjacent areas were limited and mainly were road-based surveys, which had limited or no coverage of particular habitat types. Two field survey types were used to provide representative coverage of broad avian habitat types and associated avian communities: (1) point count surveys and (2) pond and wetland surveys.

2.2 BIRD HABITAT OVERVIEW

The Project falls within Bird Conservation Region 4 (BCR 4), the Northwestern Interior Forest (Environment Canada 2013a). BCR 4 is home to 211 regularly occurring bird species, including 31 waterfowl species, 19 water bird species, 23 shorebird species, and 138 land bird species (Environment Canada 2013a). Most species are breeding season migrants, few are year-round residents. The Project is also within ~30 km of two other bird conservation regions: region 3 (BCR 3), the Arctic Plains and Mountains, and region 6 (BCR 6), the Boreal Taiga Plains. BCR 3 habitats are influenced by a short growing season and continuous permafrost; upland habitats range from heavily vegetated heath communities to sparse cryptobiotic crusts, lichens, and moss; in the southern end, dwarfed spruce trees are often found in restricted patches (Environment Canada 2013b). BCR 6 is primarily characterized by gently rolling or undulating landscapes, vegetation dominated by the boreal forest and interspersed with wetlands and several major river systems (Environment Canada 2013c). In total, BCR 3 has 159 species of birds, while BCR 6 has 288. This current study did not find species uniquely associated with either of these two conservation regions.

The RSA has three predominant bird habitat types: black spruce upland, willow and scrub birch shrubland, and scrub fens and bogs. Upland forests provide potential breeding habitat for resident Northern Goshawk (*Accipiter gentilis*), Spruce Grouse (*Canachites canadensis*), Northern Hawk Owl (*Surnia ulula*), American Three-toed Woodpecker (*Picoides dorsalis*), Canada Jay (*Perisoreus canadensis*), Boreal Chickadee (*Poecile hudsonicus*), White-winged Crossbill (*Loxia leucoptera*), and Common Redpoll (*Acanthis flammea*) (Frisch 1987, YEWG 2004, Environment Canada 2013). Migrants that breed in upland forests include Swainson's Thrush (*Catharus ustulatus*), Gray-cheeked Thrush (*Catharus minimus*), Varied Thrush (*Ixoreus naevius*), Bohemian Waxwing (*Bombycilla garrulus*), Yellow Warbler (*Setophaga petechia*), Yellow-rumped Warbler (*Setophaga coronata*), American Tree Sparrow (*Spizelloides arborea*), and Dark-eyed Junco (*Junco hyemalis*) (Frisch 1987, YEWG 2004). American Kestrel (*Falco sparverius*), Say's Phoebe (*Sayornis saya*), American Robin (*Turdus migratorius*), Orange-crowned Warbler (*Leiothlypis celata*), and Chipping Sparrow (*Spizella passerina*), as well as other species of thrush, warbler,

and sparrow, can be found in more open forests with a well-developed shrub layer, or shrublands with tall shrub and dwarfed spruce (Frisch 1987, YEWG 2004). A frequently occurring species in the Eagle Plains ecoregion, though rare elsewhere in Yukon, is Swainson's Hawk (*Buteo swainsoni*). This species is associated with isolated stands of productive white spruce for nesting habitat, mostly found in narrow riparian strips surrounded by open bogs and shrublands where they regularly forage.

Aquatic habitats for birds consist of open bodies of water (e.g., ponds, lakes), wetlands (mostly bogs and fens) and riparian zones dominated by sedges and shrubs. Open water bodies are limited in the RSA and are thus potentially inhabited by relatively few Tundra Swan (*Cygnus columbianus*), Greater White-fronted Goose (*Anser albifrons*), Canada Goose (*Branta canadensis*), American Wigeon (*Mareca americana*), Green-winged Teal (*Anas crecca*), and Bufflehead (*Bucephala albeola*) (Frisch 1987, YEWG 2004, Environment Canada 2013). Shorebirds such as Lesser Yellowlegs (*Tringa flavipes*), Solitary Sandpiper (*Tringa solitaria*), and Wilson's Snipe (*Gallinago delicata*) remain along the water's edge and in riparian zones consisting of coniferous and deciduous vegetation. Riparian zones also provide potential breeding habitat for Willow Ptarmigan (*Lagopus lagopus*), Alder Flycatcher (*Empidonax alnorum*), Yellow Warbler, Wilson's Warbler (*Cardellina pusilla*), American Tree Sparrow, and Lincoln's Sparrow (*Melospiza lincolnii*) (Frisch 1987, YEWG 2004). Spotted Sandpiper (*Actitis macularius*), Herring and Short-billed Gulls (*Larus argentatus* and *L. brachyrhynchus*), Belted Kingfisher (*Megaceryle alcyon*), Bank Swallows (*Riparia riparia*), and Cliff Swallows (*Petrochelidon pyrrhonota*) can be found along rivers (Frisch 1987, YEWG 2004).

Alpine/subalpine areas are absent from the RSA. Species that inhabit the alpine/subalpine in other parts of the ecoregion include Golden Eagle (*Aquila chrysaetos*), Rock Ptarmigan (*Lagopus muta*), Horned Lark (*Eremophila alpestris*), American Pipit (*Anthus rubescens*), Gray-crowned Rosy Finch (*Leucosticte tephrocotis*), Upland Sandpiper (*Bartramia longicauda*), and Townsend's Solitaire (*Myadestes townsendi*) (Frisch 1987, YEWG 2004).

The Project RSA does not include cliffs or bluffs that could be used by cliff-nesting raptors, such as Golden Eagle, Peregrine Falcon (*Falco peregrinus*) or Gyrfalcon (*Falco rusticolus*). These species' nearest suitable nesting cliffs are along the Porcupine River and Eagle River (Hayes and Mossop 1978).

Data on birds in the Project area are currently limited. The first evaluation of bird occurrences in Eagle Plains was *Birds by the Dempster* (Frisch 1987). Birds of the Yukon Territory (Sinclair et al. 2003) provided a more detailed description of species occurrences, habitat, and relative abundances. More recently, a general account of birds within the region was presented by Environment and Climate Change Canada in their report, *Bird Conservation Strategy for Bird Conservation Region 4 in Canada: Northwestern Interior Forest* (Environment Canada 2013a). The North American Breeding Bird Survey (NABBS) is the best local data source. Two NABBS routes along the Dempster Highway (routes 78 and 79) are close to the Project.

2.3 METHODS

This study consisted of two components: a desktop assessment to collect and summarize existing information about birds relevant to the Project area and field surveys to document the occurrence, relative abundance, and habitat associations of birds across the Project RSA. This approach, field survey design, and methods details

were discussed with CWS representatives during the project planning stage. The methods used considered specific recommendations provided by CWS representatives and a broader set of recommendations in *A Framework for the Scientific Assessment of Potential Project Impacts on Birds* (Hanson et al. 2009). The methods selected and reporting herein also comply with the the ten key considerations identified in the DRAFT updated guidelines *Canadian Wildlife Service Guidance Regarding Information Needed to Support Assessment of Project Effects on Birds* (ECCC-CWS 2022).

2.3.1 DESKTOP ASSESSMENT

A list of bird species that had the potential to occur in the Project RSA was developed from a combination of historical occurrence data in adjacent areas, a territorial field guide, and a national bird conservation assessment.

Historical data were gathered from the NABBS database for two routes (routes 78 and 79) that run along the Dempster Highway in the Eagle Plains region (Pardieck et al. 2019). The NABBS is a long-term, large-scale monitoring program that began in 1966 to track trends in avifauna. It consists of annual (one day a year) standardized roadside surveys, during the peak breeding season, by skilled observers making 50 stops spaced 0.8 km apart, along 39.4 km long routes. Observers record the number of bird species heard from any distance or seen within a 0.4 km radius of each stop during a three-minute observation period. These data are then compiled and made freely available to analyze trends in relative abundance and species composition. From 2014 to 2018, NABBS identified 48 species along Eagle Plains' two routes (above) (Pardieck et al. 2019).

General information about bird species occurrences was obtained from *Birds by the Dempster* (Frisch 1987), *Birds of Yukon* (Sinclair et al. 2003), and the Federal conservation assessment, *Bird Conservation Strategy for Bird Conservation Region 4 in Canada: Northwestern Interior Forest* (Environment Canada 2013a). These sources ranked species as 'Likely' or 'Possible' in the RSA based on habitat requirements, range boundaries, and occurrence information. Likely species were those whose range overlapped with the RSA, and suitable habitat occurred in the RSA. Possible species included (1) those with suitable habitat in the RSA, but whose range was on the edge of the RSA, and (2) those whose range overlapped with the RSA, but for which the availability of suitable habitat was in question.

2.3.1.1 Conservation Status

The conservation status of bird species was identified based on the most recent recommendations by COSEWIC (COSEWIC 2018) and current lists in the *Species at Risk Act* (SARA) registry (i.e., the most recent amendment, Environment and Climate Change Canada 2019) and BCR 4 plan. The SARA registry groups species into one of three schedules:

- Schedule 1 — the official list of species at risk in Canada includes species that are either Extirpated, Endangered, Threatened or of Special Concern;
- Schedule 2 — species designated as Endangered or Threatened, but that have yet to be re-assessed by COSEWIC under the revised criteria; and,

- Schedule 3 — species designated as Special Concern but have yet to be re-assessed by COSEWIC under the revised criteria.

Birds that fall under conservation categories of Special Concern or higher were identified. All bird species of conservation concern, identified through the designation and ranking processes described above, were evaluated against their species conservation status assessment found in the national bird conservation strategy for BCR 4 (Environment Canada 2013a). The BCR 4 strategy outlines conservation planning and priorities to support the implementation of migratory bird conservation programs. The BCR species assessment considered population size, population trend, regional abundances and densities, and species and habitat threats to designate species warranting "Concern and Stewardship at the Regional, National, or Continental level". Stewardship species are based on "having a large proportion of their world population within BCR 4". Species managed by Environment Yukon under the Yukon *Wildlife Act* were also noted.

2.3.2 HABITAT STRATIFICATION

A broad avian habitat classification system was developed to provide representative survey coverage across the RSA. A habitat stratification approach was applied to site selection for all survey sites before field surveys. Avian habitat types were initially developed using Predictive Ecosystem Mapping (PEM), later verified with Ecological and Landscape Classification (ELC) mapping for habitat-related analyses. Two key components of the initial PEM mapping to define avian habitat types were: ecosystem units and structural stage, described below.

2.3.2.1 Ecosystem Units (Ecosites)

The North Yukon PEM was used to classify 16 ecosystem units in the Project RSA. However, the PEM model was unsatisfactory when assessing ecosite predictions in the field because of its low accuracy. The PEM ecosite codes were used to guide each survey location, but adjustments were made to the classifications according to the dominant vegetation. These changes were supplemented with detailed notes and descriptions of plant and tree species (i.e., lichen cover, percent shrubs, tree height and canopy closure), as well as photographs, with the intent of reclassification.

The purpose of reclassifying PEM ecosystem units was to describe site-specific vegetation at a finer resolution and, ultimately, develop more accurate associations between species of birds and habitat in the Project RSA. A detailed review was conducted of all point count and wetland survey forms, including a review of notes on species of vegetation and structural stage (Table 2-1) and analyzing each survey station's photographs. Deciduous and coniferous (i.e., primarily black spruce) vegetation were distinguished based on their relative densities at ecosites previously classified as mixed wood. Patterns of bird occupation were then analyzed to determine whether deciduous and mixed vegetation warranted separate ecosite codes. Shrub-stage and mature-stage spruce stands were differentiated based on tree height and the degree of canopy closure. Separating these two structurally distinct stands yields two ecological communities with different bird assemblages, e.g., species requiring mature trees for nest cavities, such as owls and woodpeckers, are unlikely to be found in shrub-stage forests. These new ecosites were summarized along with their previous PEM codes

and descriptions of key vegetation characteristics. In total, 32 distinct ecosystem units were developed from the PEM model (Table 2-2).

Table 2-1. Structural and successional stages of vegetation associated with ecosystem units in the Eagle Plains Project Regional Study Area.[1]

Code	Structural Stage	Description
1	Non-vegetated	Very recent disturbance and no vegetation (or <5% vegetation).
2a	Sparse	Initial stages of primary and secondary succession with 5–10% vegetation cover maintained by environmental conditions.
2b	Cryptogram (Bryoid-dominated)	Bryophyte-dominated community maintained by environmental conditions.
3a	Herb (Forb-dominated)	Early successional stage of herbaceous communities maintained by environmental conditions or disturbance. Includes non-graminoid herbs and ferns.
3b	Herb (Graminoid-dominated)	Early successional stage of herbaceous communities maintained by environmental conditions or disturbance. Includes grasses, sedges, reeds, and rushes.
3c	Herb (Aquatic)	Early successional stage of herbaceous communities maintained by environmental conditions or disturbance. Dominated by floating or submerged plants.
4a	Tall Shrub	Early successional stage of forest or shrub communities dominated by shrub layer vegetation > 2 m tall.
4b	Low Shrub	Early successional stage of forest or shrub communities dominated by shrub layer vegetation <2 m tall.
5	Pole/Sapling	Trees >2 m tall and typically densely stocked. Vertical structure and layering not yet evident.
6	Young Forest	Forest canopy with distinct layers and somewhat open stand.
7	Mature Forest	Mature trees and well-developed understories at canopy openings.
8	Old Forest	Old and structurally complex stands composed mainly of shade-tolerant and regenerating tree species.

[1] Modified from Environment Yukon 2017.

Table 2-2. Modified predictive ecosystem mapping ecosites relative to original ecosites in the Eagle Plains Project Regional Study Area.

Modified PEM	PEM	*N*[1]	Vegetation Description
211-D	211	7	Wet deciduous shrub; predominantly willow and scrub birch. Structural stage 4b.
211-SB	211, 213	3	Wet black spruce shrub (peat bog). Structural stages 4a–6.
211-SB-ML	211, 213	2	Wet black spruce shrub with moderate lichen cover. Structural stages 4a–6.
213-tp	213	2	Wet black spruce dominant forest; tall and productive stands. Structural stages 6 and 8.
221	221	1	Moist mixed shrub; black spruce and deciduous (scrub birch and willow). Structural stage 4b.

Modified PEM	PEM	*N*[1]	Vegetation Description
221-D	221	12	Moist deciduous shrub; predominantly scrub birch and willow. Structural stages 4a–b.
221-SB	221, 223	18	Moist black spruce shrub. Structural stages 4a-6.
221-SB-LL	221, 223	3	Moist black spruce shrub with low lichen cover. Structural stage 4a.
221-SB-ML	223	2	Moist black spruce shrub with moderate lichen cover. Structural stage 6.
221-SB-HL	221	1	Moist black spruce shrub with high lichen cover. Structural stage 4a.
222	222	6	Moist mixed forest; spruce and deciduous (birch and/or alder). Structural stages 5-8.
222-D	222	1	Moist deciduous forest; birch dominant. Structural stage 6.
223-tp	222, 223	4	Moist black spruce forest; sometimes mixed with white spruce. Structural stages 6-7.
223-LL-tp	223	2	Moist black spruce forest; sometimes mixed with white spruce; low lichen cover. Structural stages 6-7.
230	230	1	Mesic herb with <15% shrub cover. Structural stages 2b and 4b.
231-D	231	4	Mesic deciduous shrub; predominantly willow and scrub birch. Structural stages 4a–b.
231-D-ML	231	1	Mesic deciduous shrub; predominantly willow and scrub birch; moderate lichen cover. Structural stage 4a.
231-SB	231, 233	7	Mesic black spruce shrub. Structural stages 4a–6.
231-SB-HL	233	3	Mesic black spruce shrub with high lichen cover. Structural stages 4a–6.
232	232	3	Mesic mixed forest; black spruce and deciduous (paper birch and/or trembling aspen). Structural stages 5–6.
232-D	232	3	Mesic deciduous forest; predominantly paper birch and willow. Structural stages 5–6.
233-tp	233	5	Mesic black spruce forest sometimes mixed with white spruce; tall and productive stands. Structural stages 6-7.
233-LL-tp	233	1	Mesic black spruce forest with some black spruce shrubs; low lichen cover; tall and productive stands. Structural stages 4b, 6–7.
233-HL-tp	233	1	Mesic black spruce forest; high lichen cover; tall and productive stands. Structural stage 6.
310	310	4	Riparian herb with little to no shrub cover. Structural stages 3b–c.
311-D	311	22	Riparian deciduous shrub; predominantly scrub birch and willow. Structural stages 4a-b.
311-SB	311, 313	4	Riparian black spruce shrub. Structural stages 4a–6.
311-SB-T	311	4	Riparian black spruce and tamarack shrub. Structural stages 4a–6.
313	313	11	Riparian spruce forest; mix of black and white spruce, as well as hybrids. Structural stages 6–8.
400	400	4	Wetland herb. Structural stage 3b.
401-D	401	1	Wetland deciduous shrub; predominantly scrub birch and willow. Structural stage 4b.
500	500	17	Open water.

[1] Sample size, the number of survey stations (point count or pond) within each modified PEM ecosite.

2.3.2.2 Bird Habitat Types

Once ecosystem units were reclassified, they were grouped according to vegetation and structural stage similarities. Mixed and deciduous vegetation, while ecologically distinct, did not differ in their use by birds; therefore, they were grouped in a single category. Ultimately, 32 ecosystem units were consolidated into ten broad avian habitat types: Herb, Deciduous/Mixed Shrub, Tall Shrub – Black Spruce, Deciduous/Mixed Forest, Spruce Forest, Riparian/Wetland Deciduous Shrub, Riparian Coniferous Shrub, Riparian Spruce Forest, Open Water, and a classification ('Unknown') for distant (>100 m) or flyover observations that prevented associating birds with habitat (Table 2-3). As a post hoc exercise, ELC ecosite types were assigned to broad habitat types based on the spatial overlap with survey sites with the ELC map and verified using field-based habitat descriptions (Table 2-3). For a complete list of ELC codes, names, and descriptions, see Attachment Table 1 in Section 2.6.1 (Attachment 2-A).

Table 2-3. Avian habitat types developed by grouping modified Predictive Ecosystem Mapping ecosites, based on their similarities in vegetation and structural stages, in the Eagle Plains Project Regional Study Area. *A posteriori* classified ELC ecosites are provided for each habitat type.

Avian Habitat Type	Modified PEM Ecosite	ELC Ecosite[1]	Structural Stages	*N*[2]	Vegetation Description
Herb	230, 310, 400	31, 33, 42, B2	2b, 3b, 3c, 4b	9	Herb dominant sites found along crests and upper slopes, riparian zones, and wetlands; <20% shrub cover.
Deciduous and Mixed Shrub	211-D, 221, 221-D, 231-D, 231-D-ML	06, 22, 23, 31, 33, 34, 35, 42, B2	4a-b	24	Predominantly scrub birch and/or willow vegetation, sometimes with a mix of black spruce; lichen cover possible.
Tall Shrub – Black Spruce	211-SB, 211-SB-ML, 221-SB, 221-SB-LL, 221-SB-ML, 221-SB-HL, 231-SB, 231-SB-HL	05, 06, 14, 20, 23, 33, 34, 42	2b, 4a-b, 6	35	Tall shrub/dwarfed black spruce dominated area often with low to high lichen cover.
Deciduous and Mixed Forest	222, 222-D, 232, 232-D	04, 05, 06, 33, 34	5, 6, 7, 8	13	Birch dominant forest or mix of spruce and deciduous (e.g., birch, aspen, and alder) stands.
Spruce Forest	213-tp, 223-tp, 223-LL-tp, 233-tp, 233-LL-tp, 233-HL-tp	05, 33, 42, B1	6, 7, 8	14	Black spruce dominant forest, sometimes mixed with white spruce, and often with low to high lichen cover. Ranges from intermediate height stands with open canopy to tall and closed canopy forest.
Riparian/Wetland Deciduous Shrub	311-D, 401-D	20, 23, 31, 33, 35, 42, 43, 44	2b, 3b, 4a-b	23	Predominantly scrub birch and willow shrub along riparian zones and wetlands.
Riparian Coniferous Shrub	311-SB, 311-SB-T	22, 33, 35, 42, 43, B1	2b, 4a-b, 6	8	Black spruce and tamarack dominant riparian shrub.
Riparian Spruce Forest	313	22, 23, 31, 35, 42, 43, B2	6, 7, 8	11	Dominated by mix of black and white spruce, as well as spruce hybrids.
Open Water	500	LA, PD	1	17	Non-vegetated open water.
Unknown	UNK	UNK	UNK	74	Unknown habitat due to distant observations (>100 m) or flyovers.

[1] Broad ELC polygons within which survey stations were located.

[2] Sample size, the number of survey stations (point count or pond) within each habitat group.

2.3.3 OCCURRENCE AND DISTRIBUTION SURVEYS

Two experienced bird biologists conducted field surveys in the Project RSA between June 25 to 30, 2019. Each biologist had more than 15 years of experience conducting point count surveys and could reliably identify all bird species by sight and vocalizations that had the potential to occur. All surveys employed a targeted, stratified habitat design to provide sampling across all broad avian habitat types.

2.3.3.1 Breeding Bird Point Count Surveys

'Point count' surveys were conducted in terrestrial habitats following standardized survey methods (Ralph et al. 1995, Resources Inventory Committee 1999a, Matsuoka et al. 2014). Point count stations were visited along walking transects to facilitate efficient survey productivity (i.e., versus individual point counts spaced more widely, which would have resulted in longer travel time and a lower number of survey stations). Point count survey stations were established within a Geographic Information System (GIS) using guided site selection to provide coverage across all avian habitat types and broad spatial coverage across the RSA (Map 2-1). Random site selection approaches were explored but ultimately not used because of challenges associated with safety (steep terrain), logistics (access), and reduced sample sizes (i.e., randomization resulted in much smaller sample sizes due to greater travel times to transect starting stations and between stations). Site selection targeted a minimum of four stations in each habitat type. The location of existing and proposed development features was also considered to ensure the surveys covered those areas. Stations were spaced approximately 500 m apart, with a minimum spacing of 400 m, to avoid counting the same birds from multiple stations. Point count locations were chosen in two ways to associate bird occurrences with habitat types: (1) locating stations within one PEM polygon, at least 100 m from the polygon edge; and (2) locating the station on the boundary between two PEM polygons where the location of birds in different habitat types could be reliably determined (e.g., on the transition between shrubland and forest type). Each point count station was surveyed once to maximize the number of sampled sites.

Survey methods followed standard point count survey methodologies (Ralph et al. 1995, Resources Inventory Committee 1999a, Matsuoka et al. 2014). Surveys used a 10-minute detection period and an unlimited recording distance. Biologists conducted surveys during the dawn chorus (i.e., a half-hour before dawn to ~8:30) when territorial singing rates are highest. Upon arriving at the predetermined survey station location, surveyors evaluated the station location and, where appropriate, revised the location by up to 50 m to aid in accurately plotting bird locations in their associated habitat types. Once on station, surveyors waited two minutes to allow any birds disturbed by the surveyor's arrival to settle and resume their activities. Once the official observation period began, surveyors recorded all birds detected (visual or auditory) during the 10-minute detection period by plotting their locations on a point count map form and recording the standardized four-letter species name abbreviation, time of detection, sex, age, number, behaviour, and the habitat type in which they occurred (i.e., ecosystem unit and structural stage). Surveyors assigned birds estimated to be >100 m distant at a distance of 101 m due to the high uncertainty of estimates at those distances. Following the surveys, a bearing and distance were measured on the point count map from the

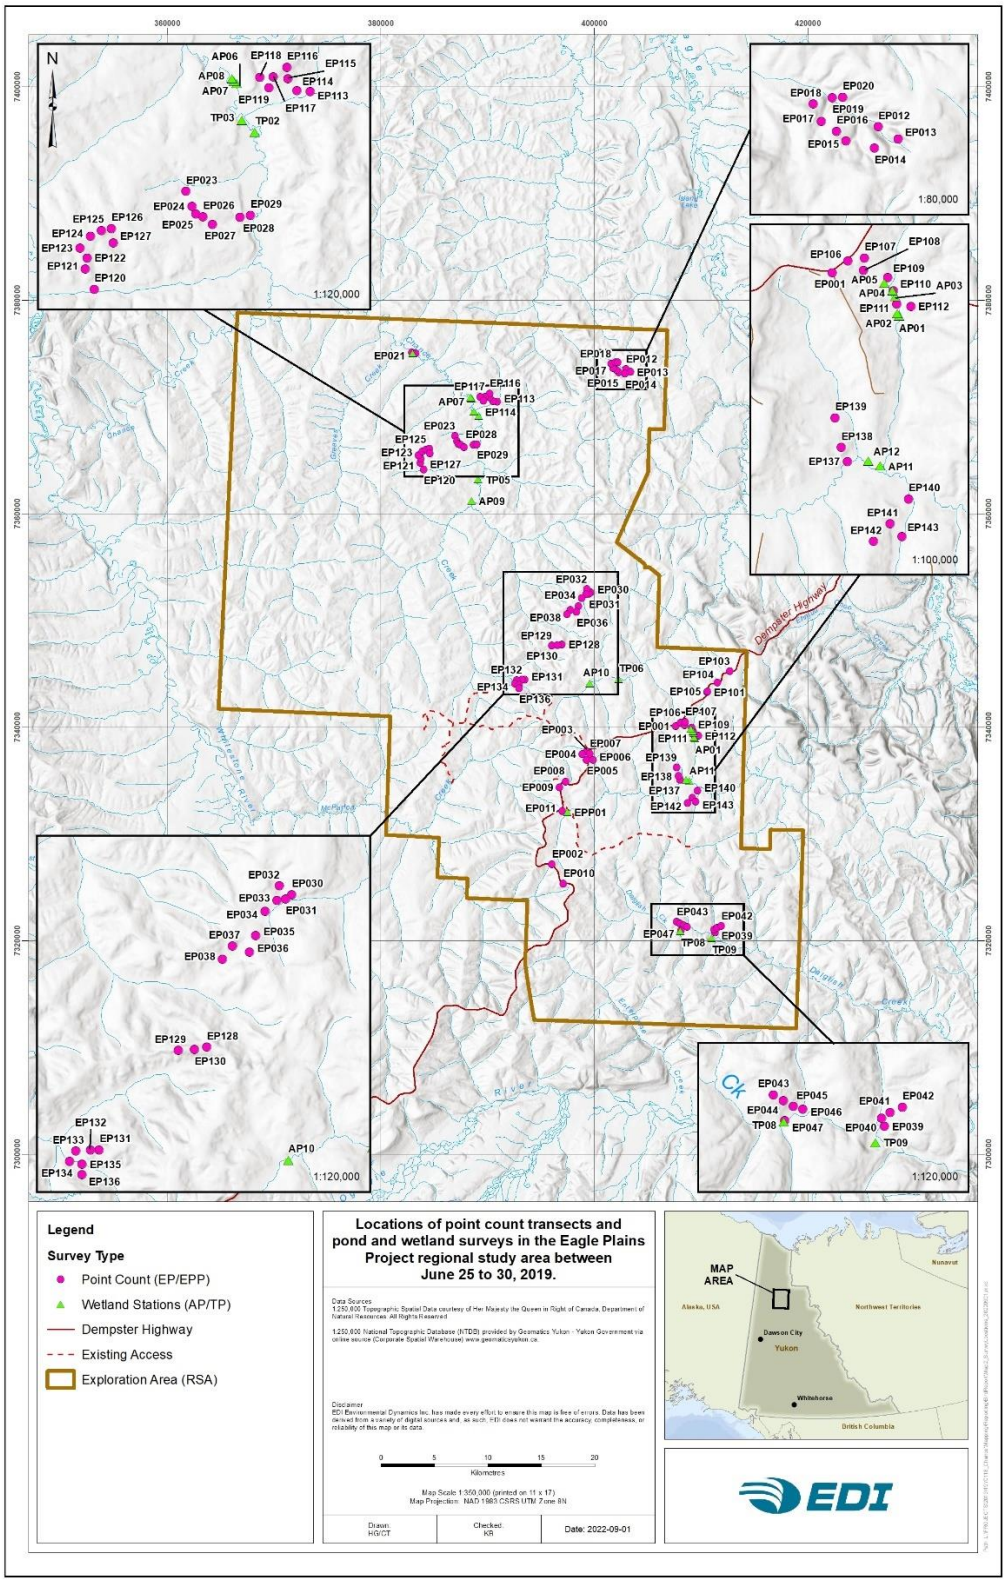
station location for each bird observation (<100 m) used to calculate coordinates for each observation. A total of 91 point count stations were surveyed over six days.

2.3.3.2 Pond and Wetland Surveys

For wetland surveys, protocols were adapted from the BC RISC Standards *Inventory Methods for Waterfowl and Allied Species* (Resources Inventory Committee 1999b). Before surveys, ponds and open water wetlands within 3 km of existing or proposed project development were identified using the PEM map. Shoreline surveys were conducted at 19 unique ponds, and observations were made from stations along the shoreline using binoculars and scopes. The number of stations varied from one to five, depending on the size and shape of the ponds. Approximately half of a pond's total perimeter was traversed along a section of shoreline parallel to the longest axis of the feature to provide complete visual coverage of the waterbody. Surveyors approached waterbodies covertly and began surveys behind screening vegetation to avoid flushing birds from the ponds before they were tallied. Ground-based surveys were thought to provide a census of birds present at each pond. However, a few birds obscured by shoreline vegetation may not have been counted. Biologists recorded the following information for each pond for all detected birds: species, sex, age, number, and habitat associations.

2.3.3.3 Cliff-nesting Raptors Habitat Assessment

Cliff-nesting raptors, including Peregrine Falcon, Gyrfalcon, and Golden Eagle, are relatively common in parts of North Yukon with suitable cliffs, such as the Ogilvie Mountains, south of Eagle Plains. Nesting occurrences of these species are not known in the Eagle Plains area. Due to the subdued topography of the Eagle Plains area, suitable nesting cliffs are likely to be uncommon or non-existent. We systematically assessed the potential for suitable nesting cliffs across the study area by mapping areas with a slope >30 degrees (the lowest gradient in which EDI Environmental Dynamics Inc. (EDI) staff have found cliff nests in other parts of the Yukon). This mapping exercise did not identify any suitable cliffs in the area. Therefore, targeted field surveys for this species group were not conducted.



Map 2-1. Locations of point count transects and pond and wetland surveys in the Eagle Plains Project Regional Study Area between June 25 to 30, 2019.

2.4 RESULTS AND DISCUSSION

2.4.1 DESKTOP ASSESSMENT

Based on range and habitat requirements, 128 species can occur in the Eagle Plains Project RSA. This includes 99 'Likely' species (52 confirmed by surveys and incidental observations presented in this report) and 29 'Possible' species. These 'Possible' species included Common Nighthawk (*Chordeiles minor*) observed once in the RSA during these surveys. Despite the confirmed occurrence, the species is still considered 'Possible' because it is outside its regular range, and none were observed during NABBS between 2014 and 2018 (i.e., the single observation during these surveys could have been an extralimital record). A summary of these potential species and conservation statuses, ordered by species groups, is provided in Table 2-4. A more detailed discussion of the species identified within the Project RSA is provided in Section 2.4.2. For an exhaustive list of all potential bird species, see Attachment Table 2 in Section 2.6.2 (Attachment 2-B).

The NABBS database is a valuable information source for the occurrence and distribution of bird species in the region because they are a recent and systematic survey. Of the two survey routes near the Project area (i.e., routes 78 and 79), route 79 was surveyed annually between 2014 and 2018, and route 78 was surveyed in each of those years except 2016. In total, observers who participated in these surveys identified 1,945 birds from 48 species (Table 2-4). Though these data are useful in identifying species common to the region, road-side surveys introduce bias in estimating species occurrences and relative abundances, especially when extrapolating to off-road areas (Sólymos et al. 2020). This may explain why 'Possible' species (e.g., Harlequin Duck [*Histrionicus histrionicus*], Surfbird [*Calidris virgata*], and Golden-crowned Sparrow [*Zonotrichia atricapilla*]) were recorded on the NABBS routes but not within the RSA, and why 18 species confirmed during surveys within the RSA (e.g., Red-necked Phalarope [*Phalaropus lobatus*], Great Gray Owl [*Strix nebulosa*], and American Three-toed Woodpecker), were not detected over five years of road-side surveys.

Overall, species occurrence and relative abundance patterns differed among years in both NABBS routes. The total number of detections decreased from 2014 to 2018, and this pattern was consistent for most bird species. This may partly correspond to the survey effort. The number of species identified and the number of birds detected were similar between route 78 (920 counts from 34 species) and route 79 (1,025 counts from 39 species) during the five-year period. No species-specific trends were evident in the data.

The NABBS data also included three species (six detections) federally designated as Special Concern: Short-eared Owl (*Asio flammeus*; one occurrence in both 2015 and 2016, and two occurrences in 2018), Rusty Blackbird (*Euphagus carolinus*; one occurrence in 2015), and Olive-sided Flycatcher (*Contopus cooperi*; one occurrence in 2018).

Table 2-4. Total number of potential (likely and possible) bird species in the Eagle Plains Project Regional Study Area, June 2019, grouped by higher-order classification. North American Breeding Bird Survey (2014–2018) confirmed species and counts are provided.

Order	Likely	Possible	Likely + Possible (Total)	NABBS Confirmed (2014–2018)[1]

[1] Count of individual bird observations for each group in brackets.

2.4.2 OCCURRENCE AND RELATIVE ABUNDANCE

A total of 974 birds from 52 species were detected during the breeding bird surveys (i.e., point count transects and wetland/pond surveys). One raptor species not included in these counts—Swainson's Hawk—was identified, incidentally, on four separate occasions between June and August 2019, totalling five individuals. These additional observations bring the number of total detections to 979 birds from 53 species.

Songbirds (*Passeriformes*) were the most diverse and abundant group of birds, while falcons (*Falconiformes*), owls (*Strigiformes*), and nightjars (*Caprimulgiformes*) were the least diverse and abundant (Table 2-5). Proportionally, more waterfowl and shorebirds were identified during wetland/pond surveys, and more songbirds and raptors were identified during point count transects. More birds were counted during point count transects (743 versus 231), but a similar number of species were identified during point counts transects and wetland/pond surveys (42 in point counts and 37 in wetlands; Table 2-5).

Table 2-5. Total counts and species of birds observed during point count transects and wetland/pond surveys in the Eagle Plains Project Regional Study Area, June 2019, grouped by higher-order classification.

Order	Point Count Transects		Wetland/Pond Surveys		Combined	
	Count	No. Species	Count	No. Species	Count	No. Species
Waterfowl – Anseriformes	3	2	99	7*	102	7
Shorebirds – Charadriiformes	18	4	38	7*	56	7

* Number of species from wetland/pond surveys were not all unique from those in point count transects.

2.4.3 SPECIES AND HABITAT ASSOCIATIONS

Analyses of the association between bird species and habitat type controlled for survey effort (i.e., average counts per point count station). The average number of birds (i.e., relative abundance) and the average number of species varied considerably among survey stations and the different avian habitat types (Figure 2-1; Table 2-6). The average relative abundance was greatest in Open Water, Deciduous and Mixed Shrub, Riparian/Wetland Deciduous Shrub, and Spruce Forest habitats; it was lowest in Riparian Spruce Forest, Herb, and Tall Shrub – Black Spruce habitats. Among habitat types, the proportion of (average) detections to the (average) number of species was consistent, with a higher relative abundance being associated with a greater number of species. In general, this pattern was related to the structural complexity and productivity of the various habitat types. For example, Herb habitat is less structurally complex and consists exclusively of graminoid ground cover; it had the fewest species (but had a relatively high number of unique species; see Figure 2-2). In contrast, Spruce Forest habitat can be structurally complex due to variations in canopy cover, understory, and ground cover, and older stands may contain a variety of forest structures that provide habitat for a variety of bird species and life requisites including nesting (e.g., Yellow-rumped Warbler), perching (e.g., Olive-sided Flycatcher), and insect foraging (either on the ground [e.g., Gray-cheeked Thrush] or on live/dead trees [e.g., American Three-toed Woodpecker]). Consequently, Spruce Forest had the greatest species richness of all avian habitat types. The exception to the general association between relative abundance and species richness was Open Water habitat, which had the highest relative abundance but one of the lowest average number of species.

The number of species (i.e., species richness) and the number of unique species (i.e., species exclusive to a habitat type) were summarized for each avian habitat type. Unequal survey effort across habitat types could bias such comparisons of species totals across habitat types; however, it does provide a useful approach to examine general patterns of bird occurrence and assemblages within and across habitat types. Spruce Forest, Riparian/Wetland Deciduous Shrub, and Deciduous and Mixed Shrub habitat types had the greatest species richness, while Herb and Open Water habitat types had the least species richness (Figure 2-2). Patterns of species richness may, in part, be due to the distribution of survey stations in each habitat type, especially in Herb habitat (only nine stations). The Open Water habitat also had low species richness despite surveys at 17 survey stations. This may reflect the limited availability of waterbodies and wetlands in the broader region (i.e., relatively few water-associated bird species occur because the habitat is so limited and dispersed).

No clear association was found between species richness and the number of unique species. For example, Open Water was one of the least species-rich habitat types but had the most unique species. This is not surprising because Open Water is a unique habitat compared to the other terrestrial habitats, and a different complement of bird species occurs there. Other habitat types with many species (e.g., 21 species in Deciduous and Mixed Shrub) had no species unique to those habitats. Likely, riparian habitat types did not have unique species because species that occupy riparian habitat often have broad, rather than specific, requirements. For example, Rusty Blackbird and Lesser Yellowlegs were found in Riparian Coniferous Shrub, Riparian/Wetland Deciduous Shrub, and Herb habitat types.

Patterns of bird occurrences were analyzed in terms of species-specific detection rates (Table 2-6). Songbird species had the highest detection rates overall because these species consistently occupied several different habitat types. Only 15 species occupied a single habitat, and the remaining 47 species occupied multiple habitats (most frequently two or three habitats; Figure 2-3). Species that occupied four or more habitat types were exclusively songbirds and had the highest detection rates. This included species groups such as thrushes, sparrows, and their respective allies. Only 10 species occurred in six or more habitats: Canada Jay, American Robin, Gray-cheeked Thrush, Swainson's Thrush, Common Redpoll, Fox Sparrow (*Passerella iliaca*), White-crowned Sparrow (*Zonotrichia leucophrys*), American Tree Sparrow, Lincoln's Sparrow, and Yellow Warbler. Overall, species with high detection rates included a combination of habitat specialists and habitat generalists. Waterfowl and obligatory wetland species (e.g., Red-necked Phalarope), which were restricted to Open Water habitat, had high detection rates in that habitat (Table 2-6).

In contrast, thrushes (e.g., Gray-cheeked Thrush) and warblers (e.g., Yellow Warbler), which occupied several different habitat types, had high detection rates in many of the habitats they occupied (Table 2-6). The five species with the highest overall (average) detection rates (i.e., across all 110 survey stations in the RSA) were Canada Jay, Swainson's Thrush, Lincoln's Sparrow, White-crowned Sparrow and Yellow-rumped Warbler. For a general overview of bird species assemblages within each habitat type, ordered by highest to lowest detection rates, see Table 2-7. General patterns of frequency and use of habitat types by species in the RSA are consistent with expectations and correspond to patterns reported in other studies (Schieck and Song 2006, Mahon et al. 2016).

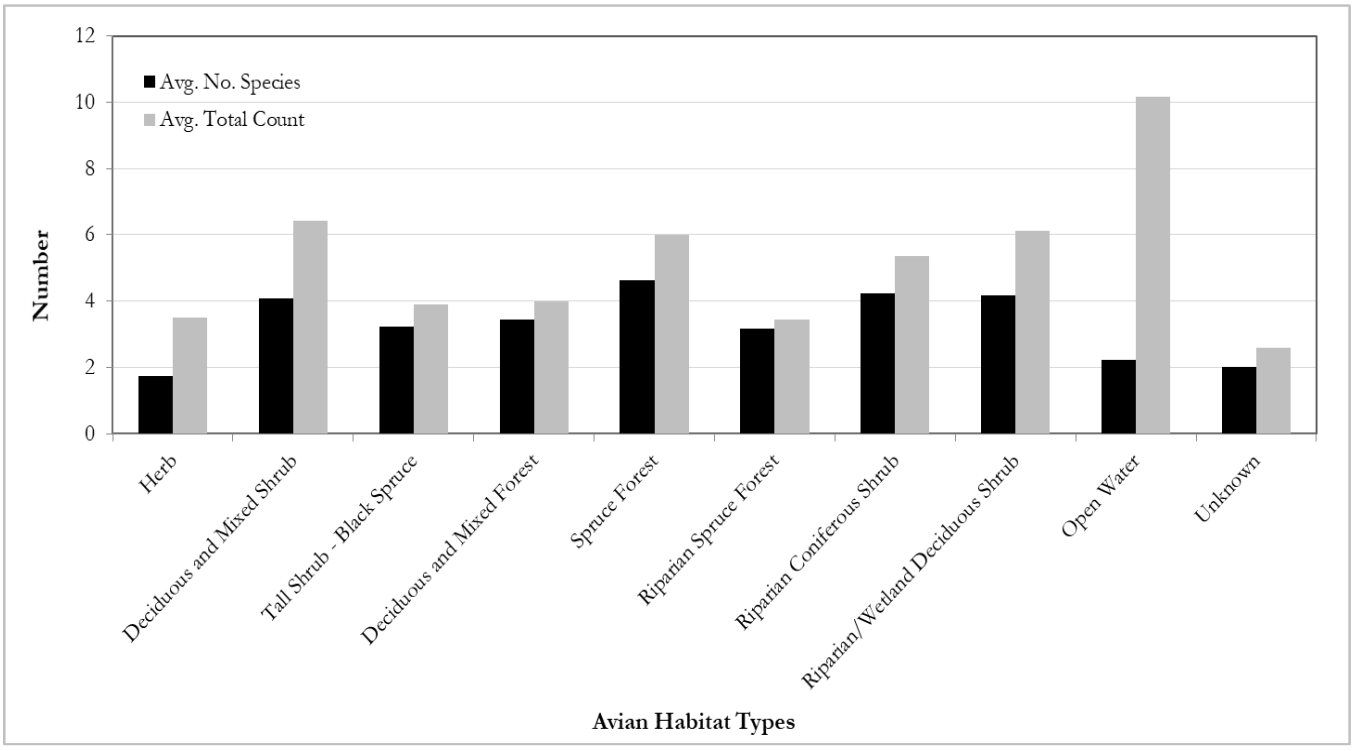

Figure 2-1. The average number of species and average total counts of birds observed among the avian habitat types in the Eagle Plains Project Regional Study Area, June 2019.

[1] Birds listed in descending order of average detection rate (values after the bird names) in each avian habitat type.

[2] Values in the column headings indicate the number of samples per habitat type.

2.4.4 SPECIES OF CONSERVATION CONCERN

Four species observed in the Project RSA (Red-necked Phalarope, Common Nighthawk, Olive-sided Flycatcher, and Rusty Blackbird) were federally listed as either Special Concern or Threatened (Table 2-8). These species are either of regional, national, or continental concern, and two are designated with regional stewardship in BCR 4. The conservation statuses of all potential bird species in the Project area are listed in Attachment Table 2 in Section 2.6.2 (Attachment 2-B). Of those species, three additional species of Conservation Concern are likely to occur in the Project RSA, including Horned Grebe (*Podiceps auritus)*, Short-eared Owl, and Bank Swallow (Table 2-8). Two cliff-nesting raptors listed as 'specially protected' species under the Yukon *Wildlife Act*, Peregrine Falcon and Gyrfalcon, can occur in the broader region but are unlikely to occur in the Project RSA because of a lack of appropriate cliffs. Another 'specially protected' species, Trumpeter Swan (*Cygnus buccinator*; not listed below), is exclusive to southern Yukon and Alaska during the breeding season and, thus, is unlikely to occur in the Project RSA.

Table 2-8. The conservation status and counts of bird species in the Eagle Plains Project RSA.

Species Common Name	COSEWIC[4]	SARA[5]	BCR 4 Priority[6]	Yukon *Wildlife Act*	RSA Count	NABBS Count (2014–2018)
Horned Grebe[1]	SC (Apr 2009)	1 – SC	R – stewardship N/C – concern	No	0	0
Red-necked Phalarope	SC (Nov 2014)	1 – SC	N/C – concern	No	15	0
Peregrine Falcon[2]	NAR (Nov 2017)	–	R – stewardship N/C – concern	Yes	0	0
Gyrfalcon[2]	NAR (Apr 1987)	–	–	Yes	0	0
Short-eared Owl[1]	T (May 2021)	1 – SC	N/C – concern	No	0	4
Common Nighthawk[3]	SC (Apr 2018)	1 – T	N/C – concern	No	1	0
Olive-sided Flycatcher	SC (Apr 2018)	1 – T	R – stewardship R/N/C – concern	No	6	1
Bank Swallow[1]	T (May 2013)	1 – T	–	No	0	0
Rusty Blackbird	SC (Apr 2017)	1 – SC	R – stewardship R/N/C – concern	No	19	1
			Totals		**41**	**6**

[1] Species that are 'Likely' to occur in the Eagle Plains Project RSA.

[2] Cliff-nesting raptors that are 'Likely' to occur in the broader region, but do not have suitable habitat in the Eagle Plains Project RSA.

[3] A species that is 'Possible' in the Eagle Plains Project RSA because of its range limits. One occurrence was observed but status remains uncertain.

[4] Most recent COSEWIC assessments; E = Endangered, NAR = Not at Risk, SC = Special Concern, T = Threatened.

[5] SARA statuses from the latest amended list in May 2023 (Legislative Services Branch 2023); Schedule 1 codes equivalent to COSEWIC.

[6] Priorities, concerns, and stewardships from BCR 4 2013 report; C = Continental, N = National, R = Regional.

2.4.5 ADEQUACY OF ONE YEAR OF SURVEYS

The official guidance provided by the Canadian Wildlife Service for avian baseline studies usually is to conduct at least two years of field surveys (Hanson et al. 2009), and the DRAFT 2022 guidelines emphasize a statistical review of the power to detect changes (ECCC-CWS 2022). Repeat surveys account for annual variation in patterns of bird occurrences and distribution and imperfect detectability associated with bird survey methods. During our initial consultation with CWS we proposed conducting a single year of surveys, dependent on the outcome of the surveys. CWS indicated that they always prefer to see multiple years of data collected. However, they may not raise objections to the Project Proposal if significant avian conservation concerns or information uncertainties do not occur. In our opinion, the one year of multi-species field surveys that we conducted, in combination with the desktop assessment, provides sufficient baseline information about bird species to proceed with the Project Proposal.

2.5 SUMMARY

The purpose of this study was to document the potential occurrence, relative abundance, and habitat associations of birds across the Project's RSA. This study consisted of a combination of a desktop assessment and field surveys. The information presented in this report was collected by Professional Biologists and qualified environmental practitioners, following generally accepted scientific survey designs and methods. The field survey design used a targeted, stratified habitat design to provide a representative sample across the RSA.

Based on range and habitat, 128 species potentially occur in or adjacent to the RSA. Forty-eight (48) were recorded from the North American Breeding Bird Survey data in adjacent areas. Possible species include eight listed under the SARA or identified in the Yukon *Wildlife Act*, and 67 are considered a priority and management concern under the federal Bird Conservation Region 4 Plan. Birds listed under the SARA observed during surveys included Red-necked Phalarope, Common Nighthawk, Olive-sided Flycatcher, and Rusty Blackbird.

Field surveys observed 53 species in the RSA. Point counts identified 42 species, and wetland surveys identified 37 species. Swainson's Hawk was identified via incidental sightings and is an interesting species. It has a disjunct breeding range in North Yukon separated by several hundred kilometres from their primary range to the south. Patterns of species relative abundance and richness (number of species) varied among the different habitat types. Average relative abundance and species richness were the greatest in Spruce Forest, Deciduous and Mixed Shrub, Riparian/Wetland Deciduous Shrub habitats, and lowest in Herb and Tall Shrub – Black Spruce habitats. These patterns were generally related to the structural complexity and productivity of these different habitat types. However, the number of unique species in each habitat did not depend on structural complexity. Many unique species were found in the Herb and Open Water habitats. General patterns of bird occurrence and habitat associations in the RSA are consistent with expectations and correspond with the limited existing information about birds in the area.

2.6 BIRD SECTION ATTACHMENTS

2.6.1 ATTACHMENT 2–A — ECOLOGICAL AND LANDSCAPE CLASSIFICATION ECOSYSTEM UNITS

Ecological and Landscape Classification (ELC) Ecosystem Units (Ecosites)

Codes, names, and descriptions of ecosites assigned *a posteriori* to habitat groups in the Project RSA are listed below.

Attachment Table 1. Ecological Landscape Classification ecosystem units developed for the Eagle Plains Project Regional Study Area.

Code	Name	Description and typical situation
10	Sparsely Vegetated	Vegetative cover <10%.
11	Dry Herb	Area dominated with herbaceous vegetation with very low shrub cover (<5%).
12	Dry Lichen	*Cladonia* sp. (i.e., caribou forage species) dominated areas with very low shrub cover (<5%) typically on south facing slopes.
13	Dry Mix Shrub	Dry shrub dominated areas with very low *Cladonia* sp. (i.e., caribou forage species) cover (<10%); disclimax community.
14	Dry Shrub/ Spruce – Lichen	Dry areas with spruce cover >5% and *Cladonia* sp. (i.e., caribou forage species) cover >10%.
15	Dry Shrub/ Aspen – Lichen	Dry areas with aspen cover >5% and *Cladonia* sp. (i.e., caribou forage species) cover >10%.
16	Dry Spruce – Birch – Lichen	Dry areas with either white spruce, black spruce, and/or Alaskan paper birch cover; spruce, scrub birch, and *Cladonia* sp. (i.e., caribou forage species) cover >10%.
17	Dry Aspen	Dry areas with aspen dominant canopy and very low *Cladonia* (i.e., caribou forage species) cover (<5%).
01	Mesic Herb	Area dominated by herbaceous vegetation with very low shrub cover (<5%); neither disclimax nor successional pathway known. No distinct mottles or seepage present; some sites may have permafrost (frozen layer contains no ice crystals or ice layers).
02	Mesic Birch – Willow	Area has a history of anthropogenic disturbance; regeneration is dominated by either Alaskan paper birch and/or willow species. No distinct mottles or seepage present, some sites may have permafrost (frozen layer contains no ice crystals or ice layers).
03	Mesic White Spruce – Alaskan Paper Birch – Alder	Area dominated by Alaskan paper birch with mixed-wood understory (i.e., white spruce and alder). Usually found along upper slope to crest positions on gentle to moderate slopes. No distinct mottles or seepage present, some sites may have permafrost (frozen layer contains no ice crystals or ice layers).
04	Mesic Black Spruce – Alaskan Paper Birch	Area dominated by black spruce and Alaskan paper birch with >30% shrub cover; mid-slope position. No distinct mottles or seepage present, some sites may have permafrost (frozen layer contains no ice crystals or ice layers).
05	Mesic Alaskan Paper Birch	Area dominated by Alaskan paper birch stands with > 30% shrub cover; mid- to upper-slope position. No distinct mottles or seepage present, some sites may have permafrost (frozen layer contains no ice crystals or ice layers).
06	Mesic Black Spruce – Labrador Tea	Area dominated by black spruce with Labrador tea shrub layer; level or mid- to upper-slope position on gentle slopes. No distinct mottles or seepage present, some sites may have permafrost (frozen layer contains no ice crystals or ice layers).

Code	Name	Description and typical situation
20	Shrubby Riparian Birch – Willow	Shrubby riparian area dominated by scrub birch, tea-leaved willow, or diamond leaved willow and bog cranberry; disclimax community.
21	Riparian White Spruce – Prickly Rose	Treed riparian zone dominated by white spruce with a mixture of shrub species; rose usually present.
22	Riparian Spruce – Birch – Willow	Treed riparian zone dominated by white and black spruce, possibly some Alaskan paper birch, and a mixture of shrub species such as scrub birch and willow.
30	Moist Herb	Area dominated with herbaceous vegetation with very low shrub cover (<5%) on gentle to moderate slopes. Faint to distinct mottles can be observed; no seepage or slight seepage present. Permafrost is present but at variable depths; some ice crystals can be observed in frozen layer.
31	Moist Shrub/ Scrub Birch – Labrador Tea – Willow	Area dominated by scrub birch and Labrador tea with <10% spruce cover; shrub layer has tea-leaved willow. Typically found at level or mid- to upper-slope position on gentle slopes. Successional pathway unknown but considered a shrub disclimax site. Faint to distinct mottles can be observed; no seepage or slight seepage present. Permafrost is present; some ice crystals can be observed in frozen layer.
32	Moist Shrub/ Spruce – Scrub Birch – Labrador Tea	Area dominated by >10% spruce cover, <5% willow cover, and >15% lowbush cranberry. Typically found at mid to upper slope position on gentle slopes; disclimax community. Faint to distinct mottles can be observed; no seepage or slight seepage present. Permafrost is present but at variable depths; some ice crystals can be observed in frozen layer.
33	Moist Spruce – Labrador Tea	Area dominated by >15% spruce tree cover. Presence of *Cladonia* sp. (i.e., caribou forage species). Typically found at level or upper-slope position on gentle slopes. Faint to distinct mottles can be observed; no seepage or slight seepage present. Permafrost is present but at variable depths due to frost boils; some ice crystals can be observed in frozen layer.
34	Moist Spruce – Alder – Labrador Tea	Area dominated by >15% spruce tree cover; alder and *Cladonia* sp. (i.e., caribou forage species) present. Typically found at mid-slope position on gentle slopes. Faint to distinct mottles can be observed; no seepage or slight seepage present. Permafrost is present but at variable depths due to frost boils; some ice crystals can be observed in frozen layer.
35	Moist Spruce – Scrub Birch – Labrador Tea	Area dominated by <15% spruce tree cover with *Cladonia* sp. (i.e., caribou forage species) present. Typically found at level or gentle slopes. Faint to distinct mottles can be observed; no seepage or slight seepage present. Permafrost is present but at variable depths due to frost boils; some ice crystals can be observed in frozen layer.
36	Moist Birch – Willow	Area dominated by willow and birch trees, often associated with old anthropogenic disturbances; successional pathway unknown. Faint to distinct mottles can be observed; no seepage or slight seepage present. Permafrost is present but at variable depths due to frost boils; some ice crystals can be observed in frozen layer.
40	Wet Herb	Area dominated with herbaceous vegetation with very low shrub cover (<5%) on level to lower-slope positions. Distinct to prominent mottles; seepage present; permafrost near surface. Ice layer present within or above frozen soil or frozen organic layer.
41	Wet Shrub – Tamarack	Area with >5% tamarack; low presence of *Cladonia* sp. (i.e., caribou forage species) and high presence of *Sphagnum* sp. or glow moss. Scrub birch and Labrador tea present. Distinct to prominent mottles; seepage present; permafrost near surface. Ice layer present within or above frozen soil or frozen organic layer.
42	Wet Shrub – Black Spruce – Tussock Cottongrass	Area dominated by >5% black spruce and >10% tussock cottongrass. Labrador tea, scrub birch, *Sphagnum* sp. and *Cladonia* sp. (i.e., caribou forage species) present. Typically found on level ground but also from toe to mid-slope positions; disclimax community. Distinct to prominent mottles; seepage present; permafrost near surface. Ice layer present within or above frozen soil or frozen organic layer.

Code	Name	Description and typical situation
43	Wet Shrub – Black Spruce – Sphagnum	Area dominated by >5% black spruce, <10% tussock cottongrass, and >25% *Sphagnum* sp.; disclimax community. Distinct to prominent mottles; seepage present; permafrost near surface. Ice layer present within or above frozen soil or frozen organic layer.
44	Wet Shrub – Scrub Birch – Tussock Cottongrass	Area dominated by <5% black spruce, >10% scrub birch, and >30% tussock cottongrass; disclimax community. Distinct to prominent mottles; seepage present; permafrost near surface. Ice layer present within or above frozen soil or frozen organic layer.
45	Wet Shrub – Scrub Birch – Graminoid	Burned area composed of <5% black spruce; dominant shrub is scrub birch, while dominant graminoid is either spruce muskeg sedge or bluejoint reedgrass; disclimax community. Distinct to prominent mottles; seepage present; permafrost near surface. Ice layer present within or above frozen soil or frozen organic layer.
46	Wet Black Spruce – Labrador Tea – Cladonia	Area with >15% black spruce, >20% *Cladonia* sp. (i.e., caribou forage species), and <5% tussock cottongrass. Distinct to prominent mottles; seepage present; permafrost near surface. Ice layer present within or above frozen soil or frozen organic layer.
47	Wet Black Spruce – Tussock Cottongrass – Sphagnum	Area with >15% Labrador tea and <10% *Cladonia* sp. (i.e., caribou forage species). Distinct to prominent mottles; seepage present; permafrost near surface. Ice layer present within or above frozen soil or frozen organic layer.
48	Wet Black Spruce – Carex	Area dominated by either a spruce muskeg sedge or bluejoint reedgrass herbaceous layer; shrub layer is a mixture of Labrador tea, scrub birch, and willow species with >30% cover. Distinct to prominent mottles; seepage present; permafrost near surface. Ice layer present within or above frozen soil or frozen organic layer.
B1	Bog – Black Spruce – Lichen	Treed or shrubby peatland ecosystem unit with poor nutrient regime within the rooting zone. Stunted black spruce with <50% *Sphagnum* sp. and >10% *Cladonia* sp. (i.e., caribou forage species) ground cover.
B2	Bog – Black Spruce – Sphagnum	Treed or shrubby peatland ecosystem unit with poor nutrient regime within the rooting zone. Stunted black spruce with >50% *Sphagnum* sp. ground cover.
F	Fen	Treed, shrubby, or graminoid peatland ecosystem unit where groundwater inflow maintains relatively high mineral content within the rooting zone. Graminoid fen has >20% *Sphagnum* sp. or moss cover.
M	Marsh	Shallowly flooded mineral wetland ecosystem dominated by emergent vegetation. Area dominated by graminoids and has less than 10% Sphagnum or moss cover.
S	Swamp	Treed or shrubby mineral wetland ecosystem unit with a flowing or fluctuating, semi-permanent, near-surface water table.
W	Shallow Water	Shallow water ecological communities dominated by rooted, water submerged, and floating aquatic plants.
AN	Anthropogenic	An area of anthropogenic disturbance not included in other definitions (e.g., areas cleared for camps).
ES	Exposed Soil	Any area of exposed soil not included in other definitions. Includes areas of recent disturbance (e.g., terrain slides) and human-made disturbances where vegetation cover is <5%.
Fa	Flood Active Channel	Ecological communities scoured by river floodwaters for prolonged periods. Usually dominated by annuals or herbs that can re-sprout from underground structures.
LA	Lake	A body of water >2 m deep or large enough to be classified as a lake (>8 ha).
PD	Pond	A small body of water greater than 2 m deep, but not large enough to be classified as a lake (<8 ha).

Code	Name	Description and typical situation
Rc	Rock Cliff	Ecological communities of vertical rocky sites commonly with some bryophyte cover (rock crusts); small pockets of soils may support vascular vegetation. Also used to map non-vegetated cliffs.
RI	River	A watercourse formed when water flows between continuous, definable banks. The flow may be intermittent or perennial.
Ro	Rock Outcrop	Bluffs and knobs of solid rock with limited soil development and high cover of exposed rock; drought tolerant cryptogams often prominent.
Rt	Rock Talus	Active and inactive talus (i.e., large rocks) and scree (i.e., smaller rocks and more soil); small pockets of soils may support some vascular plants.
RZ	Road	An area cleared and compacted for the purpose of transporting goods and services by vehicle.

2.6.2 ATTACHMENT 2–B — LIST OF ALL POTENTIAL BIRD SPECIES AND THEIR CONSERVATION STATUSES

All bird species with the potential to occur in the Project area:

Names, federal conservation statuses (SARA, COSEWIC), BCR 4 priority, territorial status (i.e., species highlighted by Environment Yukon and those considered of conservation concern in the Yukon Conservation Data Centre track list), and indication of occurrence in the Project RSA for all 128 bird species, are listed below:

Attachment Table 2. List of species with the potential to occur in the Eagle Plains Project Regional Study Area.

Species Common Name[1]	Documented in RSA[2]	COSEWIC[3]	SARA[4]	Environment Yukon (YCDC Track List)[5]	BCR 4 Priority Species[6]
Horned Grebe [L]		SC (Apr 2009)	1 – SC	*	R – stewardship N/C – concern

3 MARTEN

3.1 PURPOSE AND OBJECTIVES

American marten (*Martes americana*; hereafter marten) were selected as a Valued Component (VC) for the Project due to their value as a furbearer, as well as their relevance as an indicator species for mature and old forest values (Buskirk and Ruggiero 1994, Suffice et al. 2017). The VGFN have a community trapline within the RSA and value marten as a furbearer for its economic value, social values associated with trapping, and environmental values as a component of the regional wildlife community.

This section provides a summary of marten ecology in the subarctic taiga. That information is used to develop a habitat model to quantify the quality, amount, and distribution of potential marten habitat across the RSA. A Habitat Suitability Index (HSI) model was developed using relevant environmental data in a GIS to quantify the amount of marten habitat into relative quality categories (i.e., High, Moderate, Low, and Nil/Very Low).

3.2 TRAPPING

According to trapping records, marten were the most heavily trapped species in the two group trapping concessions that overlap the RSA between 2012 and 2018 (Figure 3-1,). Between 2012 and 2018, 715 marten were reported from the two concessions (i.e., 401, 402) overlapping the RSA. The number of marten reported varied widely among the trapping seasons: the greatest harvest was 240 marten reported in 2015 compared to the lowest harvest of 0 marten the following year. Unfortunately, trapping records from 2019 onwards were unavailable for those concessions.

Trapping mortality in marten is biased towards males and juveniles, and harvests that include a high proportion of adult females indicate potential overharvesting (Strickland and Douglas 1987, Hodgman et al. 1994, Fortin and Cantin 2005). Exhaustive trapping removes resident adult marten from the population and allows juveniles to establish home ranges in vacant areas, thus lowering the overall age of the population. Juveniles have lower reproductive output relative to adults; therefore, this change in age structure can lower population fecundity and growth rates (Archibald and Jessup 1984, Fortin and Cantin 2005). Without knowledge of the age and sex structure of harvested marten, it is not possible to assess the sustainability of trapping in the RSA.

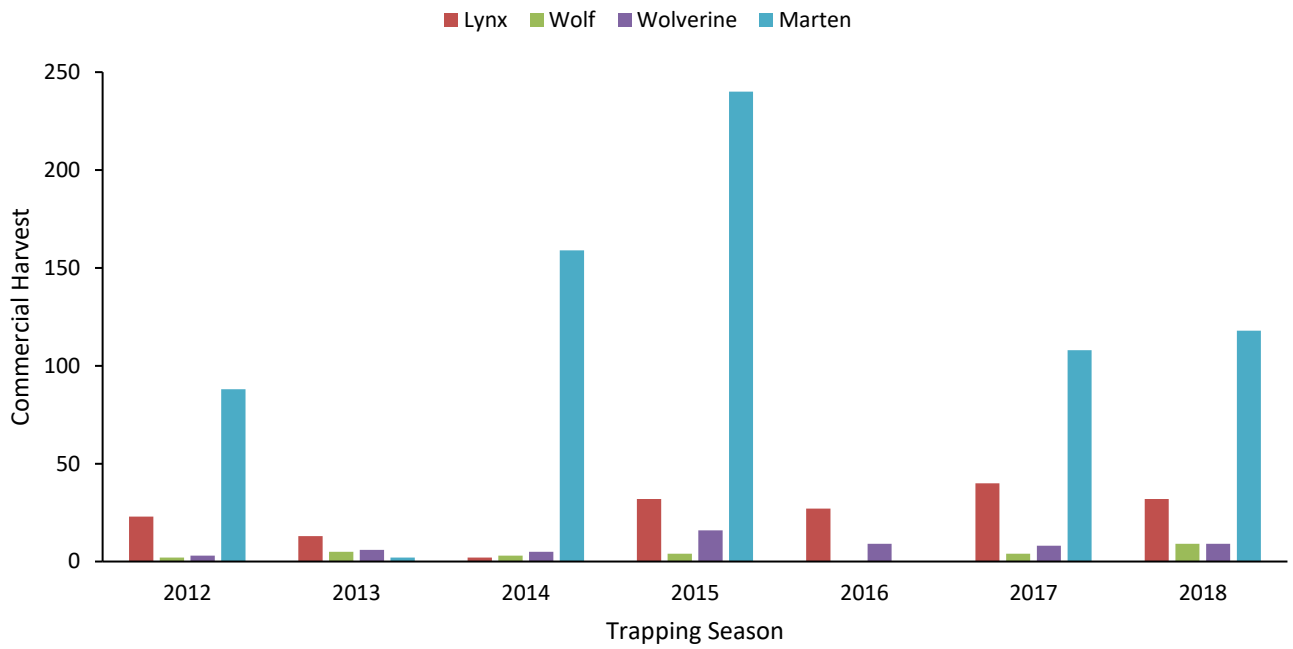

Figure 3-1. Commercial harvest returns for group trapping concessions overlapping the RSA for which records were available.

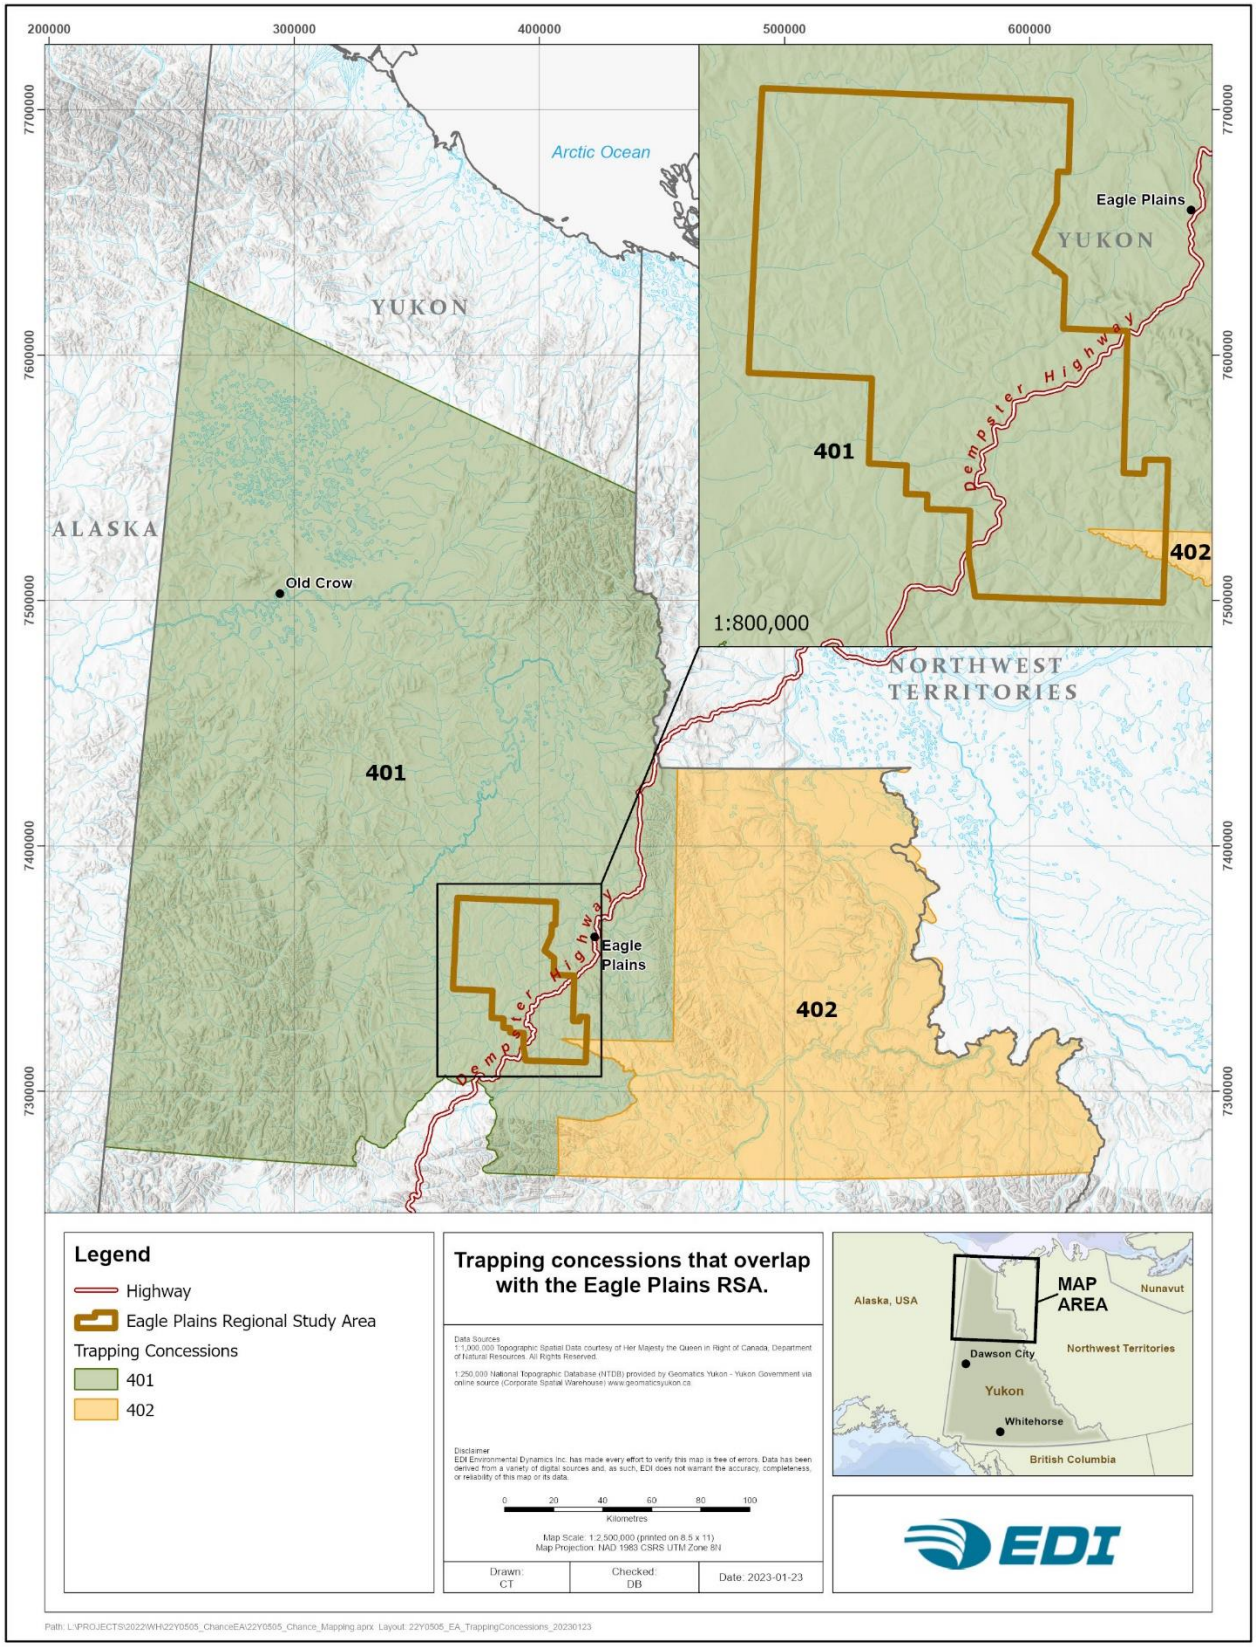

Map 3-1. Trapping concessions that overlap with the Eagle Plains RSA.

3.3 GENERAL HABITAT ECOLOGY OF MARTEN

The RSA occurs in the boreal taiga, at the northern limit of marten range (Buskirk and Ruggiero 1994, Yukon Ecoregions Working Group 2004a). While marten occur over a contiguous range across northern North America from Labrador to Alaska (Snyder and Bissonette 1987, Buskirk and Ruggiero 1994, Drew 1995, Paragi et al. 1996), little is known about their basic ecology in northern boreal forest and taiga ecosystems (Latour et al. 1994). In more productive forests to the south, marten are often associated with mature forest structures, such as large trees, snags, and coarse woody debris (CWD; Buskirk and Ruggiero 1994, Thompson et al. 2012). However, there is some evidence that in northern boreal forests, marten exploit structural stages with short, stunted trees that are sparsely distributed (Latour et al. 1994, Paragi et al. 1996). Marten in the Alaskan taiga selected habitat types with the greatest amount of CWD and the greatest abundance of vole, rather than canopy cover (Paragi et al. 1996). Across the Yukon forest-to-tundra ecotone, marten preferred open taiga areas rather than boreal forest, and were positively associated with small mammal (i.e., taiga vole [*Microtus xanthognatus*], and red-backed vole [*Myodes* spp.]) biomass (Pretzlaw 2006). Therefore, occurrence and habitat selection patterns for marten in northern boreal and taiga ecosystems can differ from those described elsewhere in North America (Pretzlaw 2006).

During 2015 and 2016, EDI performed snow tracking surveys to quantify the presence and distribution of furbearers and ungulates south of Dawson, Yukon (EDI Environmental Dynamics Inc. 2017). Snow tracking transects covered various habitat types, including 49% shrub, 13% coniferous, 10% herbs, 8% exposed land, 7% frozen rivers, and 13% other classes (i.e., broadleaf, mixedwood, rock/rubble, wetland). Marten tracks occurred in shrubland 51% of the time, coniferous forest 15% of the time, and herb sites 10% of the time. These results indicate that marten occurred across all major vegetated habitat types approximately in proportion to their availability on the landscape (EDI Environmental Dynamics Inc. 2017).

Home ranges of marten in the taiga are larger than in other regions of North America (Latour et al. 1994). In the Mackenzie Valley, NWT, mean home range sizes of adult males were 1,420 ha, and those of adult females were 680 ha. Overall, mean home range size of adult marten was 1,110 ha (Latour et al. 1994). In contrast, the average size of a marten home range in British Columbia (BC) is 525 ha for males and 316 ha for females, and in Ontario, the size of a typical marten home range is between 390 and 660 ha (Lofroth 1993, Manlick et al. 2017a). Marten density in the taiga (the carrying capacity) is likely limited by the availability of arboreal cavities for natal denning, subnivean CWD sites and underground shelters, small mammal abundance, predation, and intraguild competition (Brainerd et al. 1995). The estimated minimum density of marten was 0.0016/ha in the Mackenzie Valley, NWT (Latour et al. 1994), and 0.0025/ha in the Alaskan taiga (Paragi et al. 1996). The estimated fall density of resident adults in the northern boreal region of the Yukon was 0.006/ha (Archibald and Jessup 1984).

3.3.1 FORAGING

Marten habitat selection in the Eagle Plains Ecoregion may depend largely on prey distribution and availability (Paragi et al. 1996). Taiga vole are the prey most selected by marten in the Alaskan taiga, likely due to their larger size (mean weight = 54 g) relative to red-backed vole (mean weight = 20 g; Paragi et al. 1996). Potential

and confirmed mammalian prey in the taiga includes snowshoe hare (*Lepus americanus*), red squirrel (*Tamiasciurus hudsonicus*), red-backed vole, taiga vole, lemmings (*Lemmus* spp., *Dicrostonyx* spp.), and to a lesser extent, deer mice (*Peromyscus maniculatus*) (Paragi et al. 1996). Non-migratory grouse, including willow ptarmigan and spruce grouse, are available year-round and are likely prey for marten in the taiga (Paragi et al. 1996). However, marten are dietary generalists and their diet fluctuates seasonally with the breeding cycles of small mammal prey, bird migration and nesting periods, and fruiting periods of understory plants (Ben-David et al. 1997, Carlson et al. 2014, Twining et al. 2019).

In northern latitudes, marten foraging and population dynamics are influenced by fluctuations in the abundance of small mammal prey (Zielinski 2000). Multiple scat analyses in the NWT and Alaska found that small rodents, including vole and lemming, were the most important diet item for marten (Buskirk and Ruggiero 1994). Small rodents in northern regions undergo relatively large periodic fluctuations in population size (Krebs 1996). Marten populations are likely tightly coupled with these small mammal population cycles due to the relatively low diversity of mammalian prey species in the Eagle Plains Ecoregion (Yukon Ecoregions Working Group 2004a, Roth et al. 2007). Marten abundance and fecundity are correlated with temporal variability in the abundance of preferred prey, likely due to nutritionally demanding processes associated with reproduction and juvenile recruitment (Carlson et al. 2014, Flynn and Schumacher 2016).

Previous research has shown berries to be most important for marten diet during the summer and fall (July–November) when fruit availability is greatest (Baker 1992, Schaumann and Heinken 2002, Twining et al. 2019). Further, there is recent evidence that *Vaccinium* fruit are also an important winter food item for marten in coastal areas where they remain accessible year-round (Banner et al. 2014, Eriksson et al. 2019). Similarly, common juniper (*Juniperus communis*) berries are an important winter food item for marten in other regions (Hargis and McCullough 1984). Therefore, marten in the RSA likely consume fruit from several species of shrub depending on habitat and season, including blueberry and lowbush cranberry in upland woodlands, and crowberry (*Empetrum nigrum*), lingonberry, cloudberry (*Rubus chamaemorus*), and bog cranberry (*Vaccinium oxycoccos*) in lowland black spruce-shrub sites (Yukon Ecoregions Working Group 2004a).

The diet of marten in interior regions of North America is typically dominated by species of voles associated with structurally complex forests (Thompson and Colgan 1994, Poole et al. 2004, Eriksson et al. 2019). Habitat structures normally associated with old forests, including stumps, snags, and large pieces of downed wood, provide subnivean access to small mammal prey in areas with deep snow (Zielinski et al. 1983, Baker 1992, Delheimer et al. 2019). However, within the Yukon, red-backed voles are present across all vegetation types and appear to be more abundant in subalpine shrub habitats than lower elevation boreal forests (Pretzlaw 2006, EDI Environmental Dynamics Inc. 2017). Taiga vole are restricted to the taiga and avoid forest cover (Pretzlaw 2006). Taiga vole in Alaska appear to select post-fire structural stages and are found in black spruce forests, birch forests, forest-grassland edge, and grasslands (Wolff and Lidicker Jr. 1980). Provided there is sufficient understory shrub cover, habitat used for foraging is probably directly associated with increased prey availability regardless of forest age or structural stage (Keim et al. 2011, Vigeant-Langlois and Desrochers 2011).

3.3.2 COVER

Across much of their distribution, marten select home ranges with old or late-mature forests and avoid recently cut forests (Chapin et al. 1998, Bridger et al. 2017, Suffice et al. 2017). Older forests contain complex woody structures, including mature trees, stumps, snags, and large pieces of CWD that marten require to meet many life history requirements, including thermal cover and escape cover from predators (Zielinski et al. 1983, Mowat 2006a, Andruskiw et al. 2008). Shrub cover can also be an important factor influencing marten habitat quality, as marten use understory shrubs as cover from aerial predators such as Northern Goshawk (*Accipiter gentilis*; Poole et al. 2004, Zielinski et al. 2005, Slauson et al. 2007).

Important habitat features typically associated with old forests, including stumps, snags, and large pieces of downed wood, provide subnivean access to winter denning in areas with deep snow (Zielinski et al. 1983, Baker 1992, Delheimer et al. 2019). A winter den is a structure that may be used repeatedly for resting for prolonged periods (Birks et al. 2005). Natal dens are used for parturition and kit rearing during the breeding season, and may be used as resting sites in other seasons (Birks et al. 2005). A scarcity of tree cavities leads marten to use denning sites that provide suboptimal thermal cover and escape from predators (Birks et al. 2005). Marten dens may be found in tree branches, bird nests, rock crevices, underground burrows, occupied houses, nest boxes, or barns (Birks et al. 2005). Therefore, marten may use a range of below or above-ground structures for winter denning in the RSA, regardless of forest age or structural stage.

3.3.2.1 Thermal Cover

In winter, marten possess limited energy reserves and must reduce energetic costs by seeking insulated resting sites (Spencer 1987, Buskirk et al. 1989, Brainerd et al. 1995). Marten are shown to be more dependent on subnivean resting sites at more northern latitudes (Brainerd et al. 1995). Marten's choice of resting above or below snow cover depends on the ambient air temperature relative to the temperature in a microenvironment; in other words, marten are more likely to rest wherever is warmest (Buskirk et al. 1989). In Scandinavia, marten seek underground or subnivean resting sites instead of arboreal sites when the ambient air temperature is very low (Brainerd et al. 1995). Any subnivean spaces not entirely surrounded by snow are suitable; however, CWD is best in terms of thermal properties (Buskirk et al. 1989). Therefore, thermal cover generally increases with increased coniferous cover and associated CWD. Rock provides some protection from digging predators; however, rock provides poor insulation than wood, and rock dens may contain organic bedding for insulation (Buskirk et al. 1989, Birks et al. 2005).

3.3.2.2 Escape Cover

As a mesocarnivore, pressure from competition and predation can play an important role in the population dynamics of marten populations (Kiseleva 2012, Manlick et al. 2017b). Aside from marten, wolf (*Canis lupus*), red fox (*Vulpes vulpes*), lynx (*Lynx canadensis*), and wolverine (*Gulo gulo*) are the primary mammalian predators in the Eagle Plains Ecoregion. Marten likely select habitat with sufficient escape cover (e.g., medium-sized coniferous trees and CWD) to avoid risk of intraguild predation by these species (Slauson et al. 2007, Eriksson

et al. 2019). Furthermore, marten within the Eagle Plains Ecoregion compete with least weasel (*Mustela nivalis*), lynx, and red fox for shared small mammal prey (Slough and Jung 2007).

Marten in North America select home ranges that contain vertical forest or understory shrub cover where they perceive lower risk of predation from aerial predators as well as larger carnivores that, depending on the system they occupy, includes mustelid, canid, and felid species (Slauson et al., 2007; Eriksson et al., 2019). Red fox are the most generalist and widespread carnivore in the northern boreal-tundra ecotone, and may limit marten populations through intraguild predation (Lindström et al. 1995, Birks et al. 2005, Pretzlaw 2006). Therefore, fox predation may force marten to remain arboreal and den above ground (Birks et al. 2005). Aerial predators include Northern Goshawk and Great Horned Owl (*Bubo virginianus*), both of which are predators of marten in other regions and occur year-round in forests in the Yukon (Bull and Heater 2001, Doyle and Smith 2001, Sinclair et al. 2003). Golden Eagle also occur in northern Yukon during the breeding season and may be predators of marten. However, marten may perceive a lower risk of predation in open woodlands and shrublands of the Eagle Plains due to the absence of several predators of marten in more southern biomes, including bobcat (*Lynx rufus*) and coyote (*Canis latrans*; Thompson and Colgan 1994, Bull and Heater 2000, Moriarty et al. 2016).

3.3.3 REPRODUCTION

Natal dens are used for the parturition and rearing of neonates and are critical for recruitment and population viability (Buskirk and Ruggiero 1994). Across North America, most natal dens are found in structurally complex sites (Buskirk and Ruggiero 1994). Marten prefer arboreal cavities for parturition and rearing neonates due to the shelter they provide from terrestrial predators, including red fox (Spencer 1987, Brainerd et al. 1995). Marten kits are very vulnerable to fox predation when kits move out of arboreal dens (Brainerd et al. 1995). However, scarcity of arboreal cavities may force marten to use alternative structures for natal denning (Birks et al. 2005). For example, arboreal cavities are rarely used as resting sites in Finland and northern Russia (Brainerd et al. 1995). In the NWT, an adult female marten denned and produced young within a 21-year-old burn (Latour et al. 1994). Therefore, a better understanding of habitat selection by adult female marten in the taiga is needed (Paragi et al. 1996).

3.3.4 DISPERSAL

North American marten are sensitive to forest fragmentation and are found across landscapes with greater amounts of contiguous forest (Thompson et al. 2012). Previous studies show that 5 km of nonforested habitat between forest patches is an effective barrier to dispersal for marten (Buskirk and Ruggiero 1994). Timber harvesting and extensive road networks increase the density of forest edges and generally reduce habitat connectivity for species such as marten adapted to forest interiors (Robitaille and Aubry 2000, Mowat 2006b). However, marten use narrow strips of forest and abandoned roads as movement corridors between more suitable patches of mature forest (Potvin and Bertrand 2004, Breault et al. 2021).

Furthermore, there is evidence that in regions with sparse forest cover, marten may be adapted to meet certain resource requirements in nonforested habitats. For example, in Scotland, forest habitat is limited and pine

marten (*Martes martes*) consistently use matrix habitats, including scrub and tussock grassland, to meet life history requirements (Caryl et al. 2012). Intensively managed forests in Scotland lack resources such as den sites and important prey (e.g., short-tailed field vole [*Microtus agrestis*]), abundant in grasslands long thought to be impermeable to marten movement or at best suboptimal marten habitat (Caryl et al. 2012).

Cold temperatures and high seasonality result in different patterns of habitat use among marten in North America (Zielinski et al. 1983). Marten habitat selection was investigated in the Alaskan taiga in a landscape composed of mature coniferous forests of black spruce and larch (*Larix laricina*) from 5–20 cm diameter at breast height (DBH) 100–115 years post-fire, as well as dense, young forests 30 years post-fire, and tall shrub and pole sapling forests with some moss and herb structural stages 10 years post-fire (Paragi et al. 1996). Marten abundance, hunting intensity (based on snow-tracking), and CWD density were the greatest in 10-year burns relative to 30-year burns and mature forests (Paragi et al. 1996).

However, this study found that juveniles were more common in recent burns than in mature stands, and recent burns were likely used only by nonbreeding marten (Paragi et al. 1996). Non-transient marten used coniferous forest more often than transient adult and juvenile marten, which were more likely to use scrub habitat (Paragi et al. 1996). For natal denning, resources are limited in herb and shrub structural stages and prey populations are unpredictable relative to mature forests (Paragi et al. 1996). Therefore, post-fire clearings may be only suitable for dispersing juveniles and transient adult marten (Paragi et al. 1996). Herb and shrub structural stages may function as population sinks for immature and transient marten dispersing from contiguous mature forest (Paragi et al. 1996). Previous HSI models for marten in the taiga have ranked nonforested habitats, including post-fire clearing and shrubland as low-suitability habitat (EDI Environmental Dynamics Inc. 2018). However, habitat requirements of breeding marten in the taiga are not well-understood (Paragi et al. 1996).

3.3.5 DISTURBANCE

3.3.5.1 Fire

Marten are dietary generalists and are not limited to prey associated with mature/old forest structural stages (Baker 1992, Paragi et al. 1996, Poole et al. 2004). Marten in the Alaskan taiga use snags and windthrown trees as winter cover in recent burns before coniferous regeneration occurs (Paragi et al. 1996). Trappers in Alaska view fire as beneficial to furbearer populations. Rodent prey, including red-backed vole, tundra vole (*Microtus oeconomus*), meadow vole (*Microtus drummondii*), and taiga vole, are abundant in dense herbaceous vegetation growth following recent fires (Stephenson 1984). Extensive use of post-fire clearings occurred by marten 1– 3 years post-fire. High population abundance occurs within 3–10 years post-burn, with activity centred in unburned inclusions and burn edges (Stephenson 1984).

In the Alaskan taiga, marten abundance, frequency of investigations, hunting intensity, and CWD density were greatest in 10-year burns relative to older burns and mature forest (Paragi et al. 1996). Subnivean access based on tracks was greatest in 10-year burns relative to mature forests and 30-year burns (Paragi et al. 1996). Small mammal biomass and diversity were greatest in the 10-year burn. This structural stage provided a more stable

prey base due to greater diversity of rodents and more stable populations of red-backed vole (Paragi et al. 1996). Young forests 30 years post-fire had the least stable small mammal populations and lacked taiga voles, the prey most selected by marten in this study (Paragi et al. 1996). The suitability of post-fire clearings for marten may be low at first and increase 6–10 years post-fire as ground cover recovers and small mammals occupy the habitat (Paragi et al. 1996). Suitability begins to decrease 15–20 years post-fire and reaches minimum suitability 25–30 years post-fire when CWD has fully decayed and young forests establish. These forests lack near-ground structures for subnivean foraging, escape cover, denning, and resting sites (Paragi et al. 1996).

Adult marten in the NWT were more likely to have home ranges in unburned stands than burned stands (Latour et al. 1994). Unburned forests were open, 90-year-old black spruce-herb, or black spruce-bog forests with average tree height from 5–10 m, and average DBH from 4–14 cm (Latour et al. 1994). Burned stands were characterized by regeneration of open to sparse deciduous vegetation (40% bare ground), a primarily willow shrub layer, and a birch/balsam fir canopy (Latour et al. 1994). Wet areas were characterized by moss, lichen, and Labrador-tea in the understory with sparse, stunted black spruce in the tree layer (Latour et al. 1994). Long-term use by adult marten within home ranges indicated greater use of unburned forests relative to burned forests (Latour et al. 1994). In burns, most snags remained standing and deadfall lay directly on the ground; therefore, burns did not provide access to subnivean spaces, and hunting was mostly on the surface of snow with little protection from predation (Latour et al. 1994). However, an adult female marten with a home range partially within a burn, denned and produced young within the 21-year-old burn (Latour et al. 1994). Furthermore, home ranges of 1 adult and 1 juvenile tracked for 14 and 15 months were entirely within the burns (Latour et al. 1994). Using post-fire structural stages by breeding marten in the taiga is not well understood and should be explored in future studies (Paragi et al. 1996).

3.3.5.2 Roads

The Dempster Highway runs roughly southwest to northeast through the southern half of the RSA. The RSA includes numerous winter roads (15 m average width) from previous exploration activities dating back to the 1960s. Project activities will be accessed via existing and new winter roads. Generally, marten avoid open areas and areas of high human disturbance, including roads (Hargis et al. 1999, Potvin et al. 2000). Marten in North America generally avoid roads due to increased predation risk and lower availability of preferred prey; however, predation risk is assumed to be low in the RSA because primary predators of adult marten are absent or at low density in the Eagle Plains Ecoregion (Yukon Ecoregions Working Group 2004a, Moriarty et al. 2011, 2015, Joyce 2018). Therefore, marten may perceive a lower risk of predation along roads within the RSA due to the absence of several predators of marten in more southern biomes (Bull and Heater 2001, Mowat 2006a, Thompson et al. 2012). Further, abandoned roads (5 m average width) may provide easier pathways for marten movement than undisturbed forest and greater cover from aerial predators than openings (Breault et al. 2021). However, extensive road networks may fragment woodland and shrubland, reducing habitat connectivity and limiting marten dispersal (Caryl et al. 2012).

3.3.5.3 Seismic Lines

The RSA contains numerous 2D seismic lines (range = 5–8 m wide, mean = 5.4 m wide) from previous exploration activities dating back to the 1960s. Most 2D exploration occurred between 1961 and 1984, with new 2D exploration in 2001 incorporating Low Impact Seismic (LIS) techniques(Access Consulting Group and EBA Engineering Consultants Ltd. 2001, GEOTIR 2014). Approximately 2,200 km of new 3D LIS exploration (1.5–3 m wide) was conducted in a 32,500 ha area between November 2013 and April 2014 (GEOTIR 2014). This new 3D exploration is located near the RSA's centre, north and south of the Dempster Highway. The entire RSA, including legacy and contemporary seismic lines, was assessed as a linear feature study. There were signs of normal and magnified succession on 2D and 3D seismic lines. Among 2D lines, 89% had growth >1.5 m height and were considered fully recovered, and 22% of 2D lines made in the 1950s and 1960s showed magnified succession. All 3D lines were made in 2014 and showed normal succession.

In the northern boreal forest (i.e., southwest NWT, northeast BC, and northwest Alberta), marten use of seismic lines is strongly influenced by line width and state of regeneration (Tigner et al. 2015). In this study, forests were open black spruce bogs in lowlands, and upland white spruce-aspen with dense shrubs. Remote wildlife cameras were used to quantify marten use of seismic lines relative to adjacent interior forests. Marten were detected in open lines >3 m wide up to 90% less than forest interiors, but were detected in open lines <2 m wide or lines >6 m with at least partially recovery roughly equally to forest interiors (Tigner et al. 2015). Use of seismic lines is thought to be driven by the perceived risk of predation; marten avoid open habitats but use disturbed habitats following sufficient recovery of overhead and lateral cover (Tigner et al. 2015).

3.3.6 HABITAT SUMMARY

In more productive forests to the south, marten are often associated with mature forest structures, such as large trees, snags, and CWD (Buskirk and Ruggiero 1994, Thompson et al. 2012). Marten select habitats with structural complexity which provides subnivean access to small mammal prey, thermal cover, escape cover from predators, as well as natal denning sites (Spencer et al. 1983, Buskirk and Ruggiero 1994, Latour et al. 1994, Paragi et al. 1996). Within the Subarctic Bioclimate Region, characterized by stunted, open canopy spruce-dominated habitats, tree growth is often limited by the presence of permafrost resulting in disclimax vegetation communities with tall and low shrub structural stages. Therefore, patterns of habitat selection of marten in the RSA may differ from those in southern biomes (Pretzlaw 2006).

Habitat quality in the RSA should be evaluated within the context of reduced availability of old forest structures and lack of contiguous, coniferous forests in the Eagle Plains Ecoregion. Marten select habitat types with the most large pieces of downed wood and the largest standing live and dead trees available at the landscape scale (Zielinski et al. 1983, Baker 1992, Delheimer et al. 2019). Trees, snags, and CWD >30 cm in diameter are associated with older structural stages within the RSA. These structures would be considered too small to provide thermal cover and support natal denning requirements for marten elsewhere in North America (Buskirk et al. 1989, Delheimer et al. 2019). However, these structures are likely large enough to provide thermal cover and support natal denning requirements for marten in the northern context of the RSA (Spencer 1987, Brainerd et al. 1995).

3.4 METHODS

An HSI model was used to estimate habitat quality across the RSA (U.S. Fish and Wildlife Service 1980). An HSI model, also referred to as a knowledge-based habitat suitability model (Clarke 2012), is a common method for assessing habitat quality for wildlife species, and a method adapted for use in environmental impact assessments (U.S. Fish and Wildlife Service 1980). Habitat is defined as the particular place occupied by a specific population within a community and usually characterized by the dominant plant form or physical characteristics (U.S. Fish and Wildlife Service 1980). Each species requires habitat to supply space, food, cover, water, and other requirements for survival (U.S. Fish and Wildlife Service 1980). Suitability is defined as the habitat's ability, in its current structural stage, to provide the life requisites of the species (Resources Inventory Committee 1999c).

3.4.1 HABITAT SUITABILITY MODELLING

HSI modelling uses spatial datasets such as land cover, disturbance history, and topography. It ranks available habitats according to their ability to support a selected species. The habitat rankings can be based on various sources, including ecological survey data, local knowledge, expert knowledge, and traditional knowledge. HSI models can be based on suitability ratings for one habitat variable or the combination of ratings for multiple variables to quantify the quality, amount and distribution of potential habitat for the species (Dijak and Rittenhouse 2009).

3.4.1.1 Rating Scheme

Habitat ranking schemes reflect knowledge of the species' habitat use and ecology (Resources Inventory Committee 1999). A 4-class system was chosen to rank habitat suitability in this study because there is an intermediate level of knowledge of habitat quality for marten in the taiga (Resources Inventory Committee 1999, EDI Environmental Dynamics Inc. 2018). Thus, habitat was assigned a suitability ranking of High (H), Moderate (M), Low (L), or Nil/Very Low (N/VL) relative to the range of habitat quality across the RSA. Using a mathematical equation, the HSI score was produced by combining suitability ratings for several specific habitat variables (e.g., vegetation community type) into one final HSI score.

The developed habitat model produced HSI scores ranging from 0 to 1. Scores were used rather than classes to combine scores and adjustments from multiple variables into a final HSI score. Scores were categorized into four qualitative categories: High (>0.75 to 1.0), Moderate (>0.50 to 0.75), Low (>0.25 to 0.50), Nil/Very Low (>0.0 to 0.25; Resources Inventory Committee 1999). The rating categories correspond to qualitative predictions of the relative suitability of the habitat for supporting five life requisites of marten: reproduction, thermal cover, escape cover, foraging, and dispersal. High-quality habitat supports all five life requisites. Moderate-quality habitat supports escape cover, foraging, and dispersal. Low-quality habitat only supports limited foraging and dispersal. Nil/Very Low-quality habitat does not contribute significantly to any life requisites; however, herb and shrub structural stages and stunted disclimax forest areas likely function as permeable barriers and allow intra-territorial movements within marten home ranges (Caryl et al. 2012). Habitat conditions and suitability interpretations for each rating class are provided in Table 3-1.

Table 3-1. Description of habitat rating classes used in the marten HSI model.

HSI Score	Habitat Rating	Description
>0.75 to 1.0	High	Suitable (optimal). Provides conditions for natal denning (large live conifer trees, large snags, large CWD), thermal cover (medium/large-sized elevated CWD subnivean), escape cover, foraging, and dispersal.
>0.50 to 0.75	Moderate	Suitable (suboptimal). Provides conditions for escape cover (small/medium-sized live or dead conifer trees, and/or small CWD, and/or dense shrub cover), foraging, and dispersal.
>0.25 to 0.50	Low	Limited Suitability. Provides conditions for foraging (i.e., any size or species of tree that would support prey species and CWD large enough for subnivean access; grass and/or horsetails for hare, voles, birds, and/or berries for prey or marten), and dispersal (i.e., some herb or sparse deciduous/shrub cover).
>0.0 to 0.25	Nil/Very Low	Unsuitable. Non-vegetated areas, such as alpine, water, or highways, that do not provide conditions to support any life requisites for marten. Non-vegetated areas may be used for intra-territorial movements.

3.4.1.2 Habitat Variables

Habitat variables were identified as potentially important for describing marten habitat (Table 3-2). Variables were evaluated for inclusion based on the strength of relationships found in other studies, the ecological relevance to marten in the Eagle Plains Ecoregion, and the availability of the variable in GIS databases for the RSA. Based on these criteria, ELC and Linear Feature (LF) data were included in marten habitat modelling.

Distance to riparian areas was considered for inclusion in the model. Riparian areas are important foraging habitat for marten in North America (Spencer et al. 1983, Ben-David et al. 1997), and elder members of the VGFN observed good marten habitat in the area where the Blackstone and Peel rivers meet (Sherry and Vuntut Gwitchin First Nation 1999, p. 140). Riparian areas generally have greater prey availability relative to the surrounding landscape due to higher densities of prey and greater volumes of CWD, which increase access to subnivean spaces (Buskirk et al. 1989). ELC data accurately represent increased habitat quality in mature/old riparian forests found as narrow strips along most major watercourses in the RSA, including Chance Creek in the northwest and Dalglish Creek in the southeast. Therefore, a variable for distance to riparian was redundant with the ELC mapping and was not included in the model.

The history of fire disturbance has influenced marten distribution and was considered for inclusion in the model. However, the nature of the relationship between fire history and patterns of use by marten is unclear for the taiga biome. Recent burns and post-fire clearings are generally considered suboptimal habitat. They are used mainly by nonbreeding and dispersing juvenile marten (Paragi et al. 1996). In the NWT, adult martens were likelier to locate home ranges in unburned stands than burned ones (Latour et al. 1994). However, recent burns may provide foraging opportunities not present in older burns or mature forests (Paragi et al. 1996). Furthermore, fire history was explicitly accounted for in the structural stage of the ELC mapping. Therefore,

a separate variable for fire history was determined to be redundant with ELC mapping and was not included in the model.

Elevation was considered as a variable for inclusion in the model. Marten generally occur at higher elevations than similarly-sized mesocarnivores, due to adaptations for travelling over snowpack and hunting in subnivean spaces (Grinnell et al. 1937, Zielinski et al. 2005, 2017). However, elevation within the rolling topography of the RSA does not vary substantially (range = 343–752 m asl) and was likely not a significant driver of marten distribution. Therefore, elevation was not included as a variable in the model.

Table 3-2. Summary of habitat variables commonly associated with marten habitat quality from published literature relevant to the Regional Study Area.

Variable	Included in model?	Rationale
Ecosite (ELC)	Yes	Marten select conifer-dominated stands with dense shrub cover.
Structural Stage (ELC)	Yes	Marten select mature/old forests with complex structure.
Distance to Riparian	No	Most ecosites defined by permafrost rather than riparian. ELC data more accurately represent increased habitat quality in mature/old riparian forests than distance to riparian.
Linear Features	Yes	Generally, marten avoid linear features due to increased predation risk. It is included as a habitat modifier/downgrade to adjacent habitat.
Fire History	No	Different patterns of use by marten depending on study. Fire may affect habitat quality positively or negatively, dependent on ecosite and time since disturbance. Fire history was explicitly accounted for in the structural stage of the ELC mapping. Therefore, it would be redundant to include it in the model.
Elevation	No	Range in elevation within RSA (343–752 m asl) is not enough to affect marten distribution.

Ecological and Landscape Classification

ELC mapping refers to an integrated approach to mapping and classifying land units according to their ecological similarity (Environment Yukon 2016a). As part of another study in the RSA (EDI Environmental Dynamics Inc 2021), field plots were used to establish preliminary classification units and site/soil conditions across various ecological communities. The vegetation association organization and ecosite and coding system follows the Yukon ELC Mapping Guidelines (Environment Yukon 2016a). Non-forested and sparsely/non-vegetated ecosystem were assigned to group/realm following *Biogeoclimatic Ecosystem Classification of Non-forested Ecosystems in British Columbia* (BC MFLNRORD and BC MOE 2010, Mackenzie 2012), and anthropogenic units were classified following *Standards for Terrestrial Ecosystem Mapping in British Columbia* (Resources Inventory Committee 1998a). Wetland sites were classified according to the Canadian Wetland Classification System for class, form, subform, type and subtype.

The remaining ecosites were coded with a two-digit number that indicates, by its number series, a certain range of soil moisture conditions: 10s are dry sites, 00s are mesic sites, 20s are riparian sites, 30s are moist

sites, and 40s are wet sites. Ecosite names reflect plant species that are important indicators of the vegetation found within the ecosite (e.g., 33 – Moist Spruce – Labrador Tea).

Biologists delineated ELC polygons in a GIS based on discernible differences among vegetation, topography, terrain, soils, gradients, and patterns (relationship patterns between ecosystem units, polygon shape and orientation). Three or fewer ecosystem units (i.e., ecosites) were entered per polygon. Each ecosite had an associated structural stage modifier (e.g., pole sapling) and decile, representing the percent area of the polygon in each ecosite (i.e., all deciles sum to 100%).

A subsample (n = 97) of ELC field plots were used to describe habitat suitability rankings for marten within the context of the Eagle Plains Ecoregion. Field plots were identified as High (n = 10), Moderate/high (n = 21), Moderate (n = 20), Moderate/low (n = 44), and Low (n = 2). No field plots were in Nil/Very Low habitat suitability. ELC ecosites and structural stages were used to generalize habitat rankings from field plots to ELC GIS data (Table 3-3).

Every combination of ecosite and structural stage was assigned an initial HSI score of High (HSI >0.67 to 1.0), Moderate (HSI >0.33 to 0.67), Low (HSI >0 to 0.33), or Nil/Very Low (HSI = 0). Only ecosites and structural stages represented in the RSA were included in habitat modelling. All non-vegetated ecosites (AN, ES, Fa, LA, PD, RI, RZ) were ranked as Nil/Very Low (0.0). Vegetated ecosites in the non-vegetated structural stage (1) were ranked as Nil/Very Low (0.0). Ecosite 10 (sparsely vegetated) was ranked as Nil/Very Low (0.0) regardless of structural stage. All other vegetated ecosites with Sparse/cryptogram (2/2a) or Herb/graminoid-dominated (3/3b) structural stage were all ranked as Low quality (0.1). Vegetated ecosites in Low shrub (4b) structural stage were ranked as Low quality (0.33) and ranks increased with structural stage to a maximum of 1.0 (High quality) for conifer/mixedwood ecosites, and a maximum of 0.67 (Moderate quality) for deciduous/shrub ecosites, and 0.33 (Low quality) for wetland (bog, marsh, fen) ecosites.

Linear Features

Linear features (LF) were surveyed in the RSA as a companion study for the exploration project proposal (EDI Environmental Dynamics Inc., unpublished study). LFs were classified as 2D, 3D, winter roads (any trails or limited use roads with an obviously curving path), and the Dempster Highway. A subsample (n = 64) of field plots from the LF surveys were used to investigate habitat suitability for marten on-line and off-line. Determining the relative level of impact of various types of LFs established empirical evidence for modelling.

No linear features contained high suitability habitat; the average difference between off-line and on-line habitat suitability rankings across all types of LFs was 0.81 (SD = 0.79, range = 0–3, n = 64). All 2D lines (average width = 5.4 m, n = 27) were moderate-low habitat suitability on-line, and when compared to off-line habitat, the average difference in suitability ranking was 0.85 (off – on), (SD = 0.82, range = 0–2). 3D lines (width range = 1.75–5 m, n = 27) were mostly moderate-low habitat suitability (n = 24), and the average difference between off-line and on-line suitability was 0.63 (SD = 0.69, range = 0–2). The average difference among winter roads (average width = 5 m, n = 8) was 0.88 (SD = 0.64, range = 0–2). Along the Dempster Highway (average width = 15 m, n = 2), the average difference was 2.5 (SD = 0.71, range = 2–3). The average difference in HSI between off-line and on-line field plots was scaled to a score from 0–1 for downgrading:

- Dempster Hwy (30.0 m wide) = (2.5*0.25) = 0.625
- Winter Roads and 2D lines (10.0 m wide) = (0.87*0.25) = 0.218
- 3D lines (10.0 m wide) = (0.63*0.25) = 0.158

2D and 3D lines were mapped using a 10 m width due to limitations of the spatial scale of modelling (10 m raster). The 2D lines are wider than 3D lines and thus have a greater local effect on marten habitat suitability. The difference in effect between 2D and 3D lines on marten habitat was accounted for by applying a greater value for downgrading 2D lines (–0.218) compared to 3D lines (–0.158).

Table 3-3. HSI ratings for marten habitat quality in the Eagle Plains RSA based on an assessment of ELC field plots.

Ecosite Name	Ecosite Code	Structural Stage

3.4.1.3 Model Structure

Each ELC polygon contains up to three ecosites with deciles indicating percent cover relative to the total area of the polygon. A weighted average HSI score was calculated for each polygon using the following equation:

$$ELC_r = \frac{\sum_{i=1}^{n} d_i h_i}{\sum_{i=1}^{n} d_i}$$

where ELC_r is the initial weighted average, d_i is the decile value, and h_i is the HSI score for each ecosite. HSI polygons were converted to a 10x10 m resolution raster, and linear feature adjustments were applied to the initial HSI scores for each cell:

$$HSI = ELC_r - LF_r$$

where LF_r is the LF adjustment.

3.5 RESULTS AND DISCUSSION

The model indicated a patchwork of High, Moderate, and Low-quality marten habitat, across the RSA (Table 3-4; Map 3-1). High-quality marten habitat is associated with mesic, spruce-dominant ecosites in mature to late structural stages. It includes some of the most common ecosystem units in the RSA, including Moist Spruce – Labrador Tea (33), Moist Spruce – Alder – Labrador Tea (34), and Mesic Black Spruce – Alaska Paper Birch (04; Figure 3-1). Concentrations of High-quality habitat include Enterprise and Dalglish Creeks watersheds in the south, a band running east-west north of the Dempster Highway, and the western part of the northern half of the RSA. Moderate-quality habitat is associated with wetter or younger ecosystem units than High-quality habitat and is widespread across the RSA. High and Moderate-quality habitat is also concentrated in narrow strips of mature/old riparian forests along some of the major watercourses in the RSA, including Chance and Greaves Creeks in the northwest and McParlon Creek west of the Dempster Highway.

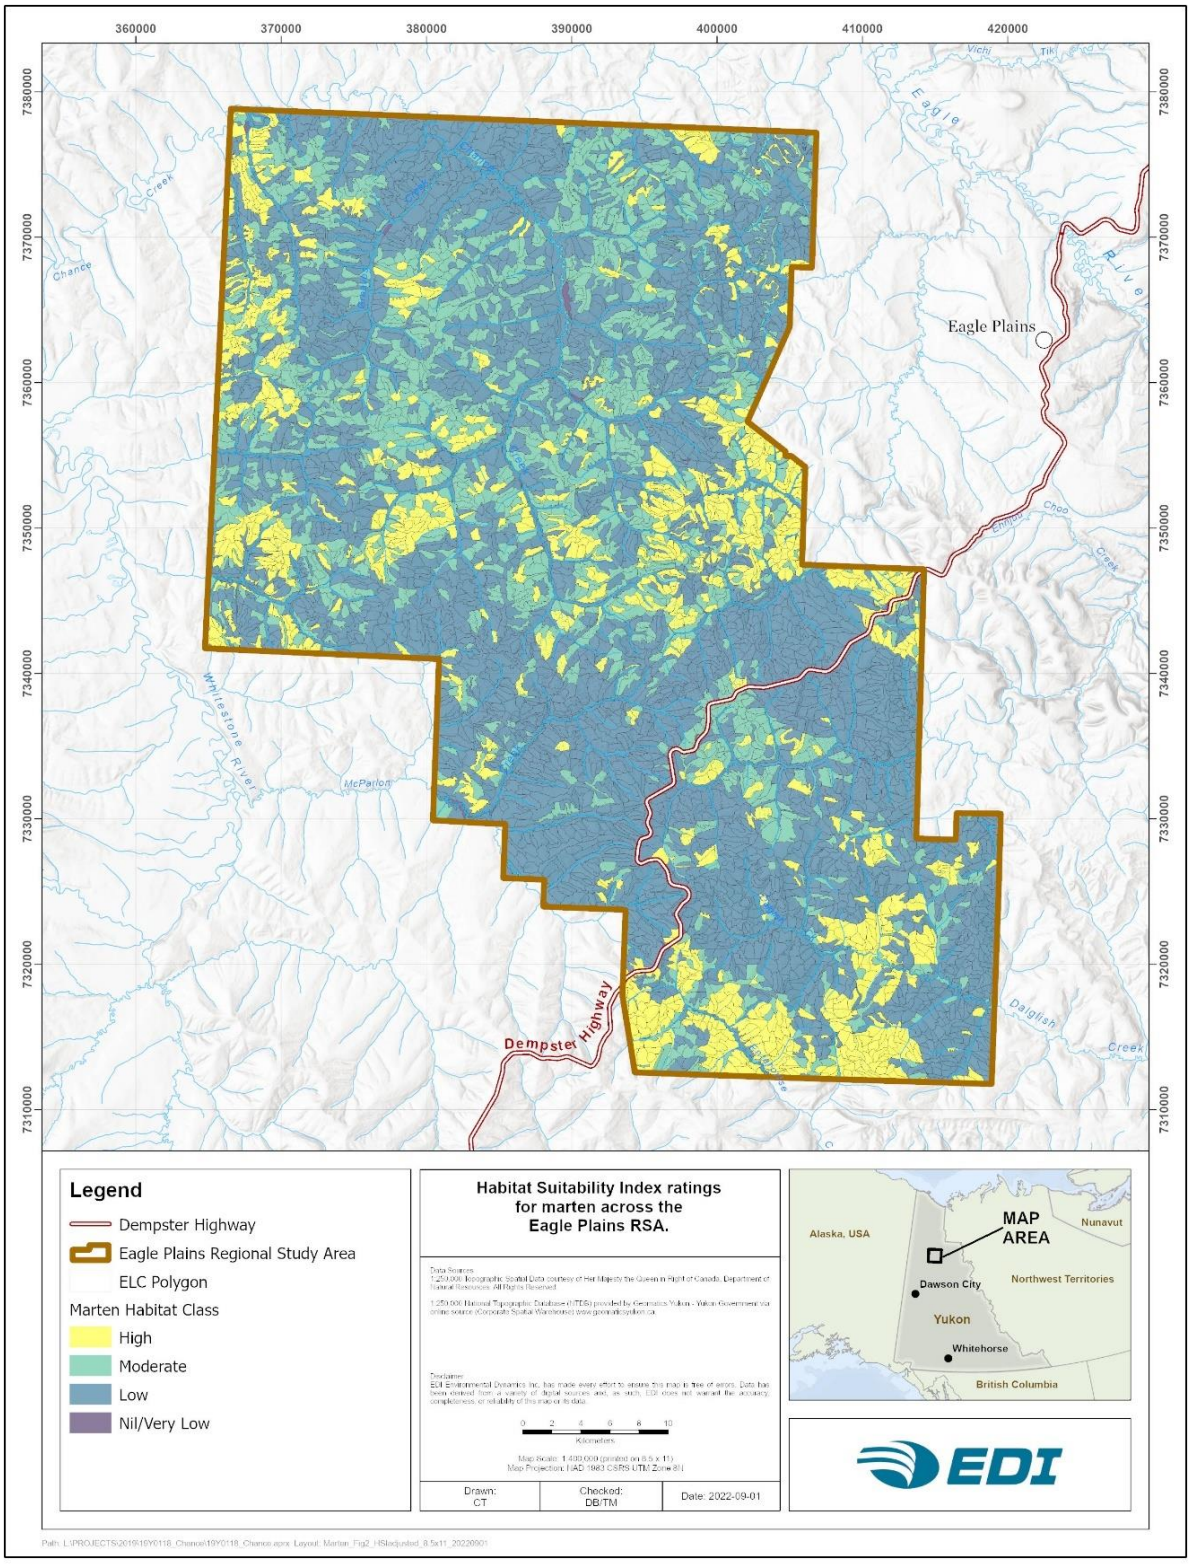
There is extensive Low-quality habitat, represented by vegetation communities in tall and low shrub structural stages found throughout the RSA (Figure 3-1). These habitats generally lack mature forest structures, such as large trees, snags, and CWD, which marten require for subnivean foraging, escape/thermal cover, and denning (Buskirk and Ruggiero 1994, Thompson et al. 2012). Low-quality habitat was associated with shrubby wetlands and stunted black spruce sites in low valley bottoms in the Chance watershed in the northwestern portion of the RSA and regenerating fire-disturbed areas on both sides of the Dempster Highway in the southern part. Completely non-vegetated areas are rare in the RSA; thus, there is almost no Nil/Very Low-quality habitat (Table 3-4; Map 3-1).

Linear features had a relatively minor effect on the overall quality, amount, and distribution of potential habitat for marten. The effect of linear features on habitat suitability for marten is mainly limited to site-level effects (Map 3-2). This effect was due to the narrow width of linear features (Moriarty et al. 2016, 2017) and their small extent relative to the overall RSA. Though existing linear features reduce habitat quality at the site level,

their effects are negligible to habitat supply at the home range scale for marten (Table 3-4). The Dempster Highway was likely the only linear feature in the RSA that could limit the movement of marten. Marten avoid crossing open areas due to increased predation risk relative to areas that provide escape cover (Slauson et al. 2017). However, the highway likely functions as a barrier, not an obstacle or constraint to their movement (Beyer et al. 2016). Therefore, it is likely that marten can and will cross the highway, so the potential barrier limits to their movement likely do not affect habitat availability at the home range scale.

Table 3-4. Relative availability of marten habitat in the Eagle Plains RSA.

Habitat Rating	HSI Scores	Area (ha)	Area (%)
High	>0.75 to 1.0	38,049.63	15.94
Moderate	>0.50 to 0.75	55,202.05	23.12
Low	>0.25 to 0.50	142,484.78	59.68
Nil/Very Low	>0.0 to 0.25	3,015.79	1.26
Total		238,752.25	100



Map 3-2. Habitat Suitability Index model ratings for marten across the Eagle Plains RSA.

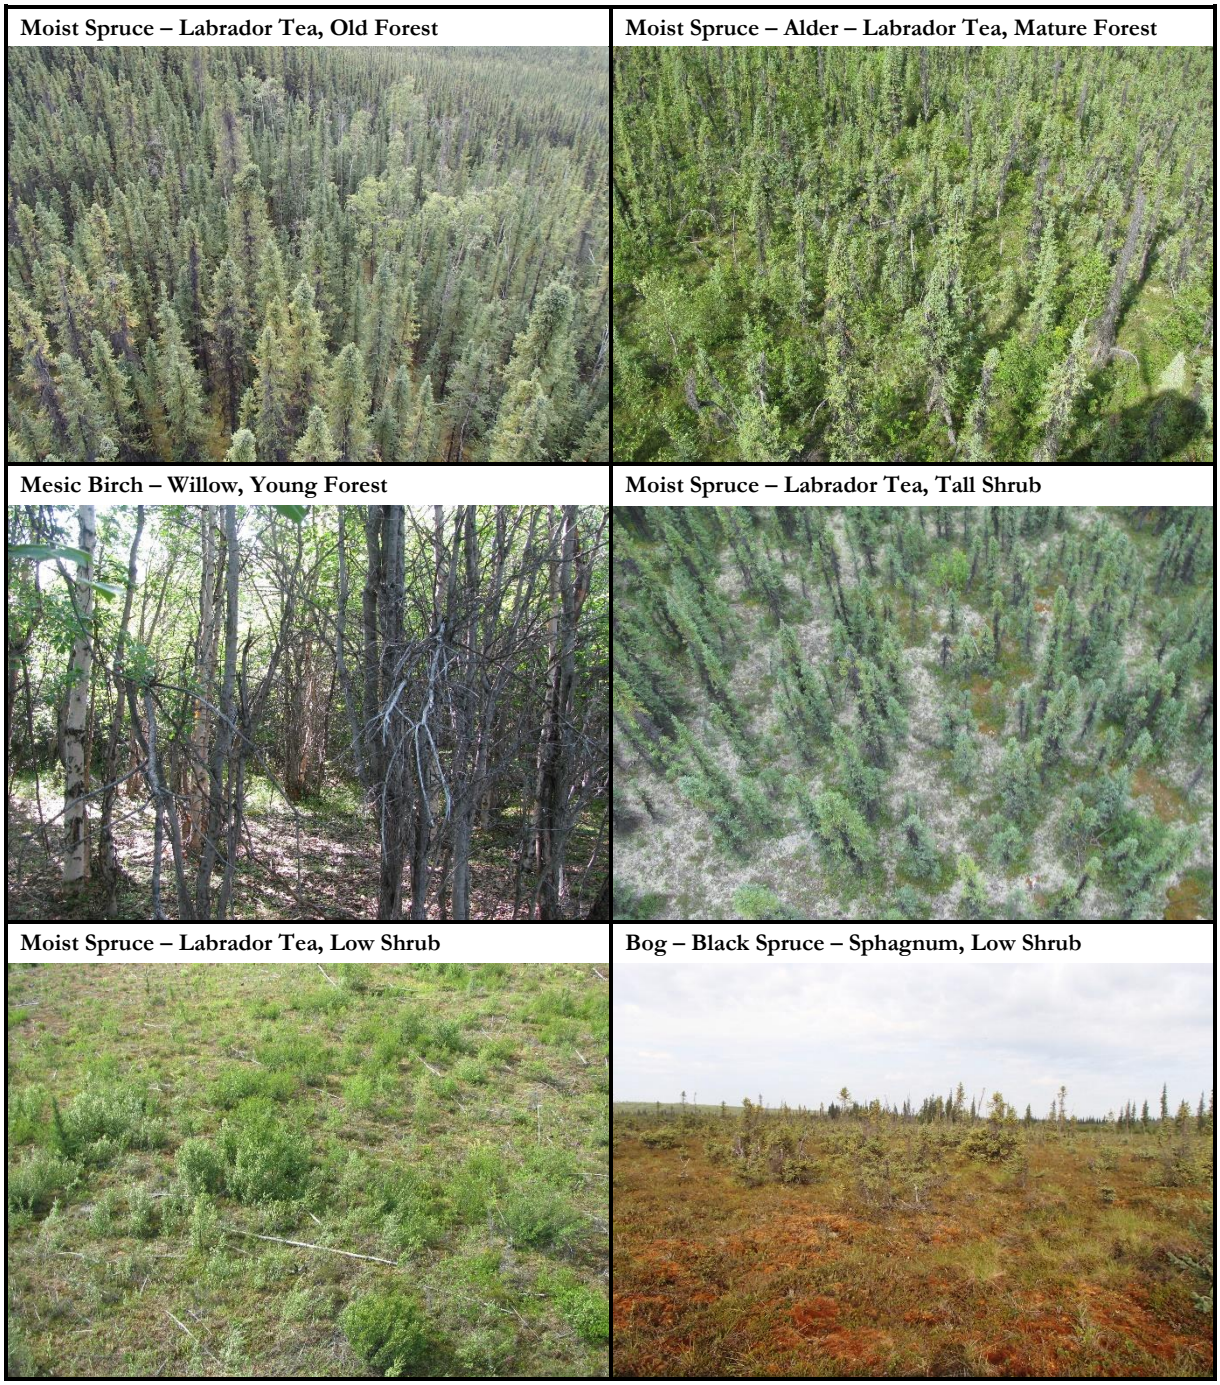


Figure 3-2. Examples of High (top row), Moderate (middle row), and Low (bottom row) quality marten habitat in the Eagle Plains RSA.

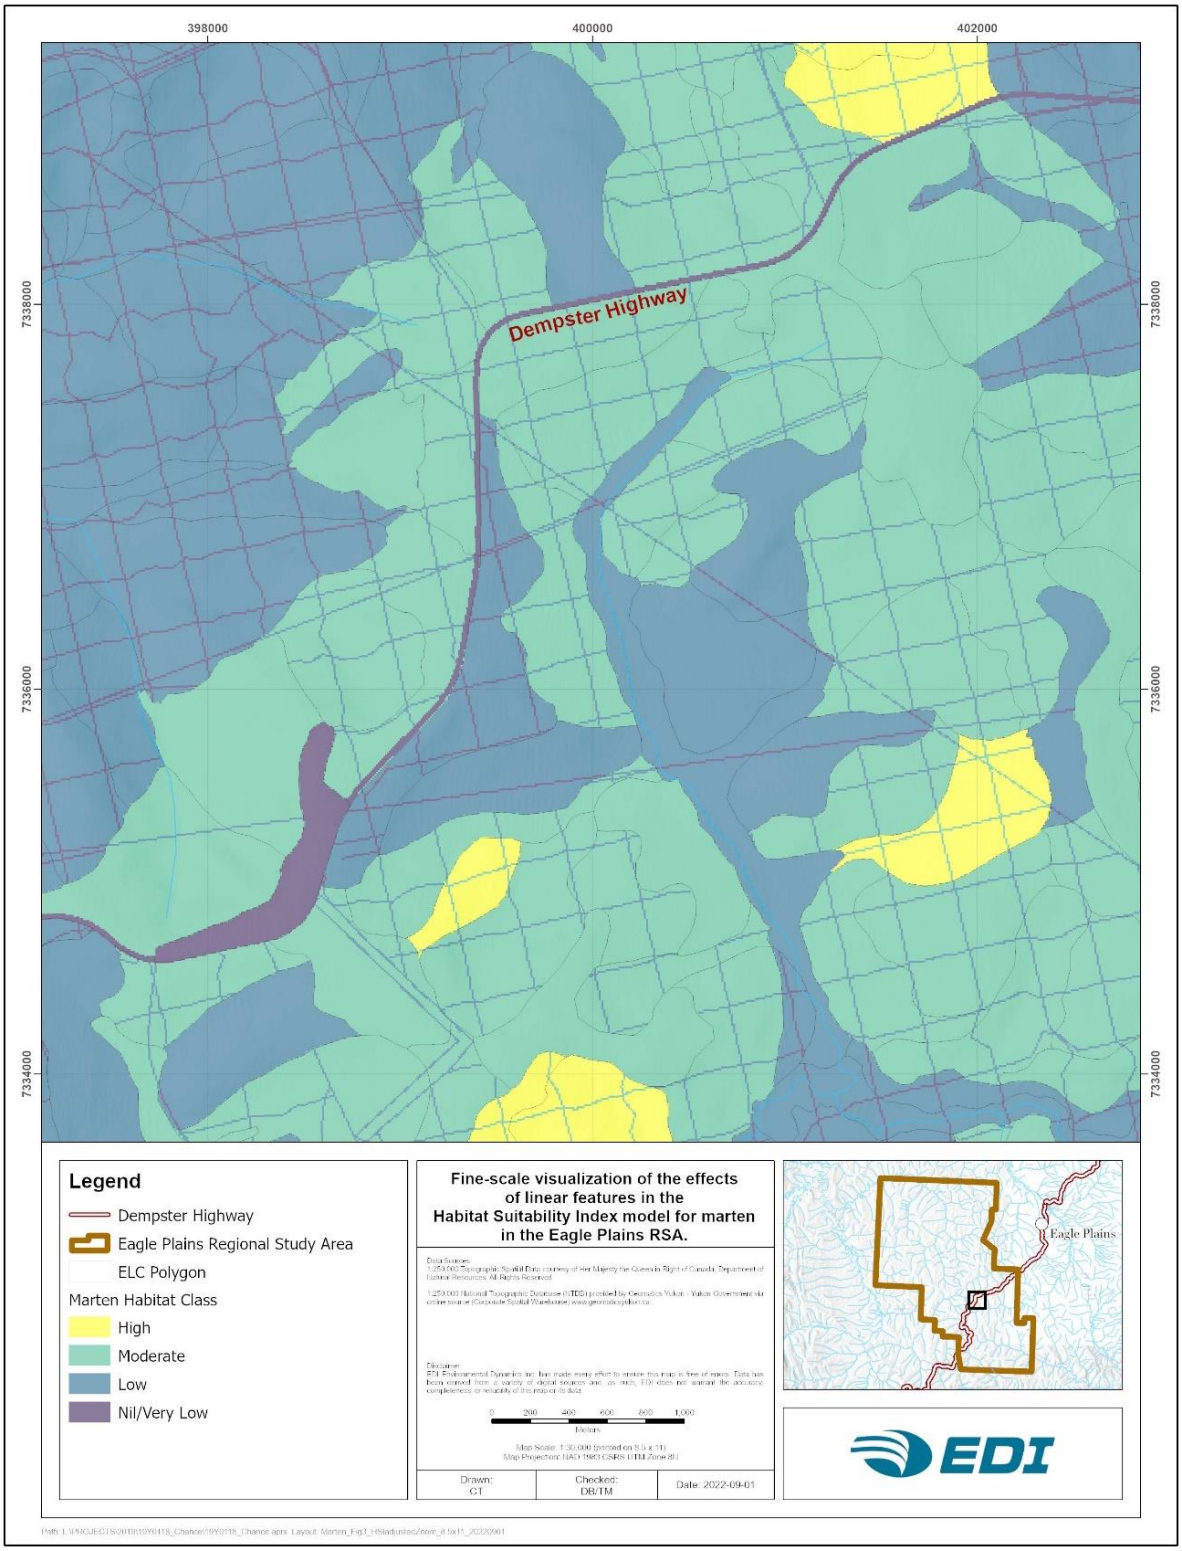


Map 3-3. Fine-scale visualization of the effects of linear features in the Habitat Suitability Index model for marten in the Eagle Plains RSA.

3.5.1 MODEL VERIFICATION AND CONFIDENCE

The frequency of use of habitat by marten in the RSA is expected to correlate to the ordinal habitat classes used in the model. However, independent marten occurrence data were not available to test that expectation. The overall confidence in the model is moderate based on moderate knowledge of marten in northern ecosystems and the lack of local field verification.

3.6 SUMMARY

The quality, amount, and distribution of potential habitat for marten were quantified across the RSA using a Habitat Suitability Index model. Ecosite and vegetation structural stages were used to assign areas an initial HSI score, which was then modified based on the presumed adverse effects of linear features on marten habitat. The HSI model indicates a patchwork of High (16%), Moderate (23%), and Low (60%) quality marten habitat across the RSA. High-quality marten habitat occurred in relatively large areas of contiguous mature/old spruce forests and narrow strips of mature/old riparian forests along major watercourses. The RSA contains extensive Low-quality habitat, associated with vegetation communities in tall and low shrub structural stages, including regenerating burns and open, stunted black spruce forest. Non-vegetated areas that constitute Nil/Very Low habitat are a minor component of the RSA. Linear features reduce habitat quality at the site level, but their effects on habitat supply at the scale of a marten's home range are limited.

4 GRIZZLY BEAR

4.1 PURPOSE AND OBJECTIVES

Grizzly bears (*Ursus arctos horribilis*) were selected as a VC for the Project due to their conservation status and social, cultural, and economic value. Grizzly bear have been assessed as a species of Special Concern in Canada, indicating their populations are at risk of becoming threatened if not adequately managed (COSEWIC 2007). Grizzly bears have cultural significance for Indigenous people of Yukon, some of which have traditional uses for their fur, fat, and meat (Benson 2014, Yukon Grizzly Bear Conservation and Management Plan Working Group 2019a). In addition, grizzly bears are managed as a Big Game species in Yukon (Government of Yukon 2002) and harvested by Yukon residents and non-residents (i.e., outfitting operations) throughout much of the territory. Grizzly bear are considered an iconic Yukon species and the opportunity to view grizzly bears attracts tourists from around the world (Yukon Grizzly Bear Conservation and Management Plan Working Group 2019a).

This section summarizes the current state of knowledge about grizzly bear ecology in the Project and broader areas, including population trends, distribution, habitat selection, diet, and sources of mortality. This report emphasizes grizzly bear ecology specific to the Taiga Cordillera Ecozone where the Project is located. The behavioural ecology and population characteristics of grizzly bears in the taiga are likely distinct from bears inhabiting coastal, boreal, and arctic barren-ground ecosystems, given substantial variation in habitat and food availability across these regions (Mowat and Heard 2006, Mowat et al. 2013). This report draws from multiple sources, including published and unpublished literature, personal communications with biologists, and traditional knowledge where available. Few studies on grizzly bears have been conducted in the region and the broader Taiga Cordillera. Thus, literature from surrounding regions was consulted when local information was unavailable.

4.2 POPULATION STATUS AND DISTRIBUTION

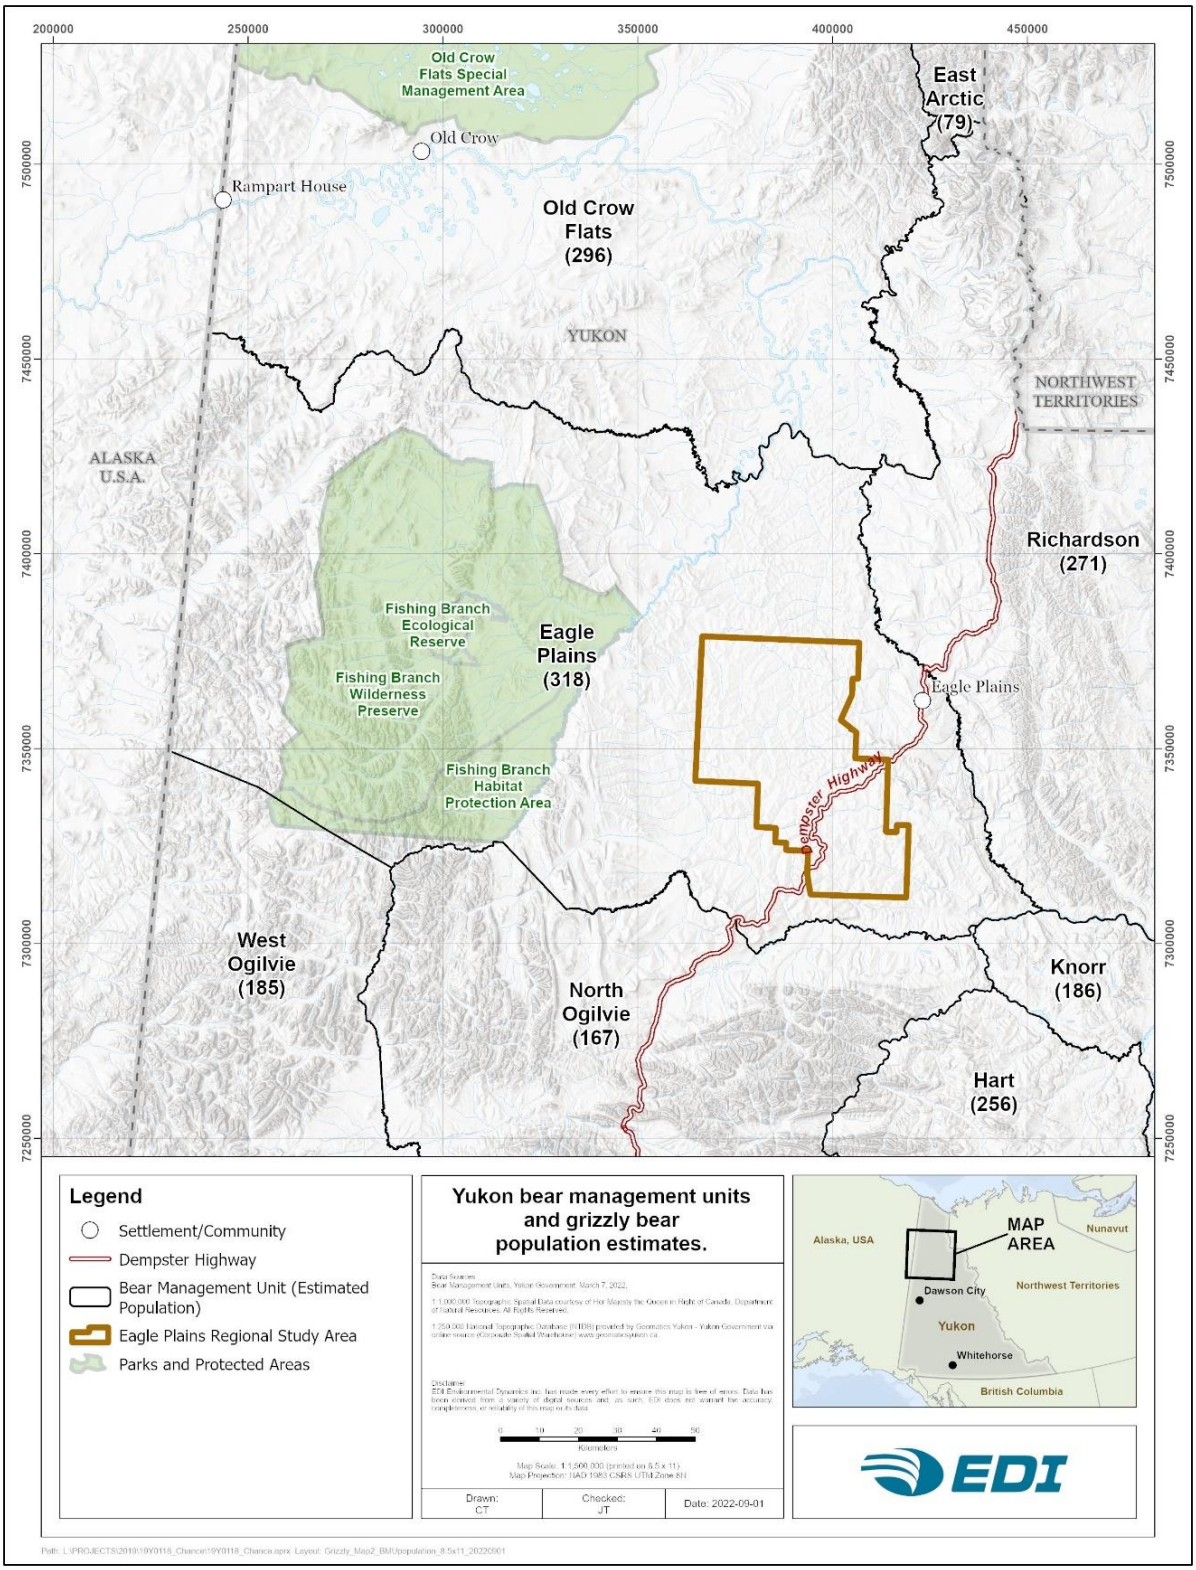
4.2.1 POPULATION

Yukon's grizzly bear population is estimated at 6,000 to 7,000 individuals, comprising approximately 25% of Canada's total grizzly bear population (COSEWIC 2007). The Yukon population estimate was derived from expert-opinion-based estimates of grizzly bear densities in each Yukon Ecoregion, using habitat information and local knowledge collected in the 1980s (Smith and Osmond-Jones 1990, Yukon Grizzly Bear Conservation and Management Plan Working Group 2019b). The exceptions are the Southern Lakes Region and Yukon North Slope, where more recent estimates are available from population assessments using genetic mark-recapture methods (Yukon Fish and Wildlife Branch 2016, 2017). The RSA is located within the Eagle Plains Ecoregion, which has a grizzly bear population estimate of 184 individuals (Yukon Grizzly Bear Conservation and Management Plan Working Group 2019b).

Yukon's grizzly bear populations are managed within bear management units (BMU), generally delineated by outfitting concession boundaries. The Inuvialuit Settlement Region is an exception, where grizzly bears are managed under a separate co-management agreement (WMAC [NS] and WMAC [NWT] 1998). Population estimates for each BMU were derived from the original expert-based Ecoregion estimates (except the Southern Lakes Region and North Slope). Population estimates for BMUs range from 43 to 503 bears; with variation attributed to differences in habitat quality and the sizes of BMUs.

The Eagle Plains BMU, which encompasses the RSA, has a population estimate of 318 bears (Map 4-1). However, the population estimate for the Eagle Plains BMU includes Ni'iinli Njik (Fishing Branch) Territorial Park, which likely has much higher grizzly bear densities than the RSA due to abundant salmon and winter denning habitat (Vuntut Gwitchin Government and Environment Yukon 2010). Grizzly bear densities are considered low throughout the RSA, although limited information is available (Pongracz and Suitor, pers. comm., 2022). Population densities for the adjacent Richardson Mountains are estimated at approximately 23 bears per 1,000 km^2 (Clarkson et al. 1993), but grizzly bears are more abundant in the mountains than the taiga plains that characterize the RSA (Benson 2014).

Grizzly bear population trends in Yukon are primarily tracked through harvest monitoring. The Yukon population is stable (Yukon Grizzly Bear Conservation and Management Plan Working Group 2019a). There is minimal data on population trends within the Eagle Plains BMU, given low grizzly bear harvest rates (refer to Section 3.1), but traditional knowledge provides some insight. Gwich'in knowledge holders suggest that grizzly bears in the Gwitch'in Settlement Area have a generally stable population (Benson 2014). However, elders noted that grizzly bears have declined in some areas from 1940 to the early 2000s due to increased hunting pressure, the opening of the Dempster Highway, increased use of snow machines, and a general northward range shift towards the Inuvialuit Settlement Region.



Map 4-1. Yukon bear management units and grizzly bear population estimates.

4.2.2 DISTRIBUTION

Grizzly bears occur throughout the Yukon, ranging from the BC/Yukon border to the Arctic coast. They are generalist omnivores that may live in various habitat types (Mowat et al. 2013), and they occur in all Ecoregions within Yukon.

In northern Yukon, seasonal grizzly bear distribution generally tracks the availability of key food resources such as berries, fish, ungulate calves, and ground squirrels (MacHutchon and Wellwood 2003). Very little information exists about grizzly bear distribution within the RSA. The Whitestone River adjacent to the RSA (Map 1-1) is an area of higher grizzly bear concentration in the region (Pongracz and Suitor, pers. comm., 2022). During the fall, grizzly bears congregate in Ni'iinli Njik (Fishing Branch) Territorial Park, approximately 20 km west of the RSA, to feed on spawning salmon in the Fishing Branch River (Vuntut Gwitchin Government and Environment Yukon 2010).

In and adjacent to the Gwitch'in Settlement Region, grizzly bears are more common in the Richardson Mountains, the Ogilvie Mountains, and the barren arctic coast than in the flat, low-elevation taiga that overlaps the RSA (Benson 2014). These distributional patterns are attributed to a lack of ground squirrels and other key food sources in the moist, hummocky spruce forest that characterizes much of the RSA.

4.2.3 CONSERVATION STATUS AND THREATS

COSEWIC has assessed grizzly bears as a species of Special Concern (COSEWIC 2007). The Western Canadian grizzly bear population is listed under Schedule 1 of the SARA, which requires measures to prevent grizzly bears from becoming Threatened or Endangered. Within Yukon, grizzly bears are not currently considered a species of conservation concern (Yukon Conservation Data Centre 2019), although a conservation plan was developed for grizzly bears in 2019 to promote healthy and viable grizzly bear populations into the future (Yukon Grizzly Bear Conservation and Management Plan Working Group 2019a).

The greatest threats to the Canadian grizzly bear population are considered to be 1) human-caused mortality, including illegal and legal hunting, conflict kills, and railway or road mortalities, and 2) habitat loss and fragmentation (COSEWIC 2007). Members of the VGFN had observed in the late 1990s that Grizzly bears did not come near to the Dempster highway but were concerned with the old garbage dump areas along the highway possibly attracting bears (Sherry and Vuntut Gwitchin First Nation 1999, p. 286, 289). Key threats to grizzly bear populations in the Yukon are human-wildlife conflict and harvest mortality, although habitat loss and climate-related changes to food availability may also be significant (Yukon Grizzly Bear Conservation and Management Plan Working Group 2019a). Northern grizzly bear populations cannot sustain high mortality rates due to their low reproductive rates and low densities (Nagy et al. 1983). Sources of mortality in the RSA and surrounding region are discussed in detail in Section 4.4.

4.3 MORTALITY AND HARVEST

Grizzly bears are managed as a big game species in Yukon (Government of Yukon 2002), and harvest is permitted in most parts of the territory outside of National Parks, including resident, non-resident, and subsistence harvest. The overall mortality management system is based on estimated total sustainable mortality rates of ≤ 2% of the female population, ≤ 6% of the male population, and ≤ 4% of the total population (Yukon Grizzly Bear Conservation and Management Plan Working Group 2019a). Total allowable mortality rates account for mortality from harvest, and other sources, including vehicle collisions and defence of life and property (DLP) kills (i.e., conflict kills).

Yukon grizzly bear harvest is managed within BMUs, although harvest rates are often reported at the scale of Game Management Subzones (GMS) or broader Game Management Zones (GMZ). The bag limit is one grizzly bear every three years in open subzones, and hunters must report all bear kills (Government of Yukon 2021). The RSA is located within GMZ 1, with the lowest licenced grizzly bear harvest rates in the Yukon. Between 1980 and 2014, the annual grizzly bear harvest in GMZ 1 varied from zero to three bears (Milligan 2018). More specifically, within the Eagle Plains BMU (Map 4-1), only two grizzly bears were harvested from 1995 to the present (Pongracz and Suitor, pers. comm., 2022). The Eagle Plains BMU does not overlap any outfitter concessions (i.e., no non-resident harvest), so reported harvest rates are attributed to licenced resident harvest.

Other sources of grizzly bear mortality include DLP kills, collisions with vehicles, and predation from other bears or large carnivores. Grizzly bear mortality rates in the Eagle Plains BMU are low relative to other BMUs in the territory, with an annual average mortality density of < 0.1 bears per 1,000 km², based on records from 2005 to 2016 (Yukon Grizzly Bear Conservation and Management Plan Working Group 2019b). Mortality rates tend to be higher in southern Yukon, where both the human population and road densities are comparatively high, with mortality densities up to 0.6 bears per 1,000 km² in some BMUs (Yukon Grizzly Bear Conservation and Management Plan Working Group 2019b). However, these rates do not account for unreported human-caused mortality (e.g., unreported DLP kills) or natural sources of mortality. Reported DLP kills accounted for an average of 11 grizzly bear mortalities per year in Yukon from 1980 to 2016. DLP mortality rates are very low within the Eagle Plains BMU; from 1995 to 2021, only one grizzly bear DLP kill was reported (Pongracz and Suitor, pers. comm., 2022).

The correlation between road density and grizzly bear mortality has been well documented in other parts of western North America (McLellan 1990, Mace et al. 1996, Boulanger and Stenhouse 2014, Proctor et al. 2019). Most historical grizzly bear mortalities in central BC and Alberta were related to human activity and occurred within 500 m of a road (Ciarniello et al. 2004, Boulanger and Stenhouse 2014). In BC, grizzly bear mortality rates are known to increase in areas where road densities exceed 0.6 km/km² (Lamb et al. 2018). Mortalities were caused by higher rates of legal harvest, poaching, and conflict kills near roads, in addition to direct mortalities from road collisions. Roadside hunting of grizzly bears is currently permitted in Yukon, although this is under review in some local areas (Yukon Grizzly Bear Conservation and Management Plan Working Group 2019a).

Grizzly bear mortalities from vehicle collisions are rare in Yukon. Fifteen grizzly bear mortalities resulted from collisions with vehicles from 2003 to 2014 on all Yukon Highways (EDI Environmental Dynamics Inc. 2015). Collisions tended to occur in spring and summer when grizzly bears were foraging on roadside vegetation. Most collisions occurred on the Alaska Highway (60%), which has higher traffic volumes than other roads in the territory. The only major road in the RSA is the Dempster Highway, which has comparatively low traffic volumes and is unpaved. From 2003 to 2014, only one bear collision was reported on the Dempster Highway near Dawson City. The bear species was unidentified.

Predation is a source of mortality for grizzly bears, but predation rates are generally unknown in the Yukon. Male grizzly bears occasionally prey on females and cubs on the North Slope (Clarkson and Liepins 1994). Wolves in packs have also been known to kill grizzly bears in northern Yukon (Benson 2014).

4.4 REGIONAL HABITAT ECOLOGY AND DIET

The distribution of available forage strongly influences habitat selection by grizzly bears during spring, summer, and fall seasons (Nielsen et al. 2010, Milakovic et al. 2012) and the supply of suitable den sites in winter (Smereka et al. 2017). Security and thermal cover are also important (McLellan 1990). However, they are generally selected with nearby foraging habitats (Milakovic et al. 2012).

Much of the available information on seasonal grizzly bear habitat selection and diet comes from the interior mountains and coastal regions of western North America (e.g., Hamilton 1978, McCormick 1999, McLellan and Hovey 2001, Ciarniello et al. 2007, Maraj 2007, Nielsen et al. 2010, Milakovic et al. 2012, McClelland et al. 2020). However, the ecological characteristics of these populations may differ substantially from that of grizzly bears in northern Yukon. At a finer spatial scale, grizzly bear ecology within the RSA differs from grizzly bears elsewhere in northern Yukon, such as the Yukon North Slope or the nearby Ogilvie and Richardson Mountains (Pongracz and Suitor, pers. comm., 2022), but very little information exists about grizzly bears within the RSA. Literature and traditional knowledge from similar ecosystems in northern Yukon have been summarized to the extent possible, including the Taiga Cordillera and adjacent Taiga Plains Ecozones. When information specific to the region was unavailable, literature from other parts of the Yukon or western North America was consulted.

4.4.1 SEASONAL DIET

Grizzly bears have broad omnivorous diets, including plants, fish, terrestrial wildlife, and insects (MacHutchon and Wellwood 2003, Ciarniello and River 2018). Grizzly bear diets differ among regions due to variations in food availability across local climates (Mowat and Heard 2006, McLellan 2011, Coogan et al. 2014). Individual grizzly bear diets are also highly variable and dependent on seasonal and annual availability of food items within their home ranges (MacHutchon and Wellwood 2003, McClelland et al. 2020).

Seasonal grizzly bear diets generally reflect the phenological progression of key food resources such as herbaceous plants, ungulate calves, berries, and fish (Hamer and Herrero 1987, MacHutchon and Wellwood 2003, McClelland et al. 2020). Vegetation is a major component of grizzly bear diet in northern Yukon; for

example, vegetation comprised more than 30% of grizzly bear diet in the Richardson Mountains (Koizumi 2012). During spring, important plant foods for grizzly bears in the Taiga Cordillera include the roots of alpine hedysarum (*Hedysarum alpinum*), sedges (*Carex* spp.), grasses, horsetail (*Equisetum spp.),* and berries leftover from winter such as kinnikinnik (*Arctostaphalos uva-ursi*), bearberry (*Arctostaphalos rubra* or *A. alpina*), and crowberry (MacHutchon 2000, MacHutchon and Wellwood 2003). In summer and early fall, grizzly bear diet in northern Yukon includes a variety of berries such as blueberry (*Vaccinium uliginosum*), soapberry (*Shepherdia canadensis*), crowberry, bearberry, kinnikinnik, cranberry (*Vaccinium vitis-idaea*), and cloudberry (MacHutchon 2000, MacHutchon and Wellwood 2003). When berries are unavailable, grizzly bears may forage on herbaceous vegetation such as sedges, grasses, and horsetails. As berry availability declines in late fall, grizzly bears may dig for alpine hedysarum more frequently (MacHutchon and Wellwood 2003).

In northern Yukon, grizzly bear diets incorporate a relatively high proportion of terrestrial wildlife, comprising up to 70% of their diet (Mowat and Heard 2006, Koizumi 2012). Mammals are likely an important food source throughout the spring, summer, and fall whenever they are available, including caribou (*Rangifer tarandus*), moose (*Alces alces*), arctic ground squirrels (*Spermophilus parryii*), and small rodents (MacHutchon 2000, MacHutchon and Wellwood 2003, Koizumi 2012). Arctic ground squirrels are an important food source, and grizzly bears may spend increasing effort pursuing them as berry availability declines in late fall (MacHutchon and Wellwood 2003). Arctic ground squirrels tend to select slopes with well-drained soils and avoid wet, flat, or hummocky terrain (Barker and Derocher 2010), which characterizes much of the RSA. Thus, grizzly bears with home ranges that overlap the RSA may rely heavily on other food sources (e.g., alpine hedysarum or ungulates). Traditional knowledge suggests that bears may travel to the nearby Richardson Mountains to forage on ground squirrels in fall (Benson 2014).

Ungulates may be a particularly important food source in spring, when grizzly bears in northern Yukon and Alaska prey on caribou and moose calves (Boertje et al. 1988, MacHutchon 2000, MacHutchon and Wellwood 2003). Barren-ground caribou (*Rangifer tarandus groenlandicus*) are a focal food source for grizzly bears in northern Yukon during caribou calving and seasonal migration periods (MacHutchon and Wellwood 2003). Grizzly bears may follow caribou as they migrate to and from their calving grounds (Reynolds and Garner 1987, Benson 2014), targeting calves or opportunistically preying on adults (MacHutchon and Wellwood 2003). Northern grizzly bear populations that prey on caribou during calving or migration have higher reproductive rates and population densities than those that do not overlap caribou range (Reynolds and Garner 1987). Grizzly bear diet has not been studied within the RSA, and there is no scientific data on the relative importance of caribou as a food source. However, the Porcupine caribou herd migrates through the RSA en route to calving grounds on the arctic coastal plain and again during their return to winter range in the Richardson and Ogilvie mountains (Russell et al. 1993, Ryder et al. 2007). Grizzly bears within the RSA likely use caribou during spring and fall migration.

Salmon, trout, and char are important seasonal foods for grizzly bears (Mowat and Heard 2006, Adams et al. 2017). During fall, grizzly bears congregate at the Fishing Branch River in Ni'iinlii Njik Territorial Park to feed on chum salmon (*Oncorhynchus keta*) (Vuntut Gwitchin Government and Environment Yukon 2010). Grizzly bears on the north slope are also known to feed on Dolly Varden trout (*Salvelinus malma*) (MacHutchon and Wellwood 2003). Baseline fish inventories for the Project found that salmon and trout were absent within the

RSA (EDI Environmental Dynamics Inc. 2022a). Arctic grayling (*Thymallus arcticus*) were the most common fish species, although longnose sucker (*Catostomus catostomus*) and round whitefish (*Prosopium cylindraceum*) were also present. Grizzly bear in the Richardson Mountains have been observed feeding on arctic grayling (Benson 2014), and whitefish and sucker are known food sources in the central Canadian arctic (Gau et al. 2002, Barker 2011).

4.4.2 FORAGING HABITAT

The availability, abundance, and distribution of important grizzly bear forage directly influence grizzly bear abundance and distribution during the growing season (McLoughlin et al. 2002a, Nielsen et al. 2017, McClelland et al. 2020). Grizzly bear populations in the subarctic and arctic are generally considered limited by food (McLoughlin et al. 2002a). Grizzly bears may balance the selection of high-quality food patches with avoidance of landscape features associated with high mortality risk, such as areas with dense human developments and roads (Nielsen et al. 2010, Proctor et al. 2017). However, given the relatively low harvest rates and low levels of human development in the RSA, it is likely that grizzly bear habitat selection is driven by food availability.

The literature on grizzly bear foraging habitat selection in the mountains, boreal forest, and coastal regions of western North America is extensive (e.g., Hamilton 1978, McCormick 1999, McLellan and Hovey 2001, Ciarniello et al. 2007, Maraj 2007, Nielsen et al. 2010, Milakovic et al. 2012, McClelland et al. 2020), but far less is known about habitat use in northern ecosystems. Studies in northern Yukon, Alaska, and NWT have focused mainly on arctic barren-ground grizzly bears (Phillips 1987, MacHutchon 1996, Gau 1998, McLoughlin et al. 2002a, Barker 2011), leaving a substantial knowledge gap about grizzly bear ecology in the Taiga Cordillera (particularly non-mountainous areas such as the Eagle Plains Ecoregion).

Grizzly bear distribution was clumped in the Richardson Mountains rather than uniform; bear densities were comparatively high in habitats with abundant food such as riparian valleys and low in flat tundra plains (Clarkson et al. 1993). Local traditional knowledge suggests that mountains are better grizzly bear habitat than taiga or barren-ground plains due to the abundance of berries and ground squirrels, and the earlier snowmelt on windblown and south-facing slopes in spring (Benson 2014). Grizzly bears in northern Yukon have large home range sizes (up to 1,250 km^2) and travel long distances to reach suitable foraging habitat (MacHutchon 2000). Thus, grizzly bears in the RSA may travel to the Richardson or Ogilvie Mountains for seasonal forage. This is consistent with the knowledge that grizzly bears have low densities in the RSA, and their behaviour is characterized by seasonal movements through the area (Pongracz and Suitor, pers. comm., 2022).

In the central Canadian arctic, barren-ground grizzly bears selected eskers, shrubby riparian zones, and tussock tundra throughout the spring, summer, and fall, corresponding with the spatial and temporal availability of food (Phillips 1987, McLoughlin et al. 2002a). Esker slopes support a relatively high abundance of berry-producing shrubs and arctic ground squirrels (Gau 1998, Barker and Derocher 2010, Barker 2011), whereas riparian zones and tussock tundra may provide herbaceous forage such as horsetails, sedges, and cotton grasses (*Eriophorum* spp.) (Gau 1998, Gau et al. 2002). Barren-ground grizzly bears also selected habitat with abundant lichen, which may attract caribou (McLoughlin et al. 2002a). During the Porcupine caribou

migration on the Yukon north slope, grizzly bears travelled along river channels or selected hillsides with long sight-lines, presumably to increase their chances of detecting caribou (MacHutchon 2001).

4.4.3 COVER (SECURITY AND THERMAL HABITAT)

Security habitat includes areas of dense vegetation that provide visual screening from other grizzly bears or humans (Mace and Waller 1997). Security cover may be particularly important for sub-adult male bears and sows with cubs to avoid adult males defending their territories or killing cubs to bring females into estrus (LeFranc et al. 1987, McLellan 2005). Female grizzly bears may select lower-quality foraging habitat if it provides high security values or spatial separation from potentially aggressive male bears (Pearson 1975, McLellan and Shackleton 1988). For example, female grizzly bears in the arctic are thought to occupy the Mackenzie Delta to avoid male bears in adjacent mountain ranges (Benson 2014).

Thermal cover includes habitat that provides relief from the elements, such as solar exposure or extreme weather. Cover from heat and solar exposure is provided by various habitats such as open water (e.g., rivers, streams, lakes), permanent snow patches, steep north aspects, and mature forest patches with high canopy closure (Pearson 1975, LeFranc et al. 1987). Grizzly bears may also select forests with high canopy closure for day beds to seek shelter from heavy rains (Pearson 1975, Munro et al. 2006). The importance of thermal cover for grizzly bears in the Taiga Cordillera has not been studied.

4.4.4 WINTER DENNING HABITAT

Grizzly bears in northern Yukon hibernate in winter from approximately October to May (Nagy et al. 1983, MacHutchon 2000), although the timing for den entry and emergence depends on annual weather patterns. Grizzly bears will enter their dens as late as mid-November and emerge as early as March if the weather is warm (Benson 2014).

No records exist of grizzly bears dens within the RSA, although grizzly bears are known to den in the mountains of Ni'iinli Njik (Fishing Branch) Territorial Park, approximately 20 km west of the RSA (Pongracz and Suitor, pers. comm., 2022). Grizzly bears in the arctic and subarctic typically excavate their dens in locations with suitable soil, such as sand, gravel, or glacier-deposited rock (MacHutchon 2000, Smereka et al. 2017). Grizzly bears in Vuntut National Park in northern Yukon preferentially select den sites in the mountainous regions of the park and avoid denning in Old Crow Flats, which is characterized by flat topography, large wetland complexes, and spruce forests (MacHutchon 2000). Denning within Old Crow Flats is likely limited to dry, steep riverbank slopes (MacHutchon 2000). Grizzly bears throughout the Gwitch'in Settlement Area are known to prefer denning in the mountains; however, in areas with flat topography (such as the RSA), grizzly bears will select small topographical features such as hills, steep riparian banks, or lakesides to excavate their dens (Benson 2014). Grizzly bears in northern Yukon have large home ranges (Section 4.5.5) and may travel long distances to reach winter den sites (up to 65 km; Craighead 1976). Thus, some grizzly bears with home ranges overlapping the RSA may travel to nearby mountain ranges (Richardson Mountains, Ogilvie Mountains, or Ni'iinli Njik Territorial Park) to hibernate.

In arctic barren-ground ecosystems, grizzly bears select river banks, lakesides, or eskers with silty or sandy soil for denning (Harding 1976, Mueller 1995) and avoid open spruce forest (Smereka et al. 2017). Grizzly bears prefer to excavate their dens on steep south-facing slopes with abundant shrub cover in the arctic (Mueller 1995, McLoughlin et al. 2002b) and the boreal forest of southern Yukon (Libal et al. 2012). The root structures of tall shrubs such as willow (*Salix* spp) and dwarf birch (*Betula glandulosa*) may provide support to the ceilings of excavated grizzly bear dens (McLoughlin et al. 2002b).

4.4.5 HOME RANGE AND SEASONAL MOVEMENTS

Grizzly bear home range sizes are variable and have an inverse relationship with food availability (Nagy and Haroldson 1990, McLoughlin et al. 2000). Thus, grizzly bear home ranges in productive coastal or interior mountain habitats of BC are typically smaller and have greater overlap than those in less productive boreal, taiga, or arctic barren-ground ecosystems (McLoughlin et al. 2000, Edwards et al. 2009, Hamilton et al. 2018). Additionally, the size of individual home ranges may vary annually in response to fluctuations in the quality and abundance of food (McLoughlin et al. 2000). The largest recorded grizzly bear home range sizes in North America were in the central Canadian Arctic, where mean home range sizes for female and male bears were 2,100 km² and 7,245 km², respectively (McLoughlin et al. 2003).

No data on grizzly bear home range sizes within the RSA are available, but studies conducted in other parts of the Taiga Cordillera provide some insight. Grizzly bear home range sizes in the Old Crow flats of Vuntut National Park were estimated at 650 – 750 km² for females and 1,150 – 1,250 km² for males (MacHutchon 2000). In the Richardson Mountains north of the RSA, female grizzly bears had mean annual home ranges of 442 km² and males had home ranges of 760 km² (Koizumi 2012). The smaller home ranges in the Richardson Mountains may be attributed to more food resources, such as berries and ground squirrels relative to the taiga plains (Benson 2014).

Grizzly bears have low fidelity to home ranges in unproductive arctic ecosystems, where food distribution is spatially and temporally heterogenous, and grizzly bear population densities are low (Edwards et al. 2009). Under these conditions, it is beneficial for grizzly bears to adjust the size and location of their home ranges to maximize forage availability. For example, in northern Yukon and Alaska, grizzly bears may travel long distances to follow the seasonal migration of barren-ground caribou (Reynolds and Garner 1987, MacHutchon 2001). Grizzly bears in northern Yukon are also thought to travel long distances to find suitable winter denning habitat in the mountains (Benson 2014).

4.5 SUMMARY

Available data suggest that a low density of grizzly bears are distributed throughout the RSA. Rates of recorded harvest mortality are low within the Eagle Plains BMU, but other sources of mortality are largely unknown and unrecorded. Grizzly bear diet in the RSA and surrounding region predominantly consists of vegetation (berries, roots, and herbaceous plants) and terrestrial wildlife, including caribou, moose, and arctic ground squirrels. Grizzly bears may rely heavily on caribou (particularly calves) during the seasonal migration of the Porcupine caribou herd through the region. Habitat quality in the RSA is generally poor compared to the adjacent mountain ranges, where berries and ground squirrels are more abundant. Lastly, grizzly bears in the RSA may excavate their winter dens in riverbanks, lakesides, and hills where suitable soil can be found, or they may travel to nearby mountain ranges to den on steep south-facing slopes. Most of the information presented in this review was based on scientific studies.

5 MOOSE

5.1 PURPOSE AND OBJECTIVES

Moose (*Alces alces*) were selected as a VC for the Project due to their importance as a managed game species, and their cultural values to First Nations living in the Yukon. Winter, and especially the late winter season, is often a difficult time for moose due to the limited availability of forage and increased energetic demands to move through crusted or deep snow. A winter habitat suitability map was developed for moose in the RSA to identify high-suitability winter forage habitat areas. The map quantifies the winter forage habitat in each habitat class (high, moderate, low/nil/very low) within the RSA.

This section summarizes information and data on moose use and ecology in the subarctic taiga that was used to develop habitat suitability mapping to quantify the suitability, amount, and distribution of potential habitat for moose in the RSA.

5.2 GENERAL HABITAT ECOLOGY OF MOOSE

5.2.1 EXISTING INFORMATION

There is limited knowledge of moose within the RSA. In 2001, Anderson Resources Ltd submitted a project application and a mitigation plan for an Eagle Plains 2001–2003 Seismic Survey Program (Access Consulting Group and EBA Engineering Consultants Ltd. 2001). This report describes moose knowledge of the area as being limited and incidental. The authors reviewed the existing data and had discussions with local wildlife biologists and other resource users about winter usage patterns by moose in the general vicinity of the Eagle Plains project area. At that time, moose were only superficially studied in the Eagle Plains Area (Access Consulting Group and EBA Engineering Consultants Ltd. 2001).

The 2001 project application report stated that an approximate moose density of about 0.05 moose/km² was estimated for the project area based on general habitat assessment. The application also provided the following information:

> "*Within the project area, moose are not commercially exploited and there are no outfitting concessions. There is limited off-road access and the moose population density within the project area is known to be low, hence the subsistence harvest is minor. YTG Renewable Resources harvest data show that, in the last twenty years, only 13 moose have been harvested in the Dempster Corridor subzones (Game Management Zone 1-55 and 1-56).*
>
> *Anderson conducted a post-rut moose survey in early November of 2000, to augment the currently very limited knowledge regarding moose populations in the project area. The survey was conducted to provide baseline information on the level of range usage by moose within the project area. During the course of the 2-day survey, 30 moose were observed and an additional 64 sets of tracks were encountered. In general, moose were more frequently associated with the higher elevations (between 400 m and 700 m above sea level), but were widely dispersed throughout all of project*

area's drainages. From the survey results, an overall population of approximately 60-90 moose was estimated (Access Consulting Group and EBA Engineering Consultants Ltd. 2001)."

These observations of greater moose abundance at higher elevations are consistent with observations from VGFN elders around the same time (Sherry and Vuntut Gwitchin First Nation 1999, p. 7). They discussed that Eagle Plains was an important moose range, but that some animal populations had changed their land use after the Dempster highway was built and there was low density near the highway (Sherry and Vuntut Gwitchin First Nation 1999, p. 287, 299).

In 2001, an aerial survey was completed from June 18–22 within the 2001 project area. During that survey, 19 moose were incidentally observed, with most observations noted in the South Eagle River and Dalglish Creek area. A general point of interest was that moose calving was expected in several drainages, but was particularly noteworthy in the South Eagle River (Access Consulting Group and EBA Engineering Consultants Ltd. 2001).

In 2013 Environment Yukon conducted an 'Eagle Plains Mammal Occupancy Aerial Survey' from March 19 to March 24, 2013 (Environment Yukon, unpublished data). The survey aimed to assess the occurrence and distribution of large mammals within the broader Eagle Plains Ecoregion. Over the 6 survey days, 64 moose were observed, including cow and calf observations. The data indicated that moose were widely distributed within the Eagle Plains area, but the area was not comprehensively surveyed, and formal analyses/reporting were not included with the data.

From October 2014 through August 2016, Yukon Environment deployed 37 (2014) to 48 (2015) pairs of remote cameras in the Eagle Plains area (Burden 2016). The objective was to assess the use of linear features by medium to large mammals (wolves, caribou, and moose) by comparing the use of wildlife on and off seismic lines by placing cameras at random locations on seismic lines, and camera locations off seismic lines. The report is a data summary with no statistical analysis, and the results are non-standardized (e.g., lacking a catch per unit effort reporting metric). Regardless, there was some information collected for moose relevant to this study. Over the two years of study, moose encounters were infrequent and varied slightly among years (0.33 moose/100 camera days in 2014–2015, 0.43 moose/100 camera days in 2015–2016). Moose were found in the study area throughout the year but were observed more often from May through November (spring through fall). No statistical analyses or apparent trends were used to determine moose associations with linear disturbances.

EDI did not complete other population or distribution surveys for moose as part of the current baseline studies. Efforts focused on developing a winter habitat model to quantify habitat suitability, amount, and distribution across the RSA.

5.2.2 HABITAT ECOLOGY OF MOOSE

Moose are one of the most widely distributed ungulates and range from the Arctic coasts of North America, Europe, and Asia down to the southern limits of the boreal forest and farther south where suitable montane biomes are located exist. In the Yukon, moose densities generally range between 100 and 250 moose for every 1,000 km^2 of suitable moose habitat (Environment Yukon 2016b). The Regional Biologist has indicated that,

based on his observations, moose densities in Eagle Plains are relatively low compared to some parts of the southern Yukon, but that moose densities in Eagle Plains are high compared to other parts of North Yukon (Mike Suitor, pers comm).

Moose make seasonal movements to various habitats such as calving, summer, rutting, and winter habitats. These seasonal movements may range from a few to many kilometres (Clarke et al. 2017, Government of Yukon 2022). Changing environmental conditions can affect the quality, quantity, distribution, and accessibility of cover and forage over a landscape. Key habitat requirements are rarely distributed evenly over space or time, so moose move to access various resources as availability changes. Periodic disturbances, such as wildfire and vegetation clearing change the abundance and availability of moose cover and forage. Moose are generally not evenly distributed across the landscape; they concentrate in particular habitats offering higher forage opportunities(Government of Yukon 2022). Moose with access to large quantities of forage are known to travel less than those in areas where forage is less abundant (McCulley et al. 2017). There is a wide variation in home range sizes for moose across the boreal forest and between seasons (Phillips et al. 1973, Addison et al. 1980, Clarke et al. 2017, McCulley et al. 2017). Moose that frequent the Old Crow Flats wetland complexes in northern Yukon are known to spend summer months within this area and then migrate 250 km to spend the winter within the Alaska Arctic National Wildlife Refuge (McCulley et al. 2017).

Moose habitat selection patterns vary among populations, individuals, seasons, and sexes (Clarke et al. 2017, McLeod and Clarke 2017). Furthermore, habitat use by moose can differ depending on the type of land cover and the availability of resources in a particular area. In northern Yukon, moose appear to frequent narrow strips of forest along the rivers (Photo 5-1), and VGFN elders have observed good moose habitat just south of the RSA along the Blackstone and Ogilvie rivers and the wetlands of the Blackstone Uplands (Sherry and Vuntut Gwitchin First Nation 1999, p. 303). In the south, moose frequent the treeline in the subalpine shrub zone. Moose in the Yukon also tend to concentrate in recent burns and along waterways with interconnecting ponds, marshes and meandering streams (Government of Yukon 2022).

Moose inhabit numerous stand-cover types and structural stages. Conifer stands are generally used primarily as cover to moderate extremes of cold, wind, heat, deep snow, and security from predators (Timmermann and McNicol 1988, McCulley et al. 2017). Early seral areas are usually shrub-dominated and used by moose because shrub species comprise more than 60% of a moose's annual diet (Renecker and Schwartz 2007). During the spring and summer, moose forage primarily on the leaves of woody plants, aquatic plants, and forbs. During winter, the diet shifts to highly lignified woody stems, resulting in higher ruminating times (Renecker and Hudson 1986). Plant form and twig diameter have also been shown to affect digestion rates, influencing moose winter foraging (Vivas et al. 1991). Some preferred moose forage species include:

- Willows (*Salix* spp.)
- Red-osier dogwood (*Cornus sericea*)
- Saskatoon serviceberry (*Amelanchier alnifolia*)
- Highbush cranberry (*Viburnum edule*)
- Mountain ash (*Sorbus sitchensis*)
- Scrub birch (*Betula glandulosa / nana*)

- Trembling aspen (*Populus tremuloides*)
- Lodgepole pine (*Pinus contorta*)
- Paper birch (*Betula papyrifera*)

These browse species may be used preferentially due to their height and growth form (Baker 1990, Van Ballenberghe et al. 1989). The palatability of shrub species can also vary from region to region. Soopolallie (*Shepherdia canadensis*) was recorded as an important forage species for moose on the Kenai Peninsula, Alaska (Edwards 1940) but appears to be unpalatable in other parts of the boreal forest (Rolley and Keith 1980). In northeast Alberta, the preferred browse species was Saskatoon serviceberry; even in areas where it was uncommon, the species was still heavily used when it was present (Nowlin 1978). In the Peace-Athabasca Delta, moose feed primarily on willow, red-osier dogwood, paper birch and balsam poplar. In one study done in the taiga region ranging from northwestern Manitoba to Great Slave Lake NWT, winter moose diet was mainly composed of *Betula papyrifera* bark (Thomas 1990). Risenhoover (1989) found that willows accounted for more than 94% of the winter moose diet in Denali National Park and Preserve.

Within the RSA, willows and scrub birch are the dominant browse species available for moose. Willows often form the predominant diet in other northern areas. Willows are well adapted to wetter soils and are commonly found in wetland and riparian habitats (Photo 5-2). Willows are also an early successional species and are often abundant in early seral habitats resulting from forest fires and human-disturbed areas (e.g., seismic lines, cutblocks, and road rights-of-way). Moose have been reported selecting previously burned habitats and areas within 100 m of streams and waterbodies, presumably due to the abundant forage (Wasser et al. 2011). In habitats with low availability of twigs and leaves, moose sometimes use a foraging technique called 'bark-stripping' where long, linear strips of bark are peeled from certain trees, such as aspen (LeResche and Davis 1973, Miquelle and Van Ballenberghe 1989). However, the bark is usually a relatively small component of moose diets (Miquelle and Van Ballenberghe 1989). It is unlikely to be a significant food source in Eagle Plains due to the dominance of spruce, whose bark is non-palatable.

Across Canada, heavily used areas by moose include wetlands, floodplains of major rivers, riparian areas, regenerating cut blocks and burns, and avalanche chutes. Their preferred habitat types include recent burns, logged areas, lake and river shores, willow and alder swamps and other wetland areas MacCracken et al. 1997). Food (including forage quality) and climate are considered important aspects of habitat for moose (Franzmann 1981). Analyses of moose range commonly stress the abundance, production, and use of woody shrubs as important characteristics when describing moose habitat requirements (LeResche and Davis 1973; Jung et al. 2009).

In Labrador, moose can be observed more often in riparian areas and hardwood stands and less often in string bogs, open conifer-lichen stands, barren hilltops than expected based on the availability of those habitat types during the winter (Jung et al. 2009). Riparian areas are often high suitability habitats for moose in winter due to the availability of high-quality forage species such as willows. Willows and birch found within the riparian shrub communities are often adjacent to a strip of closed-canopy conifer-dominated forest that provides thermal cover and snow interception. The combination of shrub communities and closed-canopy mature riparian forests offer a highly suitable habitat mosaic for moose (Jung et al. 2009).

During the winter, moose are influenced by snow depth, snow density and hardness. Moose movements begin to be impeded at snow depths of 70 cm, and moose strongly avoid areas with >100 cm of snow. Moose generally winter in areas where snow depths are less than 70 cm (Coady 1974, Franzmann 1981). In mountainous areas, where snow accumulation can vary substantially, this can result in strong patterns of seasonal range use, with moose avoiding mid an upper elevation where snow accumulation is higher. For example, in the Pelly-Macmillan River area (Central Yukon), moose concentrated along the major river valleys during late winter, where the combination of shallower snow under mature forest canopies and dense willows in wetland areas provided moose with optimal habitat (O'Donoghue 2005). However, snow is not expected to strongly influence the distribution or habitat selection in the RSA in most years. This is due to the relatively modest elevation range within the RSA. The average maximum snow depths of approximately 80 cm are just on the edge of the range that moose avoid (EDI Environmental Dynamics Inc. 2021). Over much of the winter, snow depths are less than 70 cm.

Predation is recognized as a major factor affecting the dynamic of moose populations (Gasaway et al. 1992, Ballard and Van Ballenberghe 2007). In general, prey species select security habitats at multiple scales based on various factors that can affect their perceived predation risk. Perceived security is also a dynamic factor that varies over time and is dependent on the density and behaviour of predators, including humans. Moose population growth and density in Yukon are thought to be limited by wolves (Hayes et al. 2003). Consequently, moose may avoid habitats that increase the potential for wolf encounters. However, predator avoidance may be a more prominent factor in habitat selection at the landscape scale than within a home range (Dussault et al. 2005). Habitat types with taller and denser vegetation likely provide some protection from wolves during winter. Habitat types that provide cover from predators may also contain taller trees that intercept snow, reducing snow depth and reducing the energy required to move.

At a minimum, security habitat should conceal a moose from predators. It can be assumed the security habitat for moose can be provided by any forest stand of adequate density with trees and shrubs taller than 2 m. Security cover for moose is most critical during spring calving when cow moose seek out islands and gravel bars on river floodplains for calving. At calving time, cow moose and calves can find secure habitat in dense deciduous or mixedwood stands, or tall shrubs with canopy cover >50% (MacCracken et al. 1997). During winter, deep, and persistent snow has been shown to have a greater impact on the physical condition of moose and thus increasing its risk of predation. Within one study (Dickie et al. 2020), moose seem to select riparian areas to facilitate movement instead of selecting them only for foraging opportunities. In the RSA, most wildlife trails were observed adjacent to riparian areas.

Photo 5-1. A moose observed adjacent to a narrow treed riparian area in the RSA (Photo provided by Palmer Environmental 2019).

Photo 5-2. Shrubby riparian area, on the edge of a burn, where willows have been browsed by moose.

5.2.3 DISTURBANCE

5.2.3.1 Fire

Burns are often a major factor affecting the distribution and abundance of moose across the boreal forest, with densities peaking 20 to 25 years after fire (LeResche 1974). Studies have shown that moose populations are often denser in burned areas where browse is of higher quality and greater abundance than adjacent, unburned areas (Gasaway et al. 1989). Moose have been reported selecting previously burned habitats that are 10–30 years old (Maier et al. 2005) and less than 40 years old (Wasser et al. 2011). Overall, fire creates favourable forage conditions for moose when regenerating shrubs are available for browse.

Several large wildfires have affected the RSA, occurring between 1959 and 2018. Areas that were affected by fire, and are still regenerating, were labelled with a fire disturbance code in the ELC vegetation maps. For older burn areas, the adjacent non-burned area was compared to the burn area to see if there was a noticeable difference in vegetation. Areas that did not have a noticeable difference were not characterized as fire disturbed as they were considered regenerated. The appropriate structural stage was assigned to reflect the stage of regeneration.

The post-fire successional pathways for many of the ecosystem units in the RSA were the same or very similar, making the differentiation of ecosystem units based on revegetation difficult. For example, almost all ecosystem units regenerate initially with deciduous shrubs (willow and scrub birch) and a mix of spruce and deciduous trees (primarily paper birch), and, as succession progresses, the prominence of spruce increases and deciduous shrubs and trees decreases. Often the post-fire succession also varied within an ecosystem unit depending on several factors, including the number and frequency of fires, the intensity of the fire, and the amount of permafrost present before and after the fire. Field observations suggest that hot fires likely melted a larger portion of the permafrost, permanently altering the moisture regime of the affected area; therefore, site moisture regimes are altered, and some sites do not return to the same ecosystem unit that had been established before the fire. From a moose habitat perspective, the result is that, except for some ecosystem units in riparian areas, the abundance of browse species is affected more by regeneration status and structural stage than ecosystem unit type.

The current structural stage for some of the more recent fire-disturbed areas was difficult to determine due to the range in age and variety of the imagery. To be consistent, the mappers assigned a shrub structural stage to all fire disturbed areas unless there was strong evidence suggestion another structural stage (i.e., a plot stating it was graminoid dominant, Photo 5-3).

Photo 5-3. Recent burn in a graminoid structural stage. Generally, regenerating shrubs become available as browse to moose about 10 years after fire disturbance.

5.2.3.2 Linear Features

Linear features are the primary type of anthropogenic disturbance in the Project area. However, there are many uncertainties regarding the extent, impacts, and recovery status of linear features in the area. Linear features include narrow, linear clearings on the landscape, typically used for transportation and seismic exploration activities. The Project area has numerous 2D seismic lines (e.g., Photo 5-4) and winter roads from previous exploration activities dating back to the 1960s. The majority of 2D exploration occurred between 1961 and 1984. Some 2D exploration occurred in 2001 that incorporated LIS techniques (Access Consulting Group and EBA Engineering Consultants Ltd. 2001, GEOTIR 2014). More recently, approximately 2,200 km of 3D low-impact seismic (LIS) exploration was conducted in a 325 km² area between November 2013 and April 2014 (GEOTIR 2014). This 3D exploration grid is near the centre of the Project area, spanning north and south of the Dempster Highway.

Linear features can affect predation risk on moose. Facilitated predation operates by increasing the spatiotemporal overlap and interactions between wolves and prey species (Serrouya et al. 2016, Dickie et al. 2020). The magnitude and extent of such overlap are dependent on the extent and use of linear features across the contiguous woodland habitat. Linear features may enhance predation rates by increasing predator abundance via travel corridors and, ultimately, by optimizing hunting efficiency (Serrouya et al. 2016, Dickie et al. 2017, DeMars and Boutin 2018). The degree to which facilitated predation operates and affects prey species is context dependent. The primary features possibly associated with facilitated predation in the Project area are winter roads/trails, 2D and 3D seismic lines, and the Dempster Highway. In winter, clearing and compaction of snow on linear features by plowing or snowmobiles can elevate predator movements (Keim et al. 2019b), further exacerbating predation risk.

The Dempster Highway runs roughly southwest to northeast through the southern half of the RSA. The RSA includes numerous winter roads (15 m average width) from previous exploration activities dating back to the 1960s. The Project will be accessed via existing and new winter roads. Moose have been shown to avoid human development and activity, but response varies by season, sex, and population. Reduced use by moose has been documented near roads (Rolley and Keith 1980).

Moose use of seismic lines is variable. In a study completed in northern Alberta by Dickie et al. (2020), moose selected to be closer to riparian areas and avoided being closer to linear features. Another study demonstrated that seismic lines could increase encounter rates between prey and predator by facilitating predator movement (McKenzie et al. 2012). Moose, wolves and even people tend to move faster on linear features since these features create a path with less visual and physical resistance to movement but in some cases the ease of movement can increase the risk of prey species encountering a predator. Dickie et al. (2020) noted that moose had tendency to move faster while on linear features which could support the theory that moose perceive LFs as a risk to wolf encounters.

Many uncertainties surrounding the ecological impacts and recovery potentials for linear features, particularly of 2D and 3D seismic lines, in the taiga ecosystem that characterizes Eagle Plains. EDI completed a linear feature study. The purpose of that study was to systematically describe and quantify the current conditions of linear features across the RSA by providing a baseline inventory and assessing the successional and functional status of linear features. Six types of successional pathways were defined on linear features in the Eagle Plains area (Table 5-1; after Simpson 2008).

Most sites surveyed (79%) were undergoing normal succession, and that vegetation was either in a low shrub (56.1%) or tall shrub (29.0%) structural stage along the linear features sampled. Almost all 3D plots were at a low shrub structural stage (67% less than 1 m), while 2D plots and winter roads were distributed more evenly through low shrub, tall shrub, and forested structural stages (21% greater than 4 m and 5% greater than 8 m). The analyses suggested that 2D seismic lines regenerate to a more shrub-dominated community relative to pre-disturbance conditions, 3D seismic lines had lower woody cover than off-line plots after five years of regeneration, and fire has the potential to increase shrub and tree growth on linear disturbances. Sightlines along linear features decreased substantially as the height of vegetation increased, and ease of travel along linear features decreased with the amount of woody cover. Fire played an important role in shaping functional recovery by increasing the amount of woody cover and the structural stage of vegetation.

Under normal succession, 2D seismic lines had 12% to 19% greater mean shrub cover than the corresponding off-line sites in burnt and unburnt conditions, respectively. In unburnt conditions, 2D seismic lines had considerably shorter and sparser trees than paired off-line plots, but in burnt conditions, the 2D lines showed denser trees. Burn status appeared to influence some successional classes. Magnified succession was more common at burnt sites (19 burnt versus 5 unburnt), while stagnated succession was more common at unburnt sites (3 burnt versus 7 unburnt). Sites on a normal successional trajectory did not appear to have any relationship to burnt status, while other successional classes were too uncommon to draw any conclusions.

Studies focusing on the use of linear features by moose are limited. However, Keim et al. (2019a) found that moose used 3D seismic lines the least and used well-defined 2D seismic lines and pipelines the most.

Photo 5-4. Example of a low shrub 2D seismic line within the RSA.

Table 5-1. Descriptions of successional classes documented in the RSA (Simpson 2008).

Successional Class	Description
Normal succession	Similar to adjacent forest, but at an earlier seral stage. E.g., young trees that may be surrounded by early successional shrub and forb or graminoid species. Disturbance is likely only the removal of trees and shrubs, with little to no disturbance to soil or permafrost.
Magnified succession	Increased moisture and nutrient availability due to soil disturbance. Often new seral species due to removal of original trees and shrubs. Resulting vegetation is likely shrub or deciduous tree dominant, typically with more productive growth than adjacent sites. Disturbance is likely the removal of trees and shrubs, with significant disturbance to soil or permafrost.
Retrogressive succession	Removal of insulating peat layer causes a change in the soil thermal regime. Active permafrost layer depth increases, releasing water content. Resulting habitat is likely moss, graminoid, forb, or low shrub dominated, with high moisture content. Disturbance includes the complete removal of trees and shrubs, and soil or active permafrost layer.
Successional stagnation	Suspension of succession at herb or low shrub stage. Likely dominated by graminoids; area may have been seeded. Check line age to differentiate from normal succession. Disturbance to soil or permafrost is likely. Ground may have been compacted.
No succession	No ecological differences except that the forest opening is linear instead of random. Disturbance is likely only the removal of trees and shrubs, with little to no disturbance to soil or permafrost.
Recent disturbance	Newer seismic line where successional patterns cannot yet be determined. Line age was checked to differentiate from other successional patterns.

5.2.4 HABITAT SUMMARY

The late winter season is often a difficult time for moose due to the limited availability of forage and increased energetic demands to move through crusted or deep snow. A winter habitat suitability map was developed for moose in the RSA to identify high-suitability winter forage habitat areas. Moose select winter habitat based on three criteria: food availability, snow conditions, and predator avoidance (Dussault et al. 2005). Within the RSA, moose primarily select winter habitat based on browse availability.

The development of the moose habitat model will focus on the following key points:

- Habitat use is believed to be driven by forage availability.
- Winter is the most limiting season for forage availability.
- Winter forage in the RSA is primarily willow species.
- Areas with high willow cover in the RSA are riparian areas, burn areas and some mesic and moist ecosystem units with moderate willow understory.
- Elevation and snow are not likely a significant factor given the limited topography within the RSA; and
- Linear features like seismic lines and trails may provide small patches with elevated willow cover, but their extent are too small to affect habitat selection.

Willows are the primary winter food for moose and signs of moose browsing were commonly observed in the areas that contain abundant willow during the Project baseline surveys. As willow is an early succession species, the shrub is most abundant in disturbed areas such as burns. Anthropogenic disturbances in the RSA, such as 2D seismic lines, may also have a high willow cover, but the extent of these areas is too small to provide significant forage opportunities to moose. Outside of regenerating areas, the high cover of willows is mainly associated with riparian shrublands along streams and disclimax shrublands within the RSA.

5.2.5 HABITAT SUITABILITY MAPPING

Habitat suitability mapping identifies the current ability of an ecosystem unit to provide certain life requisites for a given wildlife species or provide the environmental conditions needed for cover, food and space. A habitat suitability rating is a value given to each structural stage of each ecosystem unit in a project area. The rating is the suitability value assigned to a habitat for its potential to support a particular species for a specified season and activity. It is often expressed as a percentage of the best habitat. It also reflects the species' expected use of a habitat (Resources Inventory Committee 1999c). Habitat ratings are a product of knowledge and assumptions.

The important role of vegetation is incorporated into any wildlife habitat evaluation. Biophysical factors which are considered to influence wildlife habitats can include vegetation type, slope, aspect, and other geographic features. Since vegetation cover type is an expression of various biophysical conditions such as soil moisture, aspect, and relief, it generally offers a current and valid prediction of habitat for many terrestrial wildlife species, at least at broad scales.

The wildlife habitat evaluation is essentially a modelling process that has two primary requirements:

1. Good knowledge of the habitat needs of a species, and how these habitat needs relate to the described ecosystem units; and
2. A standard approach to establishing wildlife species-habitat relationships and ratings for ecosystem units consistently.

The suitability maps use ecosystem attributes for assigning suitability values to a polygon. Wildlife habitat suitability ratings are a widely applicable method of wildlife habitat assessments. While there are recognized limitations to any habitat evaluation and assessment procedure, suitability ratings using ecosystem unit classification have the following advantages (Resources Inventory Committee 1999c):

1. It is predictive.
2. The methodology is consistent.
3. Large areas can be covered.
4. It is flexible and can be applied to a range of map scales, wildlife species, and general to detailed habitat assessments.
5. It provides strategic planning for habitat management.
6. It ties the wildlife resource to other resource uses (e.g., forestry, recreation, and corridor analyses).

The results of this type of model can provide information on the suitability, amount and distribution of potential moose foraging habitat within the RSA.

5.3 METHODS

The moose habitat suitability model was based on habitat suitability mapping standards and methodology (Resources Inventory Committee 1999c). This methodology is commonly used in habitat assessment. The habitat suitability methodology involves three key steps:

1. Selection of relevant habitat variables to include in the model.
2. Development of rating scores for each habitat variable.
3. Building a relationship among the variables to produce overall habitat suitability scores.

A moose winter forage habitat suitability model was developed based on professional opinion and the availability of suitable datasets. Land cover datasets (vegetation, linear disturbances, and fire history) were considered for the suitability modelling. Other variables were considered but not included in the model. They were assumed to correlate with the vegetation cover types and associated structural stages.

5.3.1 RATING SCHEME

This model uses a categorical rating scheme where each category represents an ordinal measure of habitat suitability. The number of categories used in a rating scheme reflects knowledge of the species' ecology and habitat use (Resources Inventory Committee 1999c). For species like moose, where our understanding of the

species and the availability of relevant base environmental data to support habitat modelling is relatively good, 4- and 6-class schemes are typically used. A 6-class system was initially chosen to rank the base habitat units because the 6-class system facilitated finer differentiation of ratings across the numerous habitat types that occur in the RSA (Table 5-2). However, for interpretive purposes, the ratings were generalized into a 4-class system for most model outputs. In the 4-class system, High and Moderately-High were combined into one category (High) and Nil and Very Low were combined into one category (Nil/Very Low).

High and Moderately High suitability habitat provides some of the best winter foraging opportunities for moose within the RSA. Moderate suitability habitat provides some winter foraging opportunities. Low and very low-quality habitat has limited winter foraging opportunities for moose in the RSA. Nil suitability habitat provides no winter foraging opportunities. It is often associated with features without vegetation (e.g., rivers, streams, roads) or with very sparse vegetation cover.

Within the RSA, the highest rated areas included natural shrublands and regenerating burns in riparian areas, as well as small extents of deciduous and mixed-wood ecosystems on mesic and moist sites. Moderate rated areas were predominantly regenerating burns on mesic to wet sites. Low rated sites were mostly undisturbed stands of open, stunted spruce on mesic to wet sites, ranging from tall shrub to old forest structural stages. Differentiating ratings between Moderate and Low areas was often difficult. Many sites, both burned and unburned, had average willow cover less than 15%, with high variation in cover among sites in the same ecosystem units. Generally, 7% willow cover was used as the threshold to differentiate between Moderate and Low sites. This is a relatively low value of willow cover but using a higher threshold would have resulted in large areas of regenerating burn being classified the same (Low) as undisturbed areas. In Eagle Plains, a substantial amount of total winter forage appears to occur within large areas with relatively low willow cover (i.e., the Moderate suitability areas).

Although the vegetation field data confirmed that the amount of shrubby browse (i.e., willow cover) was greater in fire disturbed areas than undisturbed areas, the amount of browse in regenerating burns was not as high as reported in some other studies. For example, the percent cover of willow in burns in the most common ecosystem unit, EU33-Moist Spruce Labrador Tea, was 11% compared to 7% in unburned areas. As a result of this pattern, areas with fire disturbance attributes in the ecosystem mapping database were generally rated one class higher than the same ecosystem unit that was not burned (mostly Moderate for burns and Low for unburned areas).

Table 5-2. Rating scheme used to rate moose habitat suitability.

Rating	Code	HS Score	Description
High	1	95	Suitable. Conditions at optimal. The best foraging opportunities for moose are expected to be found in these areas of the RSA. Willow percent cover is greater than 15%. Includes both disclimax and seral shrublands areas.
Moderately High	2	75	Suitable. Conditions near optimal. Above average foraging opportunities for moose is expected to be found in these areas. Willow percent cover also typically greater than 15% but, on average, less than High.
Moderate	3	50	Suitable. Suitability is lower than optimal conditions but meet minimum requirements from an energy balance perspective. Willow percent cover generally ranges between 7% to 15%.

Rating	Code	HS Score	Description
			Although willow cover is moderate to low in absolute terms, the large extent in this rating category contributes a substantial amount of the total available forage across the RSA.
Low	4	30	Suitability Unknown. Areas in this rating class offer some forage but the amount is so low and dispersed that the energetic return of using these areas are, on average, mostly negative. Willow species present but typically less than 7% cover.
Very Low	5	10	Unsuitable. Willow species presence and cover is usually less than 2%. Moose are expected to strongly avoid these areas.
Nil	6	0	Unsuitable. Willow presence not expected.

5.3.2 SELECTION OF RELEVANT HABITAT VARIABLES

Potentially relevant foraging habitat variables were identified from published literature, other habitat models, and personal experience. A suite of different habitat variables was identified as candidates in this habitat model, based on their known importance to winter foraging ecology (Table 5-3). The variables were evaluated for inclusion based on availability in GIS database, the ecological relevance to moose in the RSA, and relationships found in other studies. Based on these criteria, ecosystem unit, structural stage data and fire disturbance, all from the ELC mapping database, were included in the moose habitat modelling. Other variables were not included in the model as they were not expected to play a major role in winter habitat use by moose or because they were correlated with one of the three selected variables.

Distance to riparian areas was considered for inclusion in the model. Riparian areas are important foraging habitats for moose (Clarke et al. 2017, McCulley et al. 2017). Within the RSA, riparian areas generally contain abundant browse species relative to the adjacent ecological units. The ELC developed ecosystem units specific to riparian habitats. The ecosystem unit data accurately represent increased habitat suitability in riparian areas found as narrow strips along most watercourse and drainages in the RSA. Therefore, a variable for distance to riparian was redundant and was not included in the model.

Elevation was considered as a variable for inclusion in the model. In winter, moose generally occur at lower elevations to minimize the energetic costs of travelling through deep snow. Moose generally start avoiding areas with >70 cm of snow and rarely occur in areas with >100 cm. However, elevation within the rolling topography of the RSA does not vary substantially (range = 343–752 masl) and was likely not a significant driver of moose distribution. Therefore, elevation was not included as a variable in the model.

Slope was considered as a variable for inclusion in the model. Moose avoid very steep slopes (i.e., generally >35 degrees). In more southerly locations, moose will select moderately steep, south aspect slopes in winter where the combination of slope and aspect reduces snow depth and favours shrubby browse cover. However, steep slopes >35 degrees do not occur in the area, and south aspect slopes do not play a significant role in snow depths at this northern latitude. Therefore, slope was not included as a variable in the model.

Linear features were considered for inclusion in the model. LFs were surveyed in the RSA as a companion study for exploration project proposal (EDI Environmental Dynamics, unpublished study). LFs that were classified as 2D had an average width of 5.4 m and, under normal succession, had greater mean shrub cover than the corresponding off-line sites. The 3D lines had narrower widths and were not as shrubby, or shrubs

were not consistent in shrub cover and species present. The few winter roads also were not consistent in available browse species. The greater shrub cover does not signify the presence of higher quality browse species such as willows. The combination of shrub species cover found within LFs, and the small extent of LF did not warrant including them as a variable in the model because these two factors would not substantially affect habitat use by moose.

Table 5-3. Summary of habitat variables commonly associated with moose habitat suitability from published literature relevant to the Regional Study Area.

Habitat Variable	Ecological Rational	Included in Model (Yes or No)
Ecosystem Unit (ELC)	Ecosystems units have specific vegetation communities associated with them and are the best predictor of winter browse species occurrence.	Yes
Structural Stage (ELC)	Moose typically select shrub structural stages or open mature forest habitats as forage habitat.	Yes
Distance to Riparian	Any shrubby feature influenced by a creek or stream was given a riparian code in the ELC. ELC data more accurately represent increased habitat quality in riparian forests than the distance to riparian	No
Elevation	Elevation can strongly affect snowpack depth, with depths >70 cm limiting winter movements by moose. The limited range in elevation within RSA (343 – 752 m), combined with average winter snowpacks just reaching critical depths for moose, is assumed to be insufficient to affect moose distribution in winter.	No
Slope	Moose avoid steep slopes (>35%) and prefer south-facing slopes. A combination of slope and aspect reduces snow depth and favors shrubby browse cover. However, steep slopes >35 degrees do not occur in the area, and south aspect slopes do not play a significant roll in snow depths at this northern latitude.	No
Fire History (ELC)	Fire may increase forage habitat quality for moose, but it is dependent on time since the disturbance and ecosystem unit. The ELC mapping accounts for the fire history by using the structural stage and a disturbance code.	Yes
Linear features	Moose may avoid linear features due to increased predation risk depending on the region. Linear features may provide foraging opportunities. Linear features within the RSA may affect habitat quality positively or negatively, dependent on ecosystem unit and time since disturbance.	No

5.3.2.1 Ecological and Landscape Classification Based Variables

Ecosystems units have specific vegetation communities associated with them and are the best predictor available of winter browse species occurrence. Moose typically select shrub structural stages or open mature forest habitats as forage habitats. The ecosystem unit and structural stage variables are based on the recently completed ELC mapping of the RSA. A summary of ELC methods and results are presented here. Refer to

the separate baseline report for more detailed information about the ELC mapping (EDI Environmental Dynamics Inc 2021).

Ecosystem Unit Variable

ELC mapping refers to an integrated approach to mapping and classifying units of land according to their ecological similarity (Environment Yukon 2016a). ELC mapping aims to provide information on the biological and physical characteristics of various landscape components to facilitate a range of interpretations and assist in sustainable management (Rowe and Sheard 1981, Environment Yukon 2016a). For example, defining ecosystem units (i.e., ecosites, ecological communities) with similar vegetation, site and soil characteristics can provide information on the current condition of vegetation, can facilitate the development of vegetation mitigation measures during infrastructure development and aid in assessing habitat suitability for wildlife across a landscape.

To best meet the needs of the Project, a manual ELC mapping approach was completed, where mappers examine and interpret digital ortho-imagery to delineate and attribute polygons with ecological information manually. Using existing GIS datasets, this method typically provides a higher level of detail and accuracy than predictive modelling approaches. The mapping and classification methodology conforms to the Yukon Ecological and Landscape Classification and Mapping Guidelines, Version 1.0 (Environment Yukon 2016a), and the Standard for Terrestrial Ecosystem Mapping in British Columbia (Resources Inventory Committee 1998b) were used as guidelines.

To complete the ELC mapping of the RSA, new broad-ecosystem classification units were developed that had similar floristic composition and clearly interpretable ecological context in terms of site-scale climate, landscape position, substrate, hydrology conditions, and moisture and nutrient regimes. The goal was to develop Project-specific ecosystem units representing the range of ecological communities within the RSA while being reliably and repeatedly identifiable from a mapping perspective. The final ELC system used for the Project merged the methodology outlined by the YBEC system with aspects of the BEC system used in BC and referenced some of the existing units.

The most common ecosystem unit mapped in the RSA is Moist Spruce – Labrador Tea (Code 33) (44%) followed by Moist Spruce – Alder – Labrador Tea (Code 34) (12%) and Mesic Black Spruce – Alaska Paper Birch (Code 04) (9%) (Table 5-4). The least common (0%) ecosystem units mapped in the RSA are Dry Sparsely Vegetation (Code 10) and Mesic Birch – Willow (Code 02), and Moist Birch – Willow (Code 36). Both Birch – Willow ecosystem units are influenced by anthropogenic disturbances. Other less common ecosystem units that occur more naturally are Dry Aspen (Code 17), Mesic White Spruce – Alaska Paper Birch – Alder (Code 03), and Wet Shrub Scrub Birch – Graminoid (Code 45).

Table 5-4. Ecosystem units mapped in the Eagle Plains RSA.

Code	Name	Total Area (ha)	% of RSA	Average percent cover of *Salix* sp.
10	Sparsely Vegetated	2.6	0.0	No data
14	Dry Spruce-Lichen (Conifer)	1,826.5	0.8	5.3%
15	Dry Aspen-Lichen (Deciduous)	280.8	0.1	No data
16	Dry Spruce-Birch-Lichen (Mixedwood)	2,103.6	0.9	4.5%
17	Dry Aspen (Deciduous)	80.1	0.0	No data
02	Mesic Birch - Willow	90.5	0.0	22.0%
03	Mesic White Spruce – Alaska Paper Birch – Alder	98.3	0.0	No data
04	Mesic Black Spruce – Alaska Paper Birch (Mixedwood)	21,150.0	8.9	4.6%
05	Mesic Alaska Paper Birch (Deciduous)	11,496.0	4.8	12.5%
06	Mesic Black Spruce – Labrador Tea (Conifer)	7,463.5	3.1	12.2%
20	Shrubby Riparian Birch – Willow	860.2	0.4	27.6%
21	Riparian White Spruce – Prickly Rose	192.1	0.1	12.0%
22	Riparian Spruce – Birch - Willow	674.4	0.3	15.3%
23	Drainage Shrubby Riparian	4,454.2	1.9	57.0%
31	Moist Shrub \ Scrub Birch – Labrador Tea – Willow	9,129.9	3.8	14.2%
33	Moist Spruce – Labrador Tea	103,696.5	43.5	6.6%
34	Moist Spruce – Alder – Labrador Tea	27,428.6	11.5	6.0%
35	Moist Spruce – Scrub birch – Labrador Tea	12,163.3	5.1	5.5%
36	Moist Birch – Willow	33.4	0.0	39.0%
41	Wet Shrub – Tamarack	177.3	0.1	1.7%
42	Wet Shrub – Black Spruce – Tussock Cottongrass	14,517.0	6.1	4.3%
43	Wet Shrub – Black Spruce - Sphagnum	3,315.6	1.4	5.6%
44	Wet Shrub – Scrub Birch – Tussock Cottongrass	6,844.7	2.9	8.3%
45	Wet Shrub – Scrub Birch – Graminoid	98.7	0.0	10.0%
46	Wet Black Spruce – Labrador Tea – Cladonia	2,498.0	1.0	7.0%
47	Wet Black Spruce – Tussock Cottongrass – Sphagnum	4,232.3	1.8	4.0%
48	Wet Black Spruce – Carex	196.6	0.1	14.0%
B1	Bog – Black spruce – Lichen	764.7	0.3	0.0%
B2	Bog – Black Spruce – Sphagnum	1,960.9	0.8	2.0%

Code	Name	Total Area (ha)	% of RSA	Average percent cover of *Salix* sp.
F	Fen	42.5	0.0	9.0%

RI	River	457.1	0.2	0
RZ	Road	58.9	0.0	0
	Total Area	238,640		

Structural Stage Variable

Within the ELC database, the structural stage attribute (Table 5-5) describes the appearance of a stand or vegetation community and defined by the codes and criteria listed in the Field Manual for Describing Yukon Ecosystems (Environment Yukon 2017).

Most of the RSA is mapped in a Shrub structural stage (74%), with 45% of the RSA in a Low Shrub structural stage (Table 5-5). Approximately 1% of the RSA is in an Old Forest structural stage, and 21% is in a Mature Forest structural stage.

Table 5-5. Structural stages mapped in the Eagle Plains RSA.

Code	Structural Stage	Criteria	Area (ha)	% of RSA
1	Non-vegetated	No vegetation or less than 5% established vegetation, often due to recent disturbance (e.g., placer mining) or unvegetated rock.	8.0	0
2	Sparse / cryptogram	Either the initial stages of primary and secondary succession or a cryptogram community maintained by environmental conditions; sparsely vegetated or dominated by bryophytes and lichens; may be prolonged where there is little or no soil development (e.g., bedrock).	76.9	0.03
2a	Sparse (5–10% vegetation cover)	5–10% vegetation cover.	2.6	0
2b	Bryoid	Bryophyte-dominated	0	0
2c	Lichen	Lichen-dominated	0	0

Code	Structural Stage	Criteria	Area (ha)	% of RSA
3	Herb	Early successional stage or herbaceous communities maintained by environmental conditions or disturbance (e.g., wetlands, post-fire forest succession); herb dominated, including forbs, graminoids and ferns; some invading or residual shrubs and trees may be present but are usually sparse or absent; many herbaceous communities are continually maintained in this stage.	7.8	0
3a	Forb - dominated	Herbaceous communities dominated (greater than 1/2 of the total herb cover) by non-graminoid herbs, including ferns.	0	0
3b	Graminoid – dominated	Herbaceous communities dominated (greater than 1/2 of the total herb cover) by grasses, sedges, reeds and rushes.	161.1	0.07
3c	Aquatic	Herbaceous communities dominated (greater than 1/2 of the total herb cover) by floating or submerged aquatic plants; does not include sedges growing in marshes with standing water.	0	0
3d	Dwarf shrub	Communities dominated (greater than 1/2 of the total herb cover) by dwarf woody species, such as kinnikinnick or dwarf willows.	0	0
4	Shrub	Early successional stage or shrub communities maintained by environmental conditions or disturbance (e.g., wetlands, flooding, post-fire forest succession); dominated by shrubby vegetation; either dominated by shrubby vegetation, including tree seedlings/saplings, or if sparsely vegetated overall, the dominance of shrubs characterizes the community as a shrubland. This may include sites where trees are stunted due to the presence of permafrost, preventing the stand from reaching a higher structural stage.	10,196.7	4.3
4a	Tall shrub	Communities dominated by tall shrub layer vegetation - woody plants > 2m tall and ≤ 7 cm dbh; may be a successional stage or may be in this stage perpetually due to environmental conditions or disturbance.	57,934.3	24.3
4b	Low shrub	Communities dominated by low shrub layer vegetation - woody plants < 2m tall; may be a successional stage or may be in this stage perpetually due to environmental conditions or disturbance.	107,861.2	45.2
5	Pole sapling	Trees > 5m tall and > 7 cm dbh, typically densely stocked. Self-thinning and vertical structure are not yet evident in the canopy. Younger stands are vigorous (usually > 15–20 years old); older stagnated stands (up to 100 years old) are also included; time since disturbance usually < 40 years; up to 100+ years for dense (5000 – 15000+ stems per ha) stagnant stands.	554.8	0.2
6	Young Forest	Self-thinning has become evident, and the forest canopy has begun to differentiate into distinct layers. A more open stand than the pole/sapling stage.	8,322.6	3.5

Code	Structural Stage	Criteria	Area (ha)	% of RSA
7	Mature Forest	Trees established after the last stand-replacing disturbance have matured; a second cycle of shade tolerant trees may have become established; shrub and herb understories become well developed as the canopy opens up.	50,518.9	21.2
8	Old Forest	Stands of old age with complex structure; patchy shrub and herb understories are typical; regeneration is usually of shade-tolerant species with composition similar to the overstory. Fire maintained stands may have a 'single-storied' appearance. Very old stands having complex structure with abundant large-sized trees, snags and CWD; snags and CWD occurring in all stages of decomposition; stands are comprised entirely of shade-tolerant overstory species with well-established canopy gaps.	2,302.7	1.0
n/a	Not Applicable (River, etc.)		692.4	0.3
	Total RSA		**238,640**	

5.3.2.2 Fire History

Fire disturbance was considered as a variable in the model. Numerous studies in boreal and sub-boreal regions have found that moose select areas regenerating from fires. Recent burns and post-fire clearings are generally considered optimal foraging habitat for moose. Forest fires are a significant component of the landscape ecology of the Eagle Plains Ecoregion. Typically, regenerating burns contain higher cover of shrubby browse species than undisturbed areas. This includes both deciduous shrubs like willow, as well as sapling deciduous trees like aspen and paper birch. Although burns are classified as Low and Tall Shrub in the ELC, structural stage alone does not uniquely identify them. Large extents of disclimax, stunted black and white spruce ecosystem unit types were also classified as Tall Shrub.

Numerous studies and data from the ELC mapping, indicate that fire disturbance results in increased shrubby browse cover during the Low and Tall Shrub structural stages of regeneration, and that regenerating burns are selected by moose in winter. Therefore, fire disturbance was included in the model.

5.3.3 WILDLIFE HABITAT RATINGS

Qualitative, categorical habitat suitability ratings were developed for each combination of ecosystem unit and structural stage in a lookup table format. For the Shrub structural stages separate ratings were provided depending on whether the area was recently burned or not. The difference in the amount of browse cover was minimal in other structural stages according to burn status and burned and unburned areas were rated equivalently. The development of ratings was based on expert opinion and primarily by the following assumptions:

- Winter habitat suitability is primarily driven by the amount of shrubby browse species that are predicted to occur and especially the percent cover of willow species. The average percent cover

of willow species by ecosystem unit per structural stage was calculated using vegetation data collected during baseline surveys (Section 5.6.1).

- Low shrub structural stages, including disclimax shrublands (wetlands and shrubby drainages) and regenerating burns, generally offer the highest value forage and are generally rated High.
- The suitability of tall shrub areas depends on disturbance status. Tall shrub areas regenerating from fire disturbance are also rated Moderate (mostly) to High, depending on the ecosystem unit. However, Tall shrub stages also include extensive areas of disclimax stunted spruce (including multiple EUs) that generally offer low to moderate browse species, which are rated accordingly.
- Older structural stages (5–8) can have similar browse and are mostly rated depending on the EU (Table 5-4). On average stage 7 and 8 tend to have slightly more browse than stages 5 and 6.

Every combination of ecosystem unit and structural stage was assigned in initial habitat suitability score based on a 6-class rating scheme (Table 5-6). If there was no structural stage listed for an ecosystem unit, it received a rating of 6 (Nil) for moose winter forage.

The extent of areas with high cover of preferred browse species (mostly willow) is limited in the RSA. The ecosystem unit by structural stage combinations with >15% willow cover was generally rated High (1) and Moderately High (2) and account for only 12% of the extent in the RSA (Photo 5-5 to Photo 5-9). Large extents of the RSA have relatively low willow cover of 5–15% and were rated as Moderate (3) and Low (4) (Photo 5-10 to Photo 5-14). Differentiating the classifications between Low and Moderate was difficult because the differences in willow presence among different sites were not consistent, and variation in willow cover within the same site type was large (i.e., resulting in overlapping confidence intervals across sites). The basis for classifying sites as Low or Moderate considered (i) average cover of willow from field plots (>7% favouring classification to Moderate), (ii) fire history (fire disturbance within 40 years favouring classification to Moderate), and (iii) a qualitative assessment of the potential for each EU and structural stage combination to support willow and other browse species.

Although Moderate and Low rated habitats have relatively low cover of willow in an absolute sense, they likely provide a substantial proportion of total winter forage for moose in the RSA due to the large extents that Moderate and Low suitability habitats cover. That is, in Eagle Plains the overall, total availability of winter forage for moose appears to be distributed in relatively low levels across large portions of the RSA, versus being concentrated in relatively small portions of the landscape, which is typical in more mountainous portions of Yukon.

Overall, EUs in sparsely vegetated or herbaceous structural stages, non-vegetated EUs and certain wetland EUs were assigned Very Low (5) or Nil (6) ratings unless the presence of willow cover was observed (Photo 5-15 and Photo 5-16).

The effect of fire disturbance in boreal ecosystems in enhancing moose browse as the stand regenerates through the low shrub and tall shrub structural stages are well documented. Although evidence of this was observed in Eagle Plains, the degree to which regenerating burns resulted in an elevated cover of browse

species was somewhat muted compared to values reported in other studies. For example, for the most extensive EU, Moist Spruce-Labrador Tea (code 33) (comprising 43% of the RSA), the average percent cover of willow was 11% in burns compared to 6% in unburned areas (Photo 5-11 and Photo 5-12). Similar patterns were evident for most other moist and wet EUs. On average, fire disturbance resulted in a modest increase in willow cover. As a result, areas with fire disturbance within the last 40 years were generally rated one class higher than unburned areas. Most frequently, this resulted in a rating change from Low to Moderate.

Photo 5-16. Low shrub – bog – black spruce – lichen habitat (code B1) rated as very low moose winter forage.

5.3.4 MODEL STRUCTURE

In the ELC map, each polygon contains up to three components. For example, a polygon could contain 80% EU34-Moist Spruce – Alder – Labrador Tea and 20% EU22-Shrubby Riparian Birch – Willow. These composite polygons occur because the pattern of ecosystem distribution occurs as a set of small patches that are too small to map as separate individual polygons. To account for this issue of composite polygons, habitat ratings were applied in two ways (1) an area weighted average of the habitat suitability scores for the components within each polygon, and (2) the proportion of High suitability habitat in each polygon.

The area-weighted average score was calculated using the habitat suitability scores from Table 5-2 and the decile proportion for each polygon component, following equation:

$$ELC_r = \frac{\sum_{i=1}^{n} w_i X_i}{\sum_{i=1}^{n} w_i}$$

Where ELC_r is the weighted average score, w_i is the decile proportion for each polygon component, and X_i is the habitat rating for each polygon component from Table 5-2. An example is provided in Table 5-7 for a polygon with two components:

Although this weighted average approach is a good approach for summarizing average habitat suitability across the study area, it has the disadvantage that, with the averaging process, you lose track of the occurrence of small extents of High suitability areas. This issue is addressed in the second version of model outputs, mapping the proportion of High suitability habitats within each polygon.

The two types of outputs compliment each other for assessment and management at different scales. The weighted average output is intended to be used for strategic assessments and planning, such as assessing the overall effects of the Project on moose habitat, or to compare the relative suitability of moose habitat in one sub-watershed to another. The proportion of High suitability habitat can be used to support finer-scale operational measures, such as locating roads and well sites to avoid high suitability winter moose habitat.

Although the initial habitat ratings for each ecosystem unit/structural stage/fire disturbance combination used a 6-class rating scheme, the composite ratings of the ELC polygon scores were generalized to a 4-class system for simpler interpretation, essentially combining Moderately High and High, and Nil and Very Low.

Due to the small size of many of the High and Moderately High habitats areas, they were frequently formed the second or third component of composite ELC polygons. Consequently, these areas of High were often 'lost' when calculating the weighted average rating for the polygon (i.e., the polygon they were in ended up being rated Moderate or even Low overall). To account for this issue, the amount and location of High and Moderately High areas were examined separately from the polygon weighted average score. This was done by mapping the amount of High and Moderately High areas in each polygon. For example, a polygon with a weighted average habitat score of Low, might contain 20% High+Moderately High.

Table 5-7. An example of a multiple component polygon habitat scoring.

Component	Proportion	Ecosystem Unit	Structural stage	Burn Status	Habitat Score
1	0.8	Moist Spruce – Alder – Labrador Tea	Tall Shrub	Not Burnt	30
2	0.2	Shrubby Riparian Birch – Willow	Low Shrub	Not Burnt	95

ELCr = 0.8*30 + 0.2*95 = 43, which corresponds to an overall categorical rating of Low

5.4 RESULTS AND DISCUSSION

The amounts of predicted moose winter habitat in the RSA are presented for the finer-scale 6-class rating scheme before averaging scores within ELC polygons in Table 5-8, and the consolidated 4-class rating scheme after averaging scores within ELC polygons, in Table 5-9. As mentioned in the Methods, the 4-class scheme essentially combines the High and Moderately High classes and the Nil and Very Low from the 6-class scheme. The 6-class scheme was originally used because it was assumed that there would be greater amounts of areas in the high and low ends of the habitat suitability gradient. However, since the amounts of highest and lowest suitability habitat are so low (i.e., 2.5% High and 0.4% Nil) it makes sense to use the 4-class scheme from this point forward.

The model results indicate that High-suitability winter moose habitat (12%) is limited, and that the remaining area is approximately split between Moderate and Low, with Nil/Very Low areas only accounting for approximately 1% of the RSA. The distribution of winter moose habitat shows clear spatial patterns across the RSA, when examining the average habitat suitability scores across ELC polygons (Map 5-1) and the percent of High-suitability habitats occurring in each polygon (Map 5-2 and Map 5-3). In the map of the average suitability scores (Map 5-1), areas of Moderate suitability are concentrated in the southern half and along the western and northern boundary in the northern portion of the RSA. These areas often correspond to regenerating burns. In the northern half of the RSA, much of the Chance Creek watershed is rated Low, corresponding to a lack of fire disturbance and dominance of open canopy, stunted spruce ecosystems, which offer limited browse for moose. High-suitability winter habitat is found scattered across the RSA, generally in much smaller patches than areas of Moderate and Low. High suitability areas are often in narrow riparian strips along streams and non-confined drainage areas (Map 5-2), but also includes certain deciduous and mixed-wood ecosystem units, like the Mesic Alaska Paper Birch (code 05), which accounts for the concentration of High suitability habitats in the northwest portion of Map 5-3.

This pattern of having a relatively large portion of the landscape in Moderate suitability winter habitat is different than occurs in other parts of Yukon, especially in more mountainous areas, where suitable winter habitat (i.e., High and Moderate suitability) are often constrained by elevation, snow depths and greater distribution of diverse vegetation communities (McCulley et al. 2017). In Eagle Plains, a substantial amount (74%) of the RSA is in a shrub structural stage mostly dominated by scrub birch and Labrador tea and almost half (44%) of the RSA is described as the Moist Spruce – Labrador tea ecological unit which are large areas with relatively low willow cover (i.e., the Moderate suitability areas).

The pattern of winter habitat across the RSA is likely to affect the broad distribution of moose. Due to the scattered occurrence of High suitability habitat across the RSA, some moose are expected to occur across the RSA. However, local densities are likely to be vary in relation to the portions of Low and Moderate that form the matrix of habitat at a larger scale. Where most of the habitat matrix is Low, such as across most of the Chance watershed, moose densities are expected to be relatively low and habitat use is expected to be largely constrained to the scattered patches of High. Where most of the habitat matrix is Moderate, such as the southern half of the RSA, moose densities are expected to be substantially higher; and, although moose use is

expected to still be relatively higher in the High habitats, considerable use of the Moderate suitability matrix is also expected.

Table 5-8. Estimated amounts of moose winter forage habitat across the Eagle Plains RSA using a 6-class rating scheme.

Habitat Rating	Area (ha)	Area (% of RSA)
High	5,961.9	2.5%
Moderately High	23,736.7	9.9%
Moderate	111,561.7	46.7%
Low	94,068.2	39.4%
Very Low	2,492.4	1.0%
Nil	842.6	0.4%
Total Area	238,663.5	100%

Table 5-9. Estimated amounts of moose winter forage habitat across Eagle Plains RSA averaging suitability scores within ELC polygons and generalizing to a 4-class rating scheme.

Average Habitat Suitability	Area (ha)	Area (% of RSA)
High	16,944.4	7.10%
Moderate	145,394.1	60.92%
Low	74,514.5	31.22%
Nil/Very Low	1,810.5	0.76%
Total	238,663.5	100%

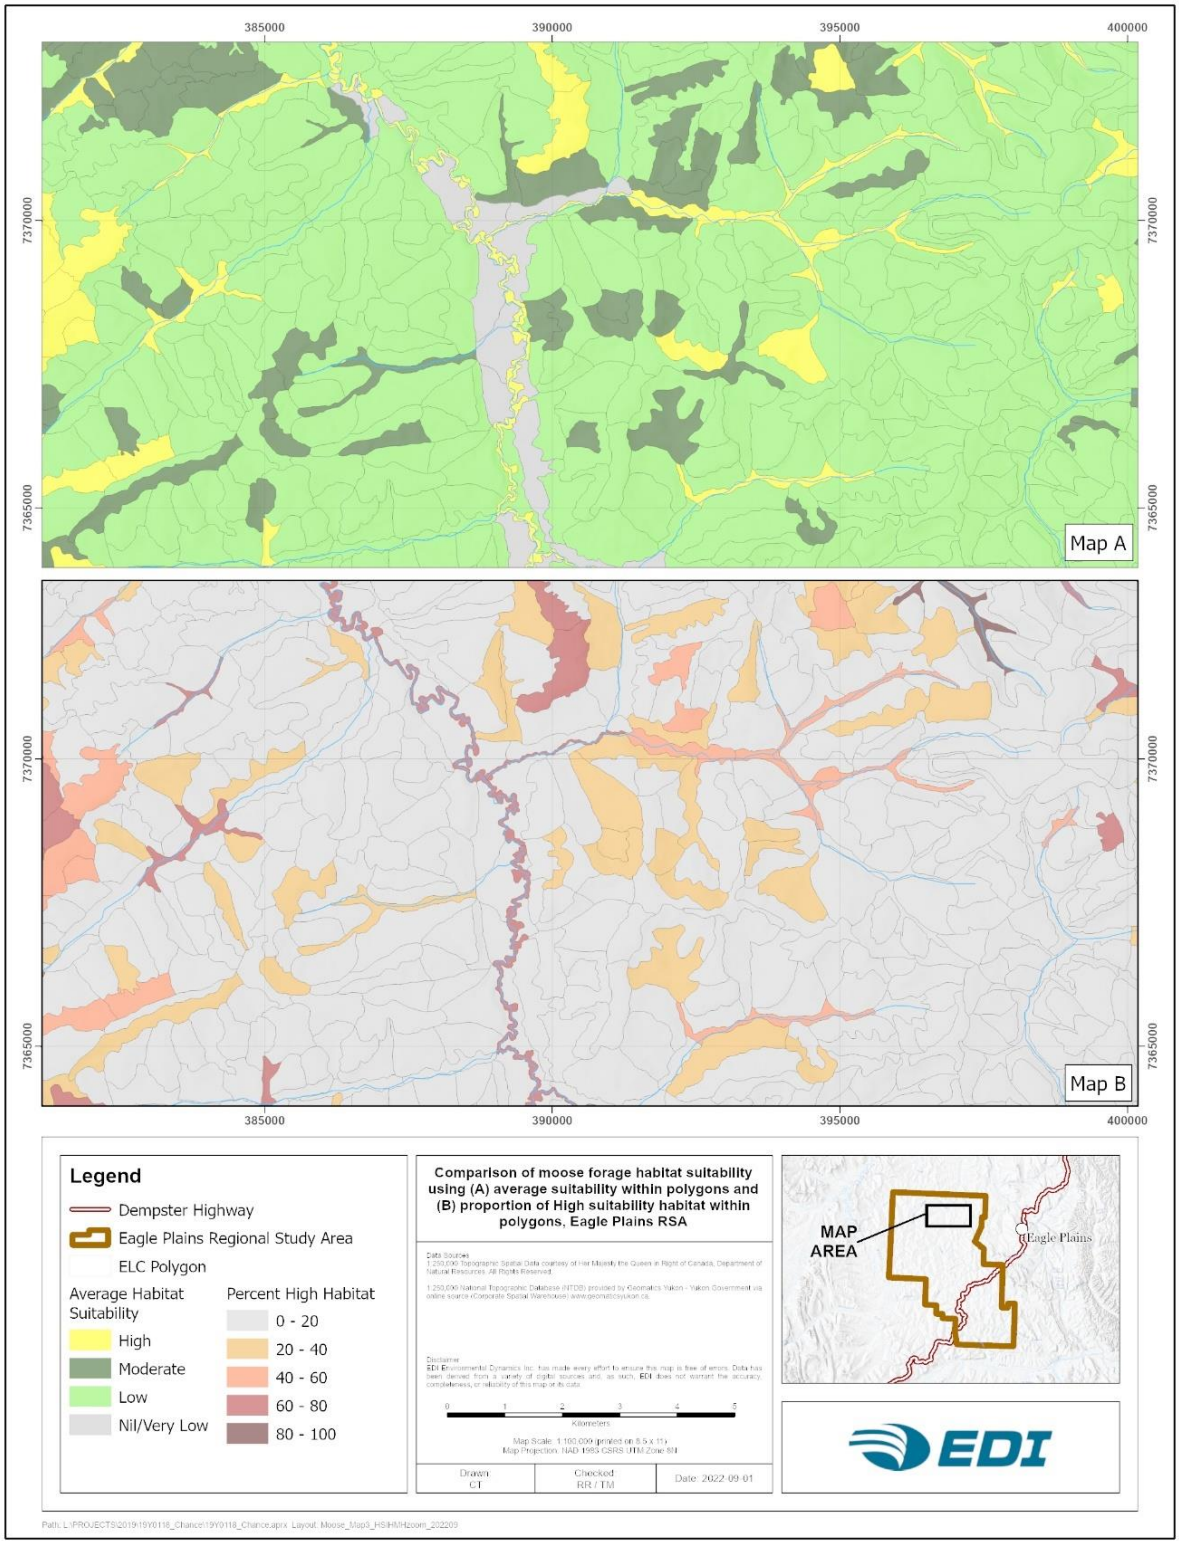
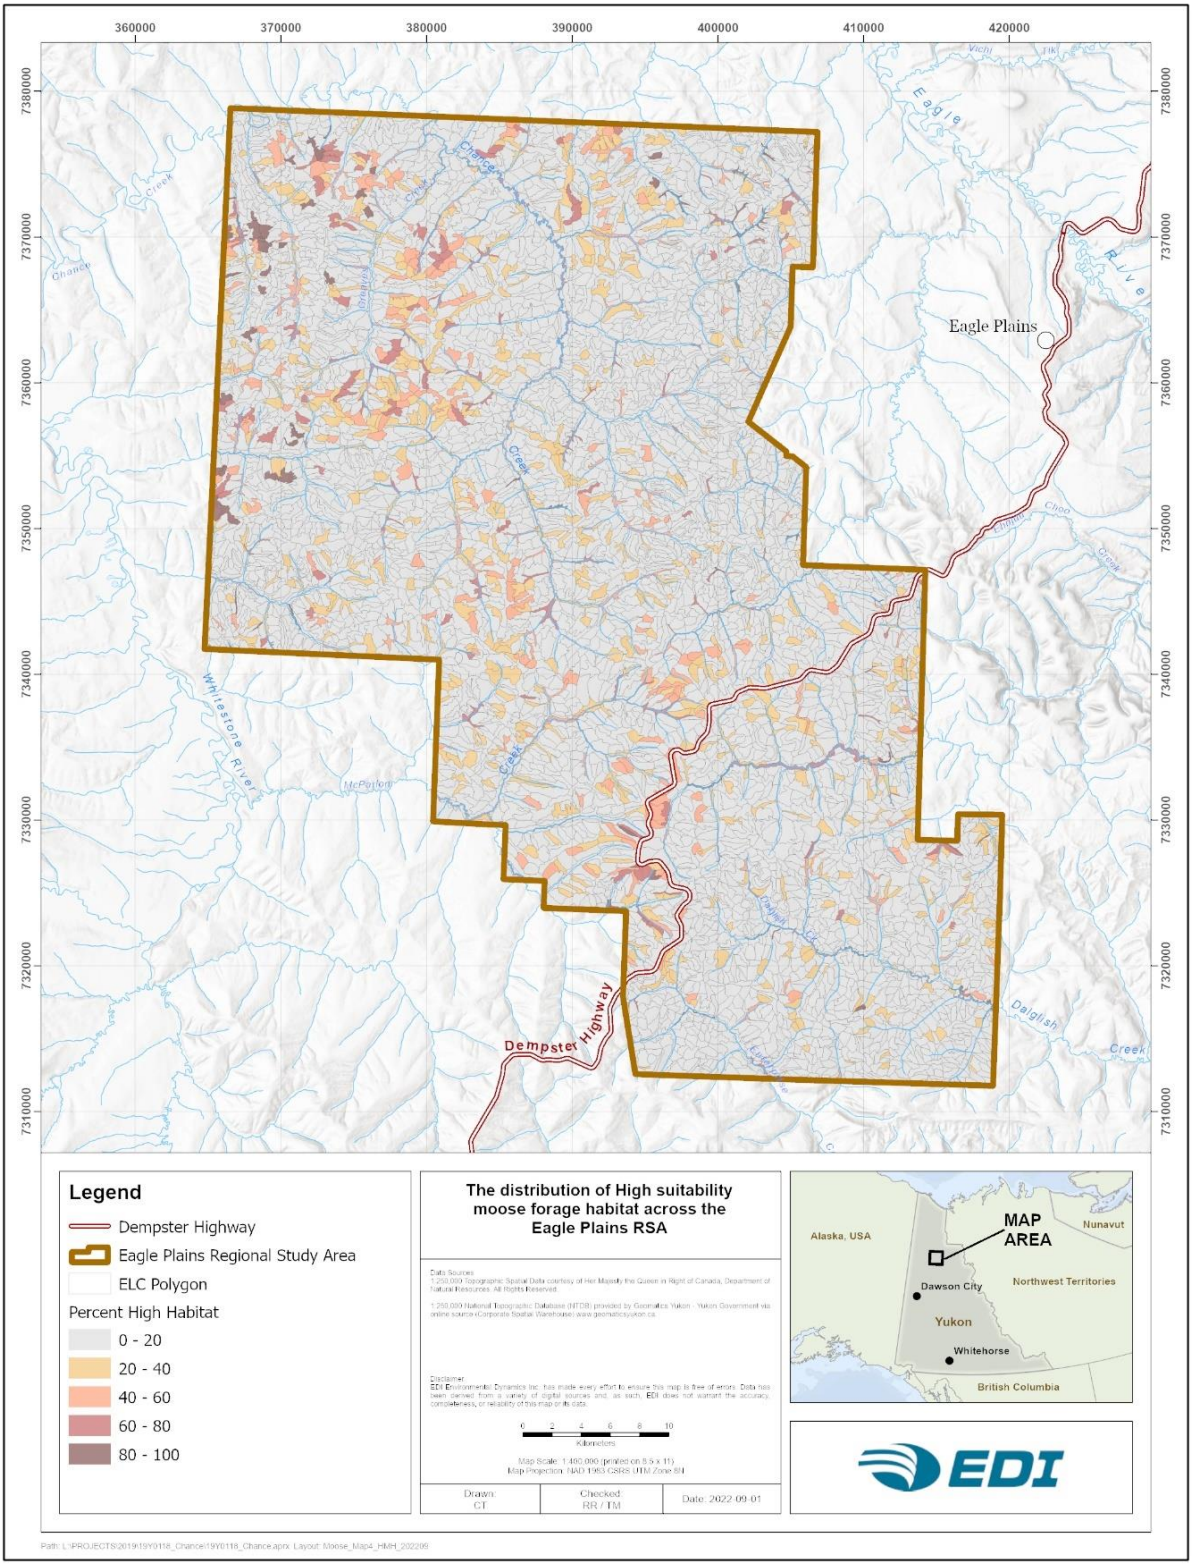


Map 5-2. Comparison of moose forage habitat suitability using (A) average suitability within polygons and (B) proportion of High suitability habitat within polygons, Eagle Plains RSA.



Map 5-3. The distribution of High suitability moose forage habitat across the Eagle Plains RSA.

5.5 SUMMARY

The suitability, amount, and distribution of potential habitat for moose were quantified across the RSA using a habitat suitability model. The habitat model was for foraging habitat during winter because this life requisite and season are believed to be the most limiting to moose in the RSA. The model consisted of qualitative ratings applied to combinations of three variables from the ELC mapping: ecosystem unit, structural stage and fire disturbance. High suitability habitats consisted of disclimax shrublands, most commonly associated with riparian areas. Moderate suitability habitats were dominated by regenerating burns but also included small areas of mixed and deciduous forests with shrubby understories. Low suitability habitats were mostly open canopy, stunted spruce forests. High-suitability moose winter foraging habitat is limited across the RSA (12%), but Moderate habitat is extensive (43%). Although moose are expected to select the High-suitability areas preferentially, a substantial amount of total winter forage appears to occur within large areas with relatively low willow cover (i.e., the Moderate suitability areas). Due to the scattered occurrence of High-suitability habitat across the RSA, some moose are expected to occur across the RSA in winter. However, local densities are likely to vary with the portions of Low and Moderate habitats that form the habitat matrix at a larger scale.

6 CARIBOU

The Porcupine Caribou Technical Committee (PCTC) provided telemetry data and seasonal range polygons for the Porcupine Caribou Herd (PCH). Technical discussions and feedback provided by the PCTC also helped align subsequent analyses conducted in this section. This section and much of the technical content reflect responses to their detailed technical review.

6.1 PURPOSE AND OBJECTIVES

Caribou were selected as a VC for the Project due to their importance to the Gwich'in people for subsistence hunting and their cultural and ecological values. The Project occurs exclusively within the range of the PCH, which is a subpopulation of the barren-ground subspecies of caribou (*Rangifer tarandus groenlandicus*). Within the North Yukon Land Use Plan, the PCH is considered "the most significant and culturally important wildlife resource in the planning region" (Vuntut Gwitchin Government and Yukon Government 2009). The herd has been the mainstay of Gwich'in culture for centuries. It is considered a keystone species whose presence or absence influences the composition and dynamics of the wildlife communities and ecosystems in North Yukon. The PCH is a migratory herd with an extensive annual range that spans most of North Yukon and a large area in north-eastern Alaska. The PCH overlaps the Project area primarily during the rut/late fall and winter seasons.

This section summarizes existing information about the ecology of the PCH, and, using telemetry data and analysis outputs to: i) Quantify the degree of seasonal range overlap by the PCH with the RSA during fall and winter, when seasonal range use overlaps the RSA; ii) Quantify habitat use patterns and selection by the PCH during fall and winter; iii) Quantify movement rates and residency periods of the PCH during fall and winter; and, iv) Quantify the potential effects of linear features on the occurrence and movements of the PCH.

6.1.1 SPATIAL BOUNDARIES

Three spatial extents were considered as part of this study:

- The Eagle Plains Project RSA (2,386 km²)
- The Eagle Plains Ecoregion (20,400 km²), and
- The Yukon portion of the PCH's rut and late fall and winter seasonal ranges (65,000 km² and 58,000 km², respectively).

The Eagle Plains Project RSA includes all proposed exploration areas. The RSA has relatively similar patterns of vegetation communities and historical exploration disturbances across it. The Eagle Plains Ecoregion (see Section 1.3) encompasses the Project RSA and provides an ecologically similar area, beyond the proposed exploration areas, that allows certain comparisons between the RSA and adjacent undisturbed areas (e.g., habitat distribution and within-season movement patterns).

The Yukon portion of the PCH's fall and winter seasonal ranges is the largest extent and covers much of North Yukon. This area occurs predominantly within the Taiga Cordillera Ecozone. This Ecozone covers most of the northern Yukon and the southwest corner of the NWT. The Taiga Cordillera includes mountainous areas (e.g., British Mountains, Richardson Mountains, and North Ogilvie Mountains) separated by subdued basins (e.g., Eagle Plains, Old Crow Flats, and Old Crow Basin). The area consists of glaciated and unglaciated terrain and continuous permafrost. The climate in the Taiga Cordillera is variable from its northern to southern extent, with summers ranging from cool to warm with extended periods of daylight, while winters are generally long, cold, and dark. The vegetation in the taiga is dominated by stunted, open spruce forests, which result from short, cool growing seasons, and poor soils over permafrost (Ecological Stratification Working Group 1995). This extent was used to reference spatially broad questions, such as the PCH's seasonal distribution and movement patterns.

6.2 GENERAL ECOLOGY OF THE PORCUPINE CARIBOU HERD

6.2.1 CONSERVATION STATUS

The PCH is a subpopulation of barren-ground caribou in Canada, known for large aggregations of individuals, dramatic population fluctuations, lengthy migrations, and significant cultural and social value to northern Indigenous peoples and other Canadians (COSEWIC 2016). All caribou belong to one species, *Rangifer tarandus*. Within Canada, caribou populations are classified within 12 "Designatable Units" based on a suite of biological, genetic, and evolutionary traits (COSEWIC 2011). All 14–15 subpopulations of barren-ground caribou are considered part of one Designatable Unit (DU 3). Barren-ground caribou were assessed as Threatened by COSEWIC (COSEWIC 2016). The subspecies is not listed on Schedule 1 of the federal SARA. Within Yukon, barren-ground caribou are considered Vulnerable/Apparently Secure (Yukon Government 2020).

6.2.2 SEASONAL RANGES AND MOVEMENTS

Like most barren-ground caribou subpopulations, the PCH has a large annual range and makes long-distance migrations, hundreds or thousands of kilometres, among different seasonal ranges. Often, seasonal ranges vary across and within years in response to variation in forage availability, snow cover, and predation or parasite risk (Russell et al. 1993). The PCH's annual range extends approximately 250,000 km² from Alaska, through Yukon, and into the western edge of NWT. The herd undertakes long-distance migrations across seasonal ranges necessary for key aspects of their life cycle. Eight (8) primary life cycle periods occur for the PCH (Porcupine Caribou Technical Committee 1993). Key information for the eight periods are summarized in Table 6-1 (using information from Russell et al. 1993, Porcupine Caribou Technical Committee 1993, Ryder et al. 2007). The Porcupine Caribou Technical Committee (1993) assessed the relative importance of seasonal ranges using six criteria: energy balance, reproductive contribution, tolerance to disturbance, escape requirements, the intensity of use, and whether alternative habitats are available. Although all seasons are important to meeting the annual life requisites of the PCH, the calving and post-calving seasons are considered

of highest importance and fall and winter are considered of lowest importance (Porcupine Caribou Technical Committee 1993).

Key information associated with each of the eight seasons is provided below, elaborating on summary information in Table 6-1, and including a combination of scientific knowledge (Russell et al. 1993, Porcupine Caribou Technical Committee 1993, Ryder et al. 2007) and traditional ecological knowledge (Sherry and Vuntut Gwitchin First Nation 1999, Ryder et al. 2007). Typical patterns of seasonal range use are shown in Map 6-1. After calving on the north slope and Arctic coastal plains, the PCH typically splits in two, with portions of the herd moving southwest in Alaska and southeast in Yukon. Animals in the Yukon typically follow a clockwise movement through the seasonal ranges from the calving grounds on the north slope, to the British Mountains in summer, to the Richardson Mountains in late summer, dispersing widely and variably across northern Yukon (as far south as the Ogilvie Mountains) in fall and winter, before returning north to the coastal plains in spring. The PCH can potentially overlap the RSA primarily in the rut/late fall and winter periods.

During the Calving and Post-Calving periods cows and bulls tend to occupy different habitats and exhibit different movement patterns, so their ranges are described separately for these periods. During the relatively short calving period (June 1–10), cows occur in the Arctic coastal plains and adjacent uplands and foothills in Alaska and Yukon. Concentrated use often occurs in the Jago Uplands between the Hulahula and Aichilik rivers in Alaska. The calving season is one of the seasons of greatest importance (rank 1) (Porcupine Caribou Technical Committee 1993). Adult females are generally in their poorest body condition and have the largest energy deficits. The calving period is critical to the survival and development of calves (i.e., the source of initial annual population recruitment). The herd occurs in a relatively concentrated range, which appears to offer reduced predation risk and abundant forage that coincides with the timing of calving, and no alternative areas of similar value are available.

During the Post-Calving and Movement period (June 11–30) cows (and new calves) travel away from the calving areas. Cows that calved in the Yukon tend to move west into Alaska. Often, movements are higher into the foothills and uplands, following melting snow and newly emerging vegetation. However, the herd can occur anywhere from the coastline well into the foothills during this period. Selection of local habitats to avoid insect harassment is often a factor by the end of June. The Post-Calving period is also considered a period of highest importance (rank 1) (Porcupine Caribou Technical Committee 1993). Lactating females have their highest energy demands. Movement rates and group sizes increase through June, and cow/calf groups are believed to be relatively intolerant to disturbance.

During the calving to post-calving movement period (June 1–30) most bulls, juveniles, and non-productive cows occur in north Yukon between the Babbage and Firth rivers across a range of habitats within the coastal plains and the British Mountains. Animals tend to be quite mobile and follow plant emergence across habitats and elevations as spring progresses. This period is considered to have relatively low importance (rank 3) for bulls and non-productive cows (Porcupine Caribou Technical Committee 1993) because they are not tending young-of-the-year, high-quality forage is becoming abundant, and insect harassment is limited.

During Early Summer (July 1–15), both cows and bulls remain concentrated in the general north slope area, but the overall range continues to expand. Group sizes increase to the tens of thousands, and movement rates can average 25 km per day. Early summer often marks the beginning of the split of the herd between Alaska and Canada. In Alaska, distribution is widespread into the Brooks Range, and, in Canada, animals typically move into the southern British Mountains by mid-July. Local habitat use is driven by both selection for high-quality forage and insect avoidance. Insect avoidance strategies include using coastal areas adjacent to the Beaufort Sea (often primarily females) and higher elevation snow patches and barren ground in the Brooks Ranges and British Mountains (mostly males). Early summer is considered to have an importance rank of 2. Though food is generally abundant, the energy balance is limited by insect avoidance, resulting in reduced feeding times and selection of areas with less forage. Animals are still susceptible to disturbance, but tolerance is higher than during the calving and post-calving periods (e.g., calves have greater mobility, and more range is available due to snow melt).

By mid-summer (July 16–August 7), the majority of the PCH has left the coastal plains. Animals in Alaska have moved into the southern portion of the Brooks Range, and animals in Yukon have moved southeast into, or are en route to, the northern Richardson Mountains. Daily movement rates remain high through the mid-summer period, and though group sizes are often still large, groups are often breaking up and more dispersed than the aggregations that occur during post-calving and early summer. Mid-summer has an importance rating of 2 for the same reasons identified for early summer. Mid-summer is the period of potentially highest insect harassment, and, similar to early summer, habitat selection may favour insect avoidance over areas with the highest forage. Lactating females suffering insect harassment may be in an energy deficit.

During late summer and fall migration (August 8–October 7), insect harassment declines dramatically. Forage quality and abundance also begin to decline but are generally still abundant. Caribou exhibit high feeding rates during this period and gain fat reserves for the winter. During this period, the herd breaks up into smaller groups and disperses widely across North Yukon, mostly staying north of the treeline for most of the period. Fall migration often follows terrain features like ridges and valleys, but movement routes are unpredictable from year to year. Late-summer and fall migration is considered to have less importance (rank 3) due to the abatement of insect harassment, the relative abundance of forage across a variety of habitat types, the dispersed distribution of the herd, and relatively high tolerance to disturbance (Porcupine Caribou Technical Committee 1993).

The rut and late fall (October 8–November 30) continue to be a period of broad distribution and movement by the PCH, including widespread movement south of the treeline. In Yukon, the rut can occur from the Richardson Mountains to the southern Ogilvie Mountains. The areas where the rut occurs do not appear to have affinity from year to year. Rather, the rut appears to occur wherever the herd happens to be at that time along the fall migration. The rut and late fall period has the lowest level of importance(rank 4), due to the lack of insects, large range extent, ample food, the dispersed distribution of the herd, and relatively high tolerance to disturbance (Porcupine Caribou Technical Committee 1993).

During early, mid, and late winter (December 1–March 31), the PCH is at its most dispersed stage, both in terms of the extent of the range it uses and group aggregations. Average daily movement distances (2 km per

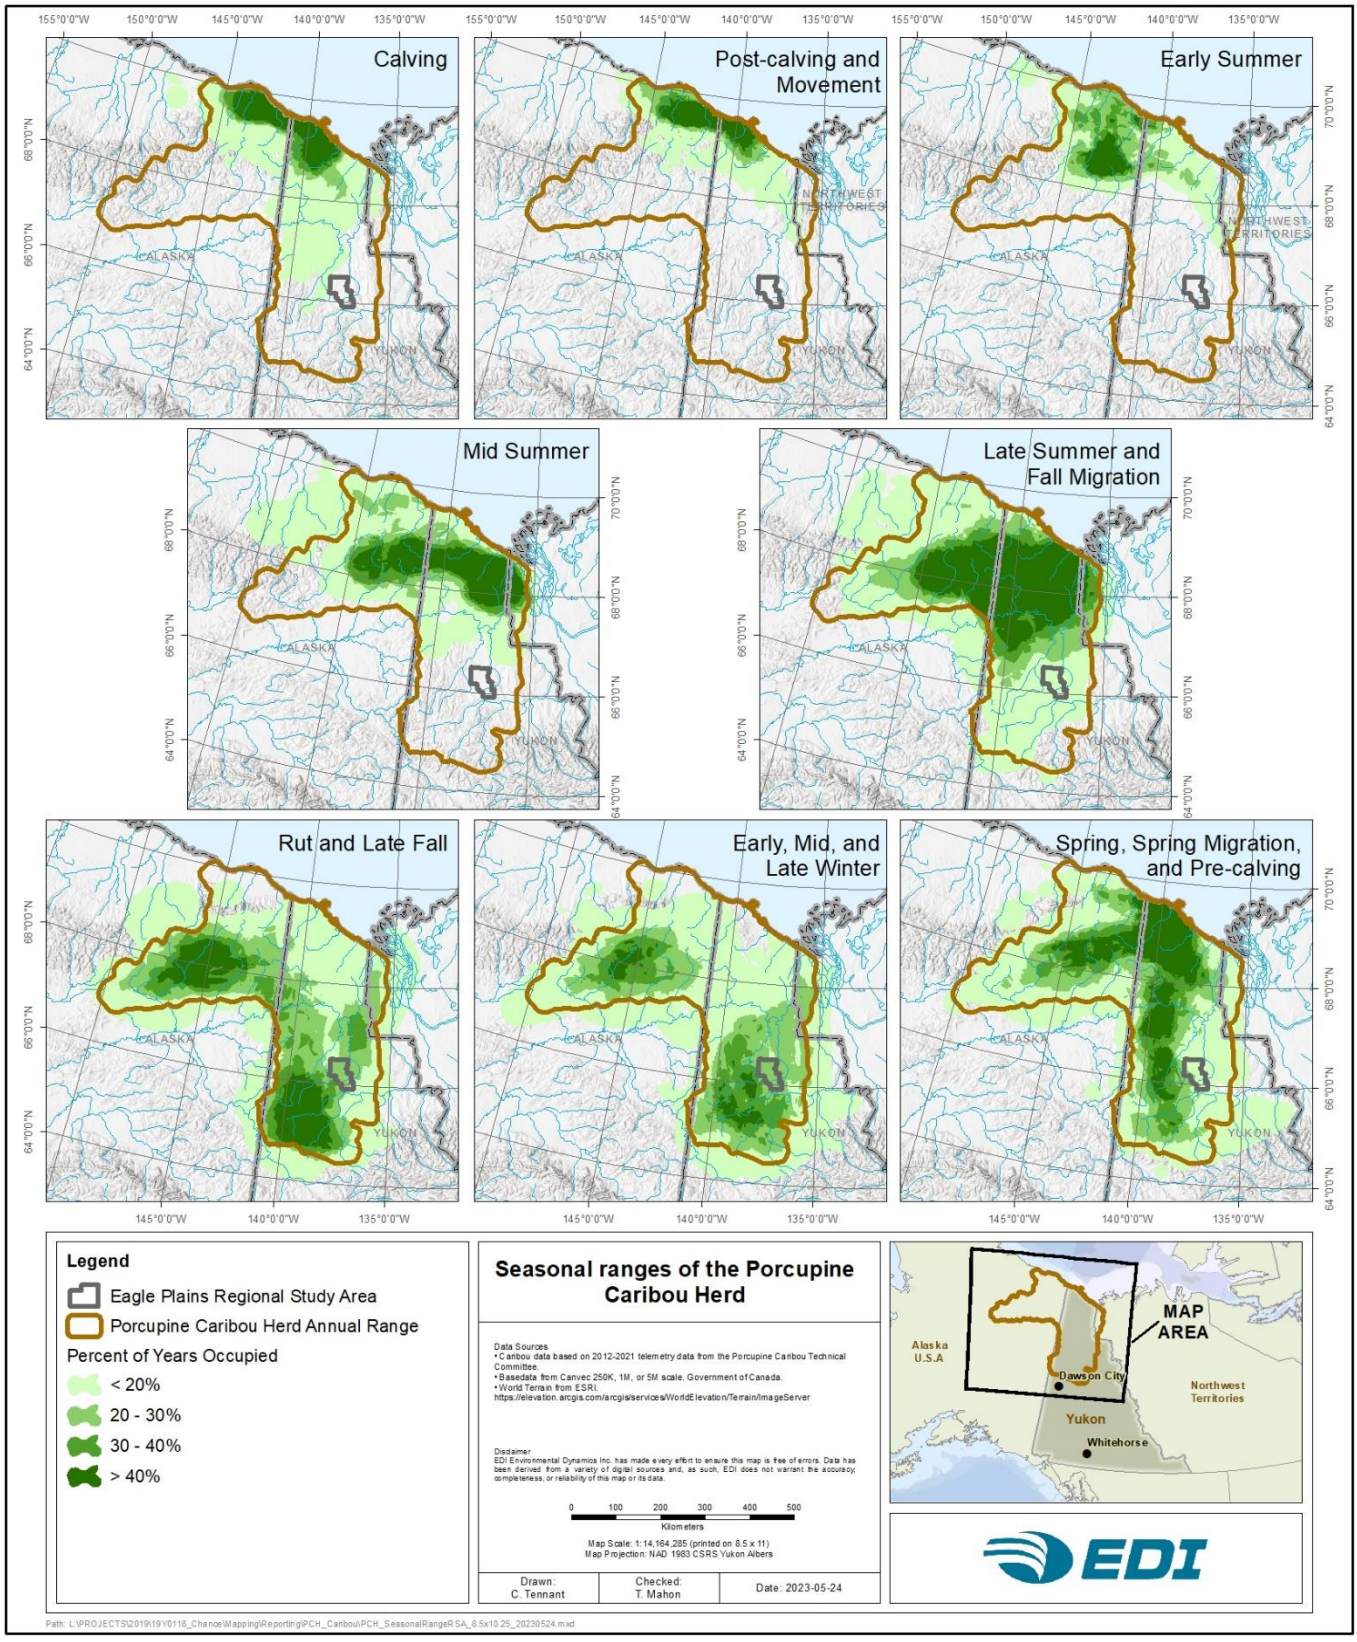
day [km/day] to 5 km/day) (Russell and Gunn 2017) are lower than in other seasons, except for cows during calving (Russell and Gunn 2017). Winter range use varies from year to year, depending on snow depth and condition. In Yukon, during deep snow years, use is concentrated in the Richardson Mountains and the Ogilvie-Hart basins. The Whitestone River and Eagle Plains areas are used more in low snow years. Forage during winter consists primarily of lichens. Unlike reports for some other caribou herds, winter habitat is generally not considered limiting for the PCH (Russell et al. 1993). In shallow to average snow years, the caribou maintain neutral to surplus energy balances (Russell et al. 1993). The PCH is relatively tolerant to human activity during the winter (Porcupine Caribou Technical Committee 1993). Similar to the rut and late fall period, winter has the lowest level of importance (rank 4) due to the lack of insects, large range extent, ample food, the dispersed distribution of the herd, and relatively high tolerance to disturbance (Porcupine Caribou Technical Committee 1993).

During the spring, spring migration, and pre-calving season, (April 1–May 31) caribou begin moving north toward the calving grounds. Average daily movement rates increase from approximately 6 km/day at the start of the season to approximately 24 km/day through May. Similar to the fall migration, no well-defined migration corridors are used consistently from year-to-year during spring migration, but certain terrain feature types like ridges and valleys are regularly used. During spring migration, local snow conditions often affect movement patterns and routes. In years or locations with low snow levels, migration tends to be more dispersed. In years or locations with high snow levels, movements tend to be more concentrated along trail networks on ridges (Porcupine Caribou Technical Committee 1993). Caribou, especially pregnant cows, typically enter an energy deficit during spring due to reduced forage availability as they leave the lichen-rich taiga and before forbs have emerged; in addition, higher energy expenditure is associated with migration. Spring is rated as higher in importance than winter, but still relatively low overall (rank 3), due to lack of association with specific habitats, relatively low threats from predators, and lack of insect harassment (Porcupine Caribou Technical Committee 1993).

Table 6-1. Key life cycle periods for the Porcupine Caribou Herd (after Porcupine Caribou Technical Committee 1993). The Porcupine Caribou Herd overlaps the Project Regional Study Area during Rut and Late Fall and Early, Mid, and Late Winter.

Season	Dates	Characteristics	Importance*
Early, Mid, and Late Winter	Dec. 1 – Mar. 31	The herd is at its most dispersed at this time across 2 winter ranges: in Yukon, mostly south of the Porcupine River in boreal taiga and in Alaska, centred in the Chandalar River/Arctic Village area. Winter range use varies from year to year, depending on snow depth and condition. Caribou at this time of year are relatively tolerant to human activity. In shallow to normal snow years, animals can gain weight.	4
Spring, Spring Migration, and Pre-Calving	Apr. 1 – May 31	Herd distribution varies depending on snowmelt; migration routes vary yearly. Pregnant females are typically in an energy deficit due to reduced forage once they leave the lichen-rich taiga.	3
Calving (cows)	June 1 – 10	Calving occurs on the coastal plain of NE Alaska and, to a lesser degree, NW Yukon. This area offers reduced predators and abundant spring forage; no alternative range is available. Cows are at the lowest point of physical condition and are least tolerant to human disturbance.	1
Post-Calving and Movement (cows)	June 11 – 30	As calves develop over the first two weeks of life, the cows and calves tend to aggregate into larger groups and increase movement rates to track plant green-up. The post-calving period imposes high energetic demands on lactating females, and cow/calf groups are relatively intolerant of disturbance. The post-calving range is primarily in Alaska, and cows that calved in Yukon tend to move west along the foothills into Arctic National Wildlife Refuge. Insect avoidance can affect distribution by the end of June.	1
Calving to Movement (bulls)	June 1 – 30	Bulls, non-pregnant cows, and subadults tend to concentrate east of the calving grounds in northern Yukon. Animals track the progression of green-up from the coastal plains to the northern foothills and into intermountain regions.	3
Early Summer	July 1 – 15	Cows continue to require a high-energy intake for milk production, but insect avoidance also drives distribution. Key areas selected for insect avoidance are the coastal plain adjacent to the Beaufort Sea (mostly cows/calves) and mountains in the Brooks and British Mountains (mostly bulls and cows without calves). Long-distance movements during this period are also an insect avoidance behaviour.	2
Mid Summer	July 16 – Aug. 7	Mid-summer continues to be a period of high insect harassment. Two areas are consistently used – the northern Richardson Mountains in Yukon and the southern portion of the Brooks Range in Alaska. Females with cows may be in energy deficit.	2
Late Summer and Fall Migration	Aug. 8 – Oct. 7	As insect activity declines, the herd disperses widely but mostly stays north of the tree line until the latter part of the period – in Alaska south of the Brooks Range and in Yukon north of the Porcupine River. Animals exhibit high feeding rates and gain fat for the winter.	3
Rut and Late Fall	Oct 8 – Nov. 30	The region where rut occurs has no affinity from year to year; rut occurs wherever the herd happens to be along fall migration. In Yukon, distribution can occur from the southern Ogilvie Mountains to the Richardson Mountains.	4

* 1 = highest importance, 4 = lowest.



Map 6-1. Seasonal ranges of the Porcupine Caribou Herd from 2012–2021.

6.2.3 DIET AND HABITAT

Barren-ground caribou are generalist foragers who feed on grasses, sedges, forbs, lichens, and shrubs during the growing season. During winter lichens constitute the primary forage of most barren-ground caribou populations (Photo 6-1 and Photo 6-2). Over three winters, the composition of PCH fecal samples was similar, consisting of, on average, 64% fruticose lichens, 11% evergreen shrubs, 8% moss, 6% horsetails, and 5% foliose lichens (Russell et al. 1993).

Russell et al. (1993) surveyed lichen distribution across the Yukon portion of the PCH range. Fruiticose lichens were widespread across survey plots and overall biomass estimates were similar to values reported in other western barren-ground caribou ranges (Joly and Cameron 2018). Within the PCH's Yukon range, lichen biomass varied across regions, habitat (range) types and stand ages. Average lichen biomass varied substantially among regions, with the highest biomass occurring in Eagle Plains (78.3 g/m^2), followed by North Fork Pass (45.0 g/m^2), Chapman Lake (33.6 g/m^2), Ogilvie Valley (32.5 g/m^2), and Richardson Mountains (29.9 g/m^2). In terms of habitat type, lichen biomass varied over three-fold across the seven habitats (range) that Russell et al. (1993) surveyed. Open conifer forest types had the greatest lichen biomass, and the forb herbaceous type had the lowest.

In terms of stand age, the generally accepted theory is that lichen biomass is greatly reduced following a fire, increases in abundance up to 125–175 years, and decreases as lichens are overtaken by mosses and shrubs (Klein 1982). Field surveys by Russell et al. (1993) found that lichen biomass in the PCH range was actually highest in stands <50 years since fire, and that lichen biomass decreased across all subsequent older age classes, to a nearly 50% reduction in the oldest age class (>270 years) (Photo 6-3). This local data suggests that younger stands may make a greater contribution to lichen forage than previously believed. Russell et al. (1993) emphasizes the importance of a mosaic of stand age classes, resulting primarily from wildlife, to maintaining lichen biomass at the regional level over time.

Although habitat selection is often driven by forge availability, especially in winter, reducing predation risk (Latham et al. 2011) and minimizing exposure to insect harassment during summer (Russell and Nixon 1990) also factor into habitat selection by caribou.

6.2.3.1 Effects of Snow

The regional patterns of PCH distribution in winter vary among years, often related to snow accumulation, which can limit forage availability (Russell et al. 1993). During the 1970s and 1980s, the distribution of the PCH in winter varied in a regular pattern across four regions with different snow regimes: Yukon/Alaska border, Richardson Mountains, Ogilvie/Hart region, and the Whitestone/Eagle region (Russell et al. 1993).

On average, the Ogilvie/Hart region had the lowest mean snow accumulation. During winters when most animals occupied this region snow depths were normal to high across the overall winter range. Heavy snows in the north early in the season seemed to emphasize concentrated use in this region, pushing animals to the south during the fall migration and rut. Once animals moved into the Ogilvie/Hart basin they typically remained in the region, taking advantage of the comparatively shallow snows, until spring migration.

During the winters when most Yukon wintering animals occupied the Richardson Mountains, snow depths tended to be normal to above normal. Strong winds in the Richardson Mountains resulted in uneven snow distribution, with many areas having reduced snowpacks, including some areas being blown completely bare. During the winters when most Yukon wintering animals occupied the Whitestone/Eagle area, snowpacks were invariably below normal. This area generally had the highest lichen biomass, but snow depths appeared prohibitive during years with normal to deep snow. In the two years when most of the Yukon wintering animals occupied the Yukon/Alaska border area (overlapping with the Fortymile Herd), snows were deeper than average in all other wintering areas.

Photo 6-1. Mesic, mature forest, with mat-forming terrestrial lichens in the Eagle Plains RSA.

Photo 6-2. Lichen communities are often diverse in Eagle Plains. This lichen mat includes *Cladonia spp.* (lighter green) that are preferred forage for caribou, as well as *Stereocaulon spp.* (darker grey) and *Flavocetraria spp.*, which are both also eaten by caribou but less preferred.

Photo 6-3. Lichen cover is generally reduced in regenerating burns. However, EDI observed high lichen abundance in some regenerating burns, consistent with previous work by other researchers (Russell et al. 1993).

6.2.4 POPULATION LEVELS AND TREND

Although most barren-ground caribou subpopulations are declining (COSEWIC 2016), the PCH numbers have increased over the last two decades. The last successful population survey in 2017 estimated the population at 218,457 (95% CI = 202,106 – 234,808) caribou (Porcupine Caribou Technical Committee 2019). Population surveys of the PCH began in the 1970s. The objective is to survey the herd every two to three years, but that period is sometimes extended depending on herd behaviour (aggregation patterns), funding, and logistical issues. Since the first survey in 1972, the PCH has had two periods of population growth, with an interceding decline (Figure 6-1). From 1972 to 1979 the population was relatively stable at just over 100,000 animals. By 1989 the herd had increased to approximately 178,000. Over the next 12 years, the herd declined by 55,000 to 123,000 in 2001. By 2010, the herd had recovered to 169,000 and increased to 218,000 in the last survey in 2017. During the latest growth phase, 2010 to 2017, the estimated population growth rate of 3.7% is almost identical to the growth rate during the 1972 to 1989 growth phase (Porcupine Caribou Technical Committee 2019).

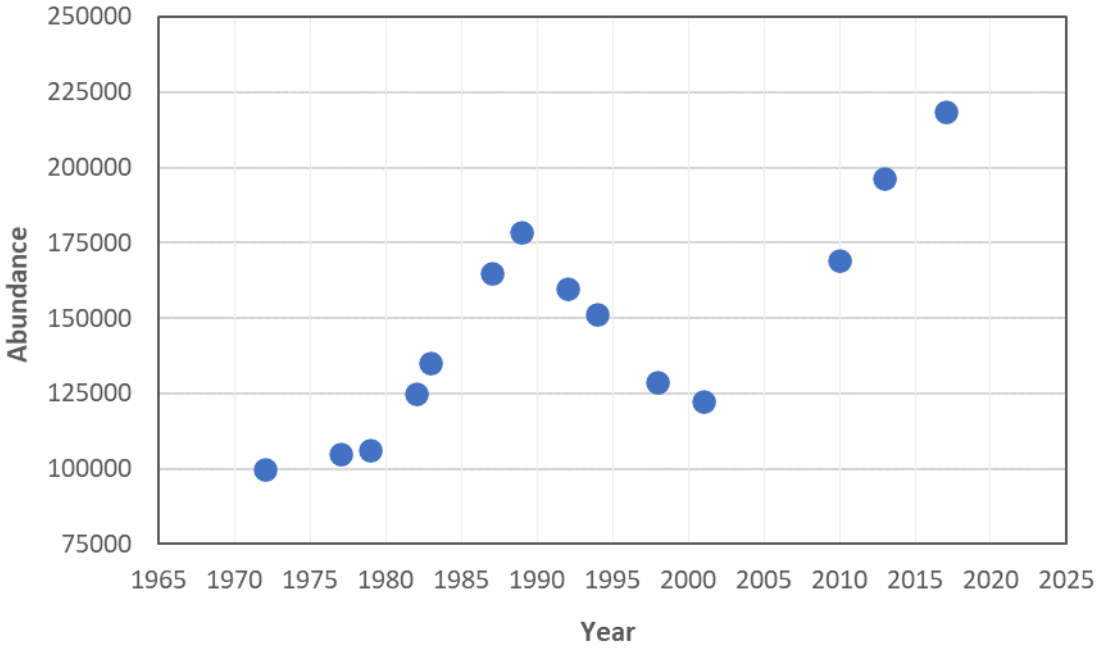


Figure 6-1. The population size of the Porcupine Caribou Herd from 1972 to 2017 (Porcupine Caribou Technical Committee 2019).

6.2.5 POPULATION DYNAMICS

Large magnitude population fluctuations are a key ecological trait of barren-ground caribou. Subpopulations (herds) often experience declines of >80% and increases >500%, which occur over several decades and caribou generations (COSEWIC 2016). Based on scientific studies and Indigenous Traditional Knowledge, the interval between population highs varies from approximately 30–80 years among subpopulations (Ferguson et al. 1998, Gunn 2003, COSEWIC 2016). There has long been debate about whether the intervals

between population highs and lows, and the population levels that occur at highs and lows, are regular enough to be considered cycles (Gunn 2003, COSEWIC 2016, Bongelli et al. 2020). A recent analytical study found that historical population fluctuations of the barren-ground caribou population overall and 9 of 11 sub-populations fit a sine-cyclic model with periods ranging from 26–55 years (Bongelli et al. 2020). However, COSEWIC (2016) points out that cumulative changes in the environment, habitat, climate, and harvest regimes for many caribou subpopulations are without historical precedent, and therefore it is uncertain whether future populations patterns will follow historical patterns.

Despite large magnitude changes in the abundance of barren-ground caribou, there is still a poor understanding of how limiting factors regulate population change. Predation, human harvest[1], parasites and disease, and food supply are all considered limiting factors of barren-ground caribou (COSEWIC 2016); however, no single factor has been conclusively demonstrated as a primary limiting factor across subpopulations and over time. Despite strong advocacy for certain factors by certain researchers (e.g., for predation by Bergerud (1996)), the weight of evidence is that population dynamics involve complex interactions among limiting factors that vary over time and among subpopulations (Klein 1991, Whitten 1996). Over the 50 years that the PCH has been monitored, the population has not exhibited population fluctuations as large as other barren-ground caribou populations (COSEWIC 2016). This may be due to the large annual and seasonal ranges and diversity of habitats across ranges (Russell et al. 1993, Whitten 1996). Whitten (1996) suggests that periods of decline are caused by nutritional stress and predation exacerbated by adverse weather. Population growth during periods of favourable weather is dampened by a combination of poor nutrition, predation, and human harvest and disease. No true density dependent regulation or equilibrium was observed for the PCH from the 1970s to early 1990s (Whitten 1996).

6.2.6 LIMITING FACTORS

6.2.6.1 Food Supply and Overgrazing

The amount and distribution of forage have implications for population distribution and demography of barren-ground caribou (COSEWIC 2016). In general, food limitation is most prevalent during winter, when caribou diet consists primarily of lichen, and does not pose a constraint to caribou from late-spring through fall when graminoids, forbs, and deciduous shrubs are bountiful and predominate their diet (Thompson and McCourt 1981, Russell et al. 1993). Lichen availability depends on both density-dependent and density-independent factors, but the degree to which either is a limiting factor depends on ecological context. For example, density-dependent competition for forage, when local densities are high, and competition is intense, can cause overgrazing of lichen and reduce its abundance (Ferguson et al. 2001, Joly 2009). Recovery of lichen communities following overgrazing can take more than 20 years (Klein 1987).

[1]Human harvest is considered a natural population factor for barren-ground caribou because hunting has occurred for centuries (Sherry and Vuntut Gwitchin First Nation 1999, COSEWIC 2016). However, it is recognized that the nature of hunting has dramatically changed over the last century with the advent of high-powered rifles and snowmobiles.

The potential for lichen supply to regulate caribou herd size and demography is most likely for herds with small ranges on low productivity tundra islands (e.g., Klein 1987). For large, widely-distributed herds, it is more likely that density-independent factors, such as climate and natural disturbance, contribute to limitations in lichen supply that affect caribou distribution (Gunn et al. 2011). Lichen is a slow-growing food source; its distribution is affected by fire (see Joly 2009) and its accessibility depends on regional snow conditions, such as snow hardness and depth (Collins and Smith 1991, COSEWIC 2016). Therefore, caribou tend to shift winter ranges and foraging locations based on burn and snow conditions so that they may access areas with higher lichen abundance (Jandt et al. 2008, Pedersen et al. 2021). In the PCH, annual variation in the distribution of caribou during winter is thought to be a result of caribou tracking available and accessible lichen patches (Russell et al. 1993, WMAC 2009).

The potential for food supply, especially lichen, to regulate the PCH is limited because of their large annual and seasonal ranges and the diversity of habitats (e.g., several broad ecoregions) found within those ranges. Variation in distribution and range use may counteract any limitations on food supply at local scales (Hinkes et al. 2005). PCH migration from the tundra, at the northern extent of their range, to the taiga cordillera, at the southern extent of their range, may serve as a strategy to maximize the available food supply. Overall, the PCH winter range is relatively rich in lichen resources and is comparable to, or better than, those of other herds that winter in taiga regions (Russell et al. 1993).

Forest Fires

Forest fires are a significant natural disturbance agent in taiga forests and play a substantial role in the availability of caribou forage, especially lichen. Occasional fires are important to maintaining lichen biomass at a landscape level. Peak lichen biomass is generally associated with forests 125-1750 years old before lichen volumes decrease due to competition from other species like moss and shrubs (Klein 1982). However, frequent fires can reduce the extent of mature and old forests where productive lichen biomass occurs. For example, forest fires in the winter range of the Bathurst Herd reduced the area of forest by 30% between 1990 and 2000 (Chen et al. 2013). More broadly, the average area burned by large fires in Canada's taiga has increased since the 1960s (Krezek-Hanes et al. 2010). Climate change modelling suggests a further increase in fire extent of 25% by 2030 and 75% by the end of the century (Wotton et al. 2010). Generally, caribou avoid burned areas in winter for several decades until lichen biomass increases to the point where it is favourable for caribou to forage. Changes in landscape vegetation patterns due to fire are believed to affect regional seasonal use areas and migration routes of caribou (Gunn et al. 2011).

The PCTC monitors the extent of burn areas across the forested portion of the PCH annual range; since 1960, 18% of the area has burned (Porcupine Caribou Technical Committee 2021a). The five-year average of the area burned in the Yukon portion of the PCH annual range is 1,552 km² (Porcupine Caribou Technical Committee 2021a).

6.2.6.2 Predation

Wolves are the primary predators of barren-ground caribou (COSEWIC 2016). However, grizzly bears can also be significant predators of caribou, especially calves (Gau et al. 2002). Predation is an important factor

affecting many facets of caribou ecology, as caribou movements and habitat choices are often made to minimize exposure to predators (Bergerud 1996). One of the hypotheses about why barren-ground caribou migrate is that it reduces predation risk. The idea is that moving throughout the year limits the numerical response of wolves (Hayes and Russell 2000). In the NWT, wolf densities in the arctic tundra calving grounds were only 22% compared to wolf densities in the taiga, where the herd wintered. However, as caribou numbers increase, their range expands, causing some caribou to return earlier to the ranges of taiga denning wolves, which results allows wolf numbers to increase (Heard et al. 1996).

A study of wolf predation on the PCH estimated that wolves killed about 7,600 adult caribou each year, regardless of herd size (Hayes and Russell 2000). In 1992 this corresponded to a predation rate of 5.8%, or about one-third of adult mortality. As the PCH declined through the 1990s, the predation rate by wolves increased from 5.8% to 7.4%. Migratory movements effectively reduced wolf predation during the calving through summer seasons due to the combination of smaller ranges and lower densities of wolves in the arctic tundra. Only 16% of the mortality occurred during the calving/summer seasons compared to 84% during the fall and winter seasons, when wolves were predominantly in the taiga zone.

Generally, wolf predation does not appear to regulate barren-ground caribou subpopulations (Crête and Huot 1993, Messier 1995, Hayes and Russell 2000). Hayes and Russell (2000) estimated that the predation rate would have had to be near twice the observed level to cause the PCH to decline during their study. However, the limiting effect of predation increases as population size decreases, which can result in a cumulative effect with other limiting factors as the population declines (COSEWIC 2016).

6.2.6.3 Hunting

Human hunting of barren-ground caribou has occurred for centuries over much of the species range in North America (Sherry and Vuntut Gwitchin First Nation 1999, COSEWIC 2016). Although humans and caribou have co-existed for centuries, technological changes (e.g., high-powered rifles, snowmobiles, and aircraft) and social changes (e.g., commercial hunting) have changed the potential effects human hunting can have on some barren-ground caribou populations (COSEWIC 2016). Over the last half-century, there has been clear evidence of population-level impacts from harvesting. From 2008 to 2011 the estimated harvest rate on north Baffin Island was 41%. During the mid-2010s harvest rates of the Southampton population were considered well beyond sustainable limits (COSEWIC 2016). Harvest is more likely to pose a threat when population monitoring data is poor and/or harvest management decisions lag population declines. For example, in the Bathurst subpopulation, a constant harvesting level during a period of population decline resulted in an increase in the harvest rate (i.e., as a percent of population size) from 2–4% to 10–16% of abundance (Boulanger et al. 2011).

There is no simple, sustainable harvest level applicable to all barren-ground caribou populations. Effects of harvesting depend on herd size, population trend, and the proportion of females that are harvested (Boulanger and Adamczewski 2016). Harvesting may also interact with other limiting factors, such as predation and weather (Klein 1991). Most harvest plans target a total harvest rate of 0–5%, depending on herd status, and with restrictions on harvesting females (e.g., Environment and Natural Resources 2013).

Recognizing the importance of effective harvest management for both the conservation and continued long-term harvest of the Porcupine Caribou, the Porcupine Caribou Management Board led the development of a comprehensive *Harvest Management Plan for the Porcupine Caribou Herd in Canada* (HMP) in 2010 (Porcupine Caribou Management Board et al. 2010)[2]. Key components of the plan include the determination of specific management actions related to the estimated herd size and a set of general best hunting practices. Management actions are determined each year using a set of six population indicators: 1) estimated herd size, 2) harvest information, 3) adult cow survival, 4) calf birth rate, 5) calf survival to nine months, and 6) body condition. In addition, descriptive indicators from people on the land include caribou health, hunting success, and weather conditions that affect caribou. The results from the indicators are rolled up into a 4-class colour chart, and management actions are specified for each colour zone. Management actions become more restrictive across each zone once the herd falls below 115,000 animals, including ceremonial harvests only below 45,000 animals (Porcupine Caribou Management Board et al. 2010).

Implementation of the HMP is guided by a formal Implementation Plan (Porcupine Caribou Management Board 2016). Key components of the Implementation Plan are to 1) guide annual monitoring of the population indictors and harvest levels, 2) provide a forum for all the HMP Parties to review and discuss the population indicators and harvest levels and 3) provide an annual recommended harvest management colour zone plus any additional management actions that are deemed appropriate. Population indictors are monitored each year by the PCTC and summarized in an annual report (e.g., Porcupine Caribou Technical Committee 2021). Annual harvest levels are monitored by each Party or user group and are compiled by the PCTC into an annual report (e.g., Porcupine Caribou Technical Committee 2021b). Each year, the HMP Parties hold an annual meeting to discuss the results of the population and harvest monitoring and determine the harvest management zone for the following year and any additional management actions the Parties feel may be required.

Over the eight-year period, 2013–2014 to 2020–2021, the annual reported harvest rates of Porcupine Caribou have ranged from 749 to 3,367 caribou. The reported annual harvest rates are considered the minimum estimated harvest (Porcupine Caribou Management Board 2022). Due to reporting challenges faced by some Parties, significant harvest may be missed in some regions in some years. Notwithstanding the reporting challenges, the reported Canadian harvest is estimated to be between 1% and 2% of the 2017 population estimate of 218,000 caribou and is not considered a threat to population decline (Porcupine Caribou Management Board 2022). The comprehensive measures within the HMP to monitor and respond to declines in the PCH (i.e., by reducing harvest) provide a solid system to minimize the potential effects that harvesting could have on the herd.

[2] The HMP was agreed to by eight Parties with authorities and responsibilities managing the PCH within Canada, including Gwich'in Tribal Council, Inuvialuit Game Council, Vuntut Gwitch'in Government, Trʻondëk Hwëchʻin Government, First Nation of Na-Cho Nyäk Dun, Government of the Northwest Territories, Government of Yukon, and Government of Canada.

6.2.6.4 Parasites and Disease

Biting and parasitic insects, pathogens (i.e., viruses and bacteria) and internal parasites are important factors in caribou ecology and population dynamics (Gunn and Irvine 2003, Kutz et al. 2012, COSEWIC 2016).

Harassment by parasitic insects can be a key driver of behaviour, movement, and body condition of caribou during summer (Downes et al. 1986, Russell and Nixon 1990). Warble flies (*Hypoderma tarandi*) and nose botflies (*Cephenemyia trompe*), both of the family Oestridae, are the primary source of harassment for Arctic caribou, though mosquitoes (Culicidae), blackflies (Simuliidae), and horseflies (Tabanidae) also are known to cause harassment (Downes et al. 1986, Toupin et al. 1996, Witter et al. 2012a). There are two primary harmful effects of insects. The direct effects of the parasitic burden can result in decreased body condition and reproduction (Albon et al. 2002, Cuyler et al. 2012). Indirect effects include the behavioural response to avoid insects, which includes a reduction in time spent foraging, increased energy expenditure, and selection of low-quality habitats such as ridge tops, coastal regions, snow patches, and unvegetated areas (Downes et al. 1986, Russell and Nixon 1990, Walsh et al. 1992, Toupin et al. 1996, Witter et al. 2012a). These behavioural responses can result in reduced body condition going into the winter with negative implications for survival and fecundity (Russell et al. 1993, Cuyler et al. 2012).

The responses of caribou to disease and other parasites are less evident and less studied than responses to insects. Most occurrences of disease and internal parasites in caribou are at subclinical levels (not severe enough to produce observable symptoms) but can still result in reduced body condition and fitness (Gunn and Irvine 2003). A range of pathogens and parasites observed in caribou includes viruses, bacteria (e.g. brucellosis), helminths (e.g., roundworms, tapeworms, and flukes) and protozoa (Tessaro and Forbes 1986, Gunn and Irvine 2003, Kutz et al. 2012, COSEWIC 2016). Gunn and Irvine (2003) suggest that caribou may have evolved foraging strategies to minimize exposure to parasites. Similar to parasitic insects, internal parasites can reduce caribou body condition and pregnancy rates resulting in population-level impacts (Albon et al. 2002, Kutz et al. 2012).

6.2.6.5 Climate Change

Climate change can potentially affect barren-ground caribou populations negatively and positively through various mechanisms. A recent literature review on this topic identified five primary factors that affect caribou population dynamics that could be affected by climate change: (i) summer range conditions, (ii) parasites and disease, (iii) movement, migration, and distribution, (iv) extreme weather and icing events, and (v) winter range conditions (Mallory and Boyce 2018). The effects of these factors are likely to be complex and interact with climate and non-climate-related factors that will result in substantial local variation and uncertainty in potential outcomes to caribou (Cebrian et al. 2008, COSEWIC 2016).

On balance, climate change is predicted to have mostly positive effects on the summer range condition of barren-ground caribou. Increasing temperatures will likely lead to longer growing seasons, increases in plant productivity, and an earlier onset of spring. Pearson et al. (2013) predict dramatic increases of 29-68% in above-ground plant biomass in the arctic by 2050. These effects could increase caribou body condition and reproductive success by lengthening the summer period of food availability, by increasing the amount of

forage and providing earlier access to forage (i.e., relative to the energetically demanding periods of birthing and lactation) (Tews et al. 2007, Cebrian et al. 2008, Mallory and Boyce 2018). This prediction is supported by a 20-year study in Norway, 1994–2015, where reindeer body mass resulted from greater plant productivity associated with warmer summer temperatures (Albon et al. 2017). In the PCH, earlier and warmer springs over the last thirty years have resulted in more food available for nursing cows, correlated with higher early calf survival (Griffith et al. 2002). However, positive effects on caribou summer range may not occur uniformly across all ranges. Some researchers have suggested the potential for a trophic mismatch between the timing of caribou and vegetation phenologies (Vors and Boyce 2009). Also, a predicted shift to greater cover of woody shrubs may be negative to caribou because shrubs tend to have greater chemical and structural defenses against herbivory and lower available protein than other forage such as grasses, forbs and sedges (Thompson and Barboza 2014).

Most studies suggest that climate change is predicted to increase the potential effects of parasitic insects and disease on barren-ground caribou (Mallory and Boyce 2018). Warmer and longer summers are likely to increase the length and severity of insect harassment, leading to lower body condition of caribou, including lactating cows and calves (Witter et al. 2012b). Climate change is also predicted to increase parasitism by other taxa, such as protozoans and helminths, and the northern expansion of some parasitic species has already been observed (Kutz et al. 2013). Certain ungulate diseases are also expanding northward as the climate warms (Arifin et al. 2020). Arctic ecosystems and species may be more susceptible to the spread of parasites and diseases than southern populations because they have had less exposure and opportunity to develop resistance from an evolutionary perspective.

Extreme weather, such as icing events, large changes in snowfall patterns, and summer heat episodes, is predicted to increase with climate change and negatively affect caribou (Mallory and Boyce 2018). Restricted or total loss of access to forage due to icing in the winter range can significantly affect survival and body condition for barren-ground caribou (Tyler 2010, Hansen et al. 2014). These events tend to be more catastrophic in the high Arctic but have been reported broadly across caribou ranges; including within the VGFN territory where the refreezing of wet snow one winter restricted access to food and greatly affected the health of a caribou herd (Sherry and Vuntut Gwitchin First Nation 1999, p. 186). Ice crusts on snow can also negatively affect travel abilities, body condition, and predation risk of caribou (Griffith et al. 2002). Deep snowpacks can reduce the availability of terrestrial lichen forage in winter. The Porcupine Caribou are known to vary winter range use in response to regional weather patterns (Russell et al. 1993). Changes to regional snow patterns may make areas, such as Eagle Plains, less available to the herd (Russell and Gunn 2017).

Several studies have predicted that climate change could affect the movements, migration and distribution of barren-ground caribou (Mallory and Boyce 2018). Effects are predicted to be most dramatic for subpopulations that travel over ice during the winter and where warming temperatures are already reducing the extent and duration of ice (Poole et al. 2010). Changes in regional snow conditions predicted due to climate change can also affect the migration patterns and seasonal distributions of barren-ground caribou. Russell et al. (1993) observed that the PCH adjusted the concentration of winter range use in relation to winter snowpacks. Areas such as Eagle Plains, which receive the greatest use during low snow years may become less available if regional snowpacks increase. Other studies have indicated that snow depths and snow conditions

(e.g., crusting) affect the migration routes, behaviours, and energetic costs of Porcupine Caribou during spring migrations (Whitten 1996, Griffith et al. 2002).

During winter, many barren-ground caribou subpopulations forage primarily on terrestrial lichen. Climate change is predicted to reduce terrestrial lichen biomass due to increased productivity from other plants (notably shrubs) and, in the boreal/taiga forest, due to increased forest fires (Mallory and Boyce 2018). Some studies indicate the area burned each year in northern Canada could double by the end of the century (Wotton et al. 2010). The potential adverse effects of climate change on caribou winter range depend mainly on the assumption that caribou require lichen-rich diets in winter. Some researchers have long questioned the need for lichens during the winter (Bergerud 1974), and more recent studies suggest that winter diets dominated by graminoids rather than lichens were not detrimental to caribou populations (Heggberget et al. 2002, van der Wal 2006). However, in the Western Arctic Herd a decline in recruitment and abundance in the herd occurred when the winter diet showed increased graminoids and decreased lichens being consumed (Joly 2009). In the past, the conditions of winter range and winter weather were not considered to be limiting to the PCH (Russell et al. 1993, Porcupine Caribou Technical Committee 1993). However, the combination of reduced lichen forage, deeper snow in some areas, and extreme weather events that are predicted to occur with climate change has the potential to increase the limiting effect of the winter range on the PCH.

6.3 PORCUPINE CARIBOU HERD MANAGEMENT

There is a long history of co-management of the PCH among indigenous, state, territorial and federal governments, with international and national management boards formalizing in the mid-1980s. Canada and the United States of America co-manage the herd under the *Agreement Between the Government of Canada and the Government of the United States of America on the Conservation of the Porcupine Caribou Herd (1987)*. The International Porcupine Caribou Board (IPCB) is comprised of Canadian and American representatives. The Porcupine Caribou Management Board (PCMB) is a co-management board for the Canadian portion of the herd's range, formed under the *Porcupine Caribou Management Agreement (1985)*. The *Porcupine Caribou Management Agreement (1985)* was established to coordinate management efforts toward conserving the herd and maintaining and protecting special harvesting rights in the Porcupine Caribou for indigenous users while providing for other users to share in the harvest. The PCMB and IPCB have led or contributed to the development of several plans for the PCH, including:

- *Plan for the International Conservation of the Porcupine Caribou Herd (1987),*
- *Wildlife Conservation and Management Plan for Yukon North Slope (2002),*
- *Porcupine Caribou Harvest Management Plan (2010)* and an associated *Implementation Plan (2010, revised 2016),*
- *Porcupine Caribou Herd Strategic Framework 2015-16 to 2019-20.*

The international agreement also provided for a joint technical committee to coordinate research and monitoring activities and advise the IPCB on scientific matters surrounding the herd. This committee, known

as the "Porcupine Caribou Technical Committee" (PCTC), has been functioning since the 1970s. Over time, the PCTC has taken on the role of advising the Canadian PCMB and the IPCB. The PCTC comprises biologists and scientists from Yukon, Alaskan, Canadian and American government agencies, university researchers, and other caribou experts.

The PCTC leads most of the monitoring and research initiatives associated with the PCH on behalf of the PCMB and the IPCB. Core monitoring work that the PCTC does includes population abundance surveys (normally every two to five years depending on herd behaviour, funding, and logistics), population demographic monitoring (e.g., calf birth and survival rates and important age and sex ratios), seasonal movement monitoring (via GPS telemetry tracking), caribou body condition monitoring, habitat and human disturbance assessments, and annual snow surveys. Monitoring results are normally provided to the PCMB and the IPCB via annual reports (e.g., Porcupine Caribou Technical Committee 2019) and via presentations at the annual harvest meetings. The PCTC also intermittently conducts specific data analyses, such as habitat selection studies and seasonal range mapping, to support land use planning and other management initiatives.

6.3.1 PROTECTED AREAS AND MANAGEMENT AREAS AND PLANS

A network of parks protects the portion of the PCH annual range that occurs within Yukon, special management areas, conservation areas, wilderness areas, protected areas, ecological preserves, habitat protection areas, and IMA zones within the North Yukon Regional Land Use Plan and the Peel Watershed Regional Land Use Plan (Map 6-2). In total, 54% of the annual range of the PCH within Yukon falls within some type of protected area where industrial activity is prohibited, 36% of the annual range occurs within regional LUP IMA zones, and 9% of the annual range is not covered by any type of land management zonation. A summary of the overlap of different types of protected areas and management areas with the seasonal ranges of the PCH is provided in Table 6-2.

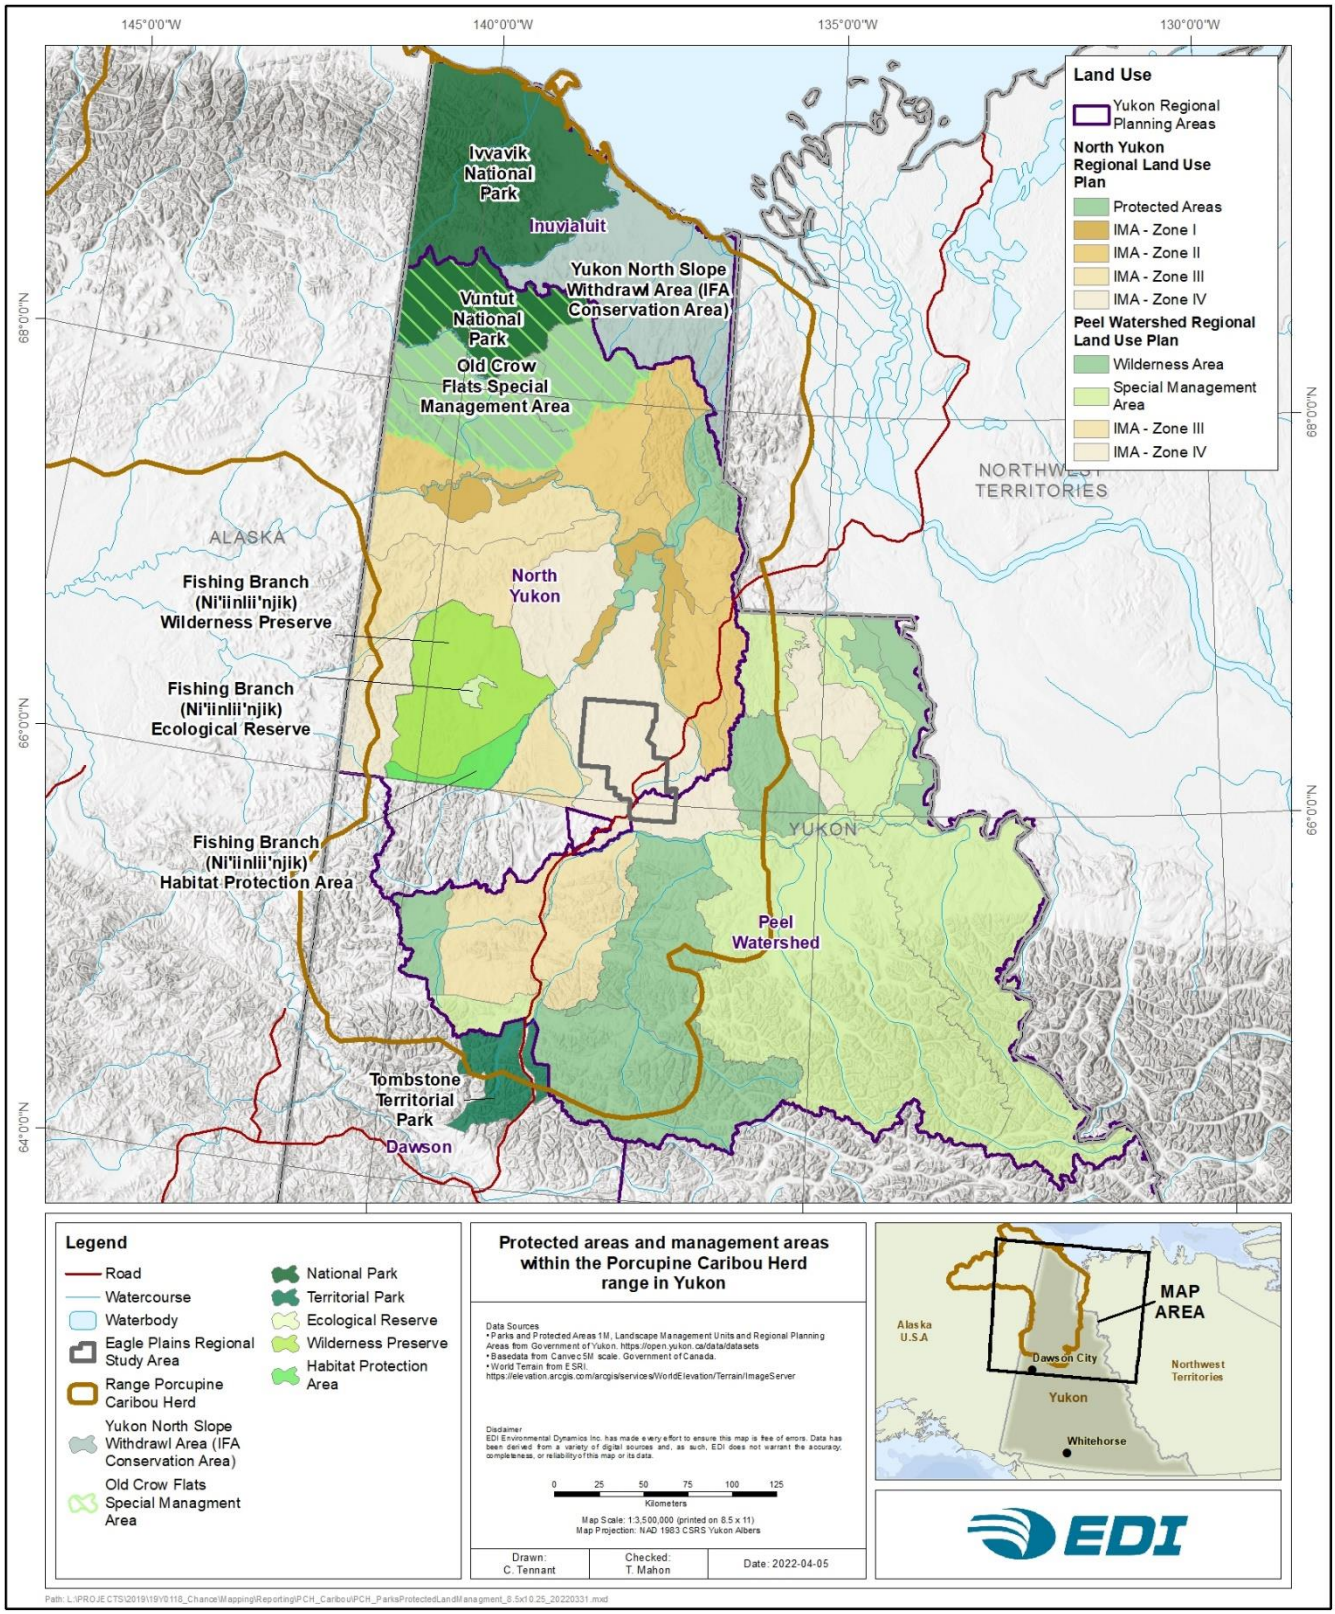
The Project is within the North Yukon Planning Region and Peel Watershed Planning Region and is subject to the NYLUP (Vuntut Gwitchin Government and Yukon Government 2009) and PWLUP (Peel Watershed Planning Commission 2019). The project falls within IMA Zone IV of both plans, a zone with lower ecological and cultural values and the highest permissible development of the four IMA zones. The NYLUP and PWLUP include management objectives and strategies to minimize the effects of human development activities on wildlife and wildlife habitat, generally, and specific objectives and strategies for caribou.

In addition to the Regional Land Use Plans, the Habitat Programs Section of the Yukon Department of Environment, Yukon Government maintains an inventory of important habitat areas for focal management species, including caribou, within the Wildlife Key Area Inventory (Environment Yukon 2014b). Wildlife Key Areas are specific geographic locations used by wildlife for critical, seasonal life functions, such as calving areas and mineral licks. No Wildlife Key Areas for caribou occur within the Project RSA (Government of Yukon 2015).

Table 6-2. Summary of the overlap of different types of protected areas and management areas with the seasonal ranges of the Porcupine Caribou Herd.

Season	Area (km²)	% of Seasonal Range					
		Protected Areas [1]	IMA I	IMA II	IMA III	IMA IV	Not Zoned
Early, Mid, Late Winter	58,090	37	2	8	19	18	15
Spring, Migration and Pre-calving	68,463	55	1	7	21	7	9
Calving	14,636	100	0	0	0	0	0
Post-Calving and Movement	7,622	100	0	0	0	0	0
Early Summer	5,901	100	0	0	0	0	0
Mid Summer	24,417	86	0	14	0	0	0
Late Summer and Fall Migration	57,928	60	4	15	13	8	0
Rut and Late Fall	65,249	31	3	10	23	13	20

[1] including parks, special management areas, conservation areas, wilderness areas, protected areas, ecological preserves, and habitat protection areas.



Map 6-2. Protected areas and management areas within the Porcupine Caribou Herd range in Yukon.

6.4 SEASONAL DISTRIBUTION

Considerable effort has been placed towards quantifying and mapping space use of PCH caribou in Yukon. Satellite-telemetry collaring programs have allowed for the tracking of individuals within the herd to delineate the herd's seasonal distributions. The PCTC supplied EDI with spatial polygons of PCH seasonal ranges spanning 37 years (1970–2016), which provided an opportunity to determine the amount of overlap between seasonal ranges and the RSA. Simple measures of overlap (%) can yield useful insight into the historical frequency of occupation and how PCH caribou are likely to interact with the Project.

The Project RSA overlaps a relatively small proportion of late fall (October 8 to November 30) and winter (December 1 to March 31) ranges. Most of the overlap occurs in portions of the ranges that are less frequently used on an annual basis. No overlap occurs with frequently used portions of late fall and winter ranges.

6.4.1 METHODS

The seasonal ranges used for this analysis consisted of mapped 'sensitive habitat' polygons provided by the PCTC that correspond to eight seasonal life cycle periods for the PCH (Porcupine Caribou Technical Committee 1993). Within each season, the PCTC identified four levels of use based on the frequency of overlap among annual estimates of seasonal home ranges computed for collared caribou, 1970–2016. The four use levels correspond to the proportion of years that home range estimates overlapped any given area: >40 %, 30–40 %, 20–30 %, and <20 %. The lowest category (<20 %) corresponds to very low use and is not considered part of the regular seasonal ranges of the PCH. The degree of overlap of the Project RSA with the PCH seasonal ranges was calculated in a GIS by measuring the overlap of the RSA with each 'frequency of use' category for each seasonal range. All eight life cycle periods were considered for the analysis, but only late fall (including rut, October 8 to November 30) and winter (December 1 to March 31) ranges overlapped the RSA. The overlap analysis was constrained to Yukon because fall and winter ranges in Yukon and Alaska are functionally discrete. Including the Alaskan ranges would dilute the degree of overlap of the RSA with the Yukon ranges.

6.4.2 RESULTS

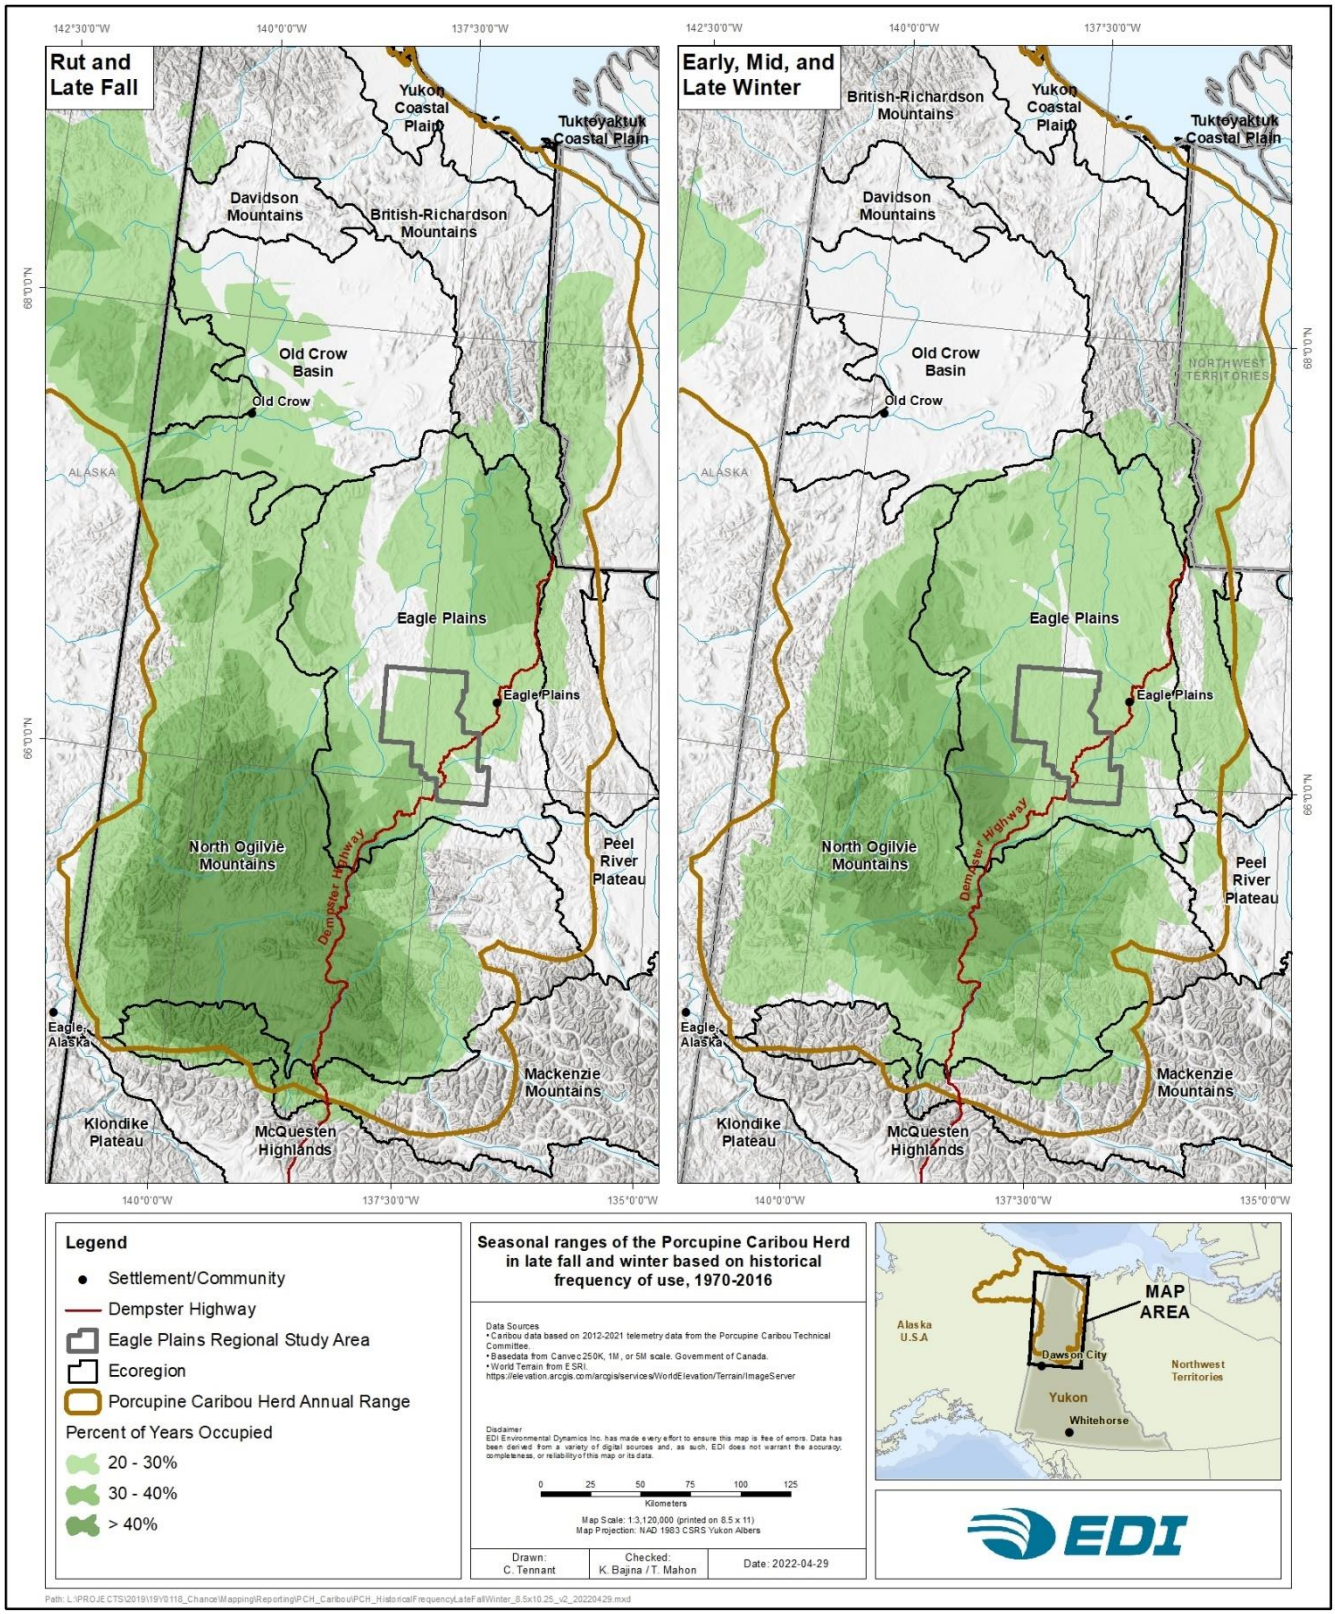
Only two seasonal life cycle periods had relatively frequent overlap (i.e., >20 % across years) with the RSA: (1) rut and late fall, and (2) early, mid, and late winter. For simplicity in this and subsequent analyses, these two periods are referred to as 'late fall' and 'winter' seasons. The RSA overlaps a relatively small portion of the seasonal ranges for both late fall and winter seasons: 5.97% in late fall and 6.54% in winter (Map 6-3). The greatest overlap occurred with the 20–30 % frequency of use areas; 5.90% and 6.12% of late fall and winter ranges, respectively (Table 6-3). No overlap occurred between the Project RSA and the most frequently used areas (>40 %) for either season.

PCH caribou have a wide-ranging distribution in late fall and winter and occupy a large portion of northern and central Yukon. Though some use occurs in the Project RSA and the broader Eagle Plains ecoregion, more frequent use occurs further southwest in the taiga cordillera of the North Ogilvie Mountains in late fall and

winter, and in the Richardson Mountains in late fall (Map 6-3). As discussed in the background sections, Section 6.2.2 *Seasonal Ranges and Movements* and Section 6.2.3.1 *Effects of Snow*, the distribution of the PCH in winter varies across four regions with different snow regimes: Yukon/Alaska border, Richardson Mountains, Ogilvie/Hart region, and the Whitestone/Eagle region (Russell et al. 1993). Use of the Whitestone/Eagle region is highest in years with lower than average snowpacks.

Table 6-3. Percent overlap of the Porcupine Caribou Herd late fall and winter ranges with the Project RSA based on the annual frequency of use by caribou, 1970–2016.

Seasonal Range	Annual Use by Caribou (%)	Percent Overlap with RSA (%)
Late Fall	< 20%	0.55
	20–30%	5.90
	30–40%	0.07
	> 40%	0.00
Winter	< 20%	0.07
	20–30%	6.12
	30–40%	0.42
	> 40%	0.00



Map 6-3. Annual frequency of use by the Porcupine Caribou Herd in late fall and winter ranges relative to the RSA, 1970–2016.

6.5 HABITAT USE

The general distribution of PCH caribou across seasons provides some context for their potential interaction with, and overlap of, the Project RSA. However, to caribou, all space on the landscape is not equivalent. Habitat needs to be considered to predict how often caribou might occur in the area based on the amount and distribution of necessary resources, such as forage. To better understand how PCH caribou use habitat across their late fall (including rut) and winter (i.e., early, mid, and late season) ranges, statistical models were developed to describe the relationship between caribou locations and relevant habitat components. These models considered habitat available to caribou broadly across their seasonal range. Habitat models were developed for late fall and winter using GPS location data (2012–2021) of satellite-collared caribou provided by the PCTC. Habitat model outputs were used to estimate the amount and distribution of habitat within the Project RSA and across the PCH's late fall and winter ranges.

The chosen models for late fall and winter performed reasonably well in predicting PCH caribou habitat selection based on several measures of model performance. Light macrolichen cover was the key driver of caribou habitat use in both seasons, though preference for lichen was strongest during winter. During late fall, caribou tended to select flat, mid-elevation regions near large waterbodies. During winter, caribou tended to select flat areas at low and high elevations while remaining distant from waterbodies. Caribou also avoided areas with dense conifer trees, shrub (deciduous and evergreen), forb, and graminoid cover. Base habitat models predicted the distribution and proportion of selected habitat in the Project RSA to be approximately equivalent during late fall and less during winter relative to the full extent of those seasonal ranges.

6.5.1 METHODS

6.5.1.1 Spatial Extent

Habitat modelling was conducted across the Yukon portion of the late fall and winter seasonal ranges defined in Section 6.5, *Seasonal Distribution* (i.e., areas with >20% frequency of annual use). Analyses were limited to the Yukon portion of late fall and winter ranges because of the potential differences in the ecology of caribou occupying Alaska versus Yukon. Using the full Yukon range yields the benefit of identifying broad patterns of habitat selection that affect the territory-wide distribution of the PCH. However, use of a broader scale may dilute patterns of habitat selection at local scales, e.g., only within Eagle Plains ecoregion. Whether such dilution leads to a loss of information depends on caribou habitat preferences in different ecoregions.

6.5.1.2 Data Preparation

The PCTC provided EDI with GPS location data (2012–2021) of satellite-collared PCH caribou. These data covered the entire annual range of the PCH and were reduced to include locations only within the late fall and winter range extents, as described above. The reduced data set consisted of 164 caribou in late fall and 172 caribou in winter. Most of these data (39.02% in late fall and 42.74% in winter) were attributed to locations collected in 2020–2021.

Spatial habitat data were acquired to relate caribou locations to environmental conditions within fall and winter seasonal ranges (as defined above) and, where appropriate, account for variation in conditions across time. For example, temporal changes (from 2010 to 2020) in the distribution of plant functional types (PFTs) due to grazing, fire, and climate-driven vegetation dynamics were captured using predicted top cover percentage (%) raster layers developed by Macander et al. (2022). Based on initial data exploration exercises, the PFTs that were considered ecologically relevant to habitat use of the PCH included light macrolichens (also see Macander et al. 2020), graminoids, forbs, evergreen shrubs, deciduous shrubs, and conifer trees. Data for topography on the landscape were acquired from a Digital Elevation Model (DEM; 1:250,000) for Yukon and were used to develop measures of absolute elevation (metres), slope percent (slope tool in the Spatial Analyst extension, ArcGIS 10.7; ESRI 2019), aspect (degrees), and a terrain ruggedness index (TRI; Sappington et al. 2007). A measure of relative elevation was created by combining absolute elevation and a simplified stream network (CanVec; nearest main watercourse from a 1:1,000,000 scale watercourse layer) and then employing the HAR tool from the Riparian Topography Toolbox in ArcGIS (Dilts 2015). A CanVec (1:1,000,000) waterbody layer was also used to map distances to waterbodies >1 ha. Caribou may use frozen waterbodies as an antipredator tactic to increase sightlines. They may also be mineral licks (Ferguson and Elkie 2005).

6.5.1.3 Statistical Models

Determining which resources (habitat features) are selected most often by animal populations is important because it provides information about how those animals meet fundamental requirements for survival and reproduction (Manly et al. 2002). Resource selection functions (RSF) are a statistical method that quantifies how resources are chosen by relating animal observations to resources available across the landscape. RSFs predict the probability of an animal occurring at specific locations (e.g., within a study extent) based on the combination of resources available at those locations. Results of a RSF can be mapped to identify important areas of resource selection for caribou and, therefore, can inform the conservation and management of the species.

Caribou observations were first overlayed with environmental spatial data layers to develop RSFs for PCH late fall and winter ranges. Environmental values were extracted for each known location of caribou plus ten times as many randomly sampled locations (spaced a minimum distance of 50 m apart). Availability was deemed global, so available locations were randomly selected within the late fall and winter study areas. Independence among observations of caribou was assumed by resampling caribou locations to a maximum of one per day. Available locations were compared to locations known to be occupied or 'used' by caribou to identify the combination of resource units preferred by caribou. Logistic regression was used to develop RSFs within a generalized linear mixed model framework. The general formula for logistic regression is as follows:

$$logit(P) = \beta_0 + \beta_1 x_1 \ldots \beta_n x_n + Y$$

where the predicted value P is dependent on the linear predictor ($\beta_0 + \beta_1 x_1 \ldots \beta_n x_n$) through a logit-link function, and x is the *i*-th environmental covariate and β is its associated coefficient. An interaction was included between Ecoregion and macrolichen cover to account for the varied distribution, and possibly selection, of lichen among ecoregions. An additional random effect term, Y, was added to account for (a) the

variation in habitat selection associated with each caribou year and (b) the unequal sample sizes among years. Large weights were applied to all available locations ($weight_{avail}$ = 1,000) relative to used locations ($weight_{used}$ = 1) to ensure that parameter estimates were not biased by the sampling ratio of used and available points (Muff et al. 2020). The linear predictor was used to calculate the probability of selection P:

$$P = \frac{e^{(\beta_0+\beta_1 x_1 \ldots \beta_n x_n+Y+E)}}{1+e^{(\beta_0+\beta_1 x_1 \ldots \beta_n x_n+Y+E)}}$$

where e is the natural exponential function and P is bounded by $0 < P < 1$.

6.5.1.4 Exploring Covariate Relationships

Before analyses, all continuous covariates, such as PFT top covers, elevation, slope, TRI, HAR, and distance to waterbodies, were standardized to have a mean of zero and a standard deviation of one. Standardizing the values across covariates ensures model convergence and improves the ability to rank the relative importance of each covariate in a model. The aspect was converted from continuous (degrees) to categorical (cardinal directions) based on 90° intervals. To prevent biased estimates of coefficients and inflated errors, multicollinearity among covariates was assessed using a correlation matrix (dropping variables with Pearson's product moment correlation $|r| > 0.7$ [see Dormann et al. 2013]) and variance inflation factor scores (dropping variables with VIF scores > 3 [Zuur et al. 2009]). For example, absolute and relative (HAR) elevation in winter were highly correlated (r = 0.69). The decision to choose one over the other was based on univariate response curves assessed using generalized additive modelling (GAM; see below). In other words, of the highly correlated covariates, the one with the greatest selection response (slope) was chosen. In this case, absolute elevation was retained over HAR.

Data exploration consisted of (1) univariate analyses with the response variable (i.e., used versus available), and (2) univariate and multivariate GAMs to assess the potential marginal effect of each covariate on the (non-linear) shape of the response curve (i.e., probability of use). These exercises informed model development. For example, rather than assuming a linear increase for percent light macrolichen cover, the variable was logarithmically transformed to fit the expectation that the probability of selection increased at incrementally smaller values as the quantity of lichen in a patch increased (Figure 6-2). Additionally, different patch sizes were considered for PFT covers by estimating the mean percent cover within 100 m, 500 m, and 1,000 m buffers around used and available points.

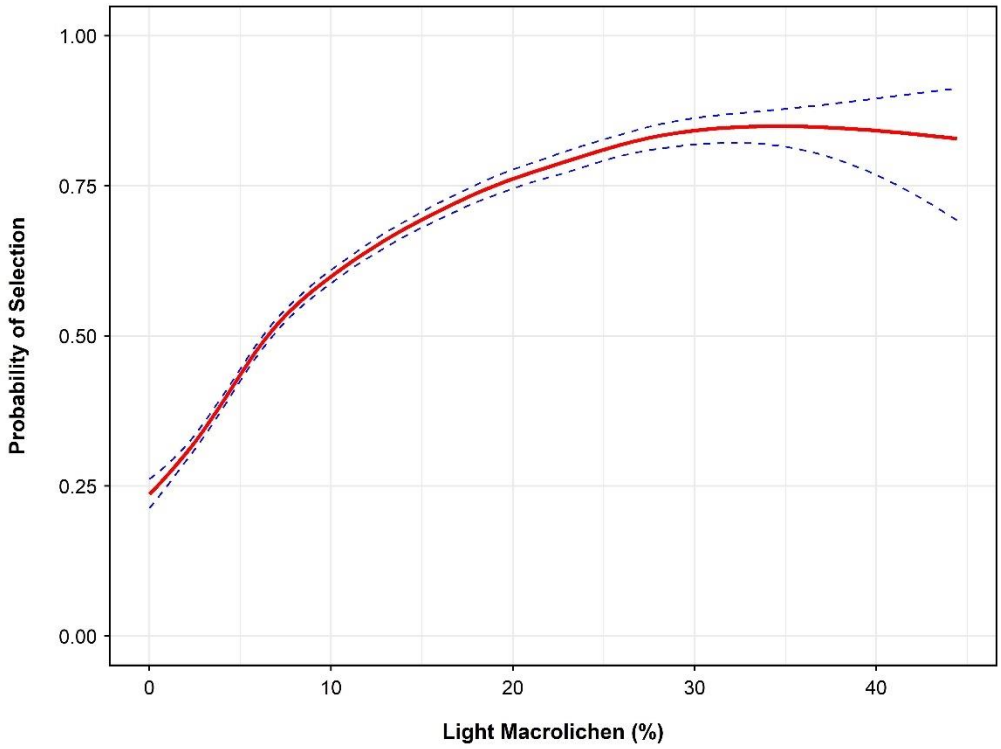


Figure 6-2. Generalized additive model assessing the probability of selection of light macrolichens by PCH during winter.

6.5.1.5 Model Selection and Validation

Habitat models were selected for late fall and winter by implementing 'full' models (with all relevant covariate terms) and assessing the variation explained by the inclusion of each covariate. The best models were chosen based on (1) statistical considerations using Akaike's information criterion (AIC; Burnham and Anderson 2002), which balances the trade-off in the amount of variance explained (i.e., model likelihood) with the number of parameters considered, and (2) ecological significance to caribou in the late fall and winter seasons. Since the goal of the model was prediction, as many covariates as necessary were retained. Thus, alternative candidate models were considered not by testing competing hypotheses but rather by dropping covariates with low magnitude (scaled) coefficients $< |0.1|$. Model diagnostics were run on simulated residuals to assess (a) goodness-of-fit (i.e., Kolmogorov-Smirnov test), (b) issues related to dispersion, (c) the frequency of outliers, (d) variance among categorical predictors, and (e) quantile regressions of observed versus expected residuals.

The predictive performance of late fall and winter models were assessed using a 5-fold cross-validation approach as per the steps outlined in Johnson et al. (2006). (1) The original data were partitioned into 5-fold groups. For each iteration of the evaluation procedures, four groups were combined into the training dataset. The remaining group was used as the testing dataset. (2) The RSF was estimated for each training dataset. (3) RSF values from the training dataset were predicted in a GIS and reclassified into 10 quantile rank bins. (4) Midpoint (median) values of raw RSF scores were calculated for each quantile bin. (5) Percent utilization was

calculated for each quantile bin using equation 4 in Johnson et al. (2006). (6) The number of used observations from the testing dataset that fell in each quantile bin were counted. (7) The number of expected observations from the testing dataset was calculated for each quantile bin using equation 5 in Johnson et al. (2006). (8) Observed versus expected counts and proportions from the testing dataset were compared and tested formally using linear regression, spearman's rank correlation, chi-square goodness-of-fit (i.e., observed versus expected counts), and tests of proportions for each quantile bin (i.e., chi-square observed versus expected proportions). These steps were repeated until each fold was used as the testing dataset. The 5-fold cross-validation procedure was implemented for several candidate models for both late fall and winter to determine whether simpler models yielded more accurate predictions.

6.5.1.6 Habitat Quality, Amount, and Distribution

Models selected for late fall and winter were used to generate predictive habitat maps across those seasonal ranges. These mapped predictions aimed to identify the amount and distribution of habitat available to PCH caribou. To facilitate the comparison of relative habitat quality across the study area, the RSF predictions were classified into four ordinal ratings: Very Low, Low, Moderate, and High. To help objectively define ecologically relevant classification of the RSF values we conducted a post-hoc selection-ratio test of the caribou locations against the RSF predictions. This approach identified the point within the RSF value range where values switch from avoided to being selected. The portion of the 'selected' RSF value range was divided at the midpoint into the Moderate and High ratings and the portion of the 'avoided' range was divided at the midpoint into the Very Low and Low ratings. For example, for RSF output with a range from 0 to 1, if the selection-ratio calculation determined the breakpoint between avoidance and selection occurred at 0.6, the habitat quality ratings would be Very Low = 0.0-0.3, Low = 0.3-0.6, Moderate = 0.6-0.8, and High = 0.8-1.0.

To determine the breakpoint within the RSF value range that switched from avoided to selected, the frequency distributions of mapped RSF predictions were partitioned into 50 quantile bins with each bin consisting of two-percentile intervals. Selection ratios were calculated for each quantile bin by associating mapped RSF predictions to used and available collar locations and then assigning each location to a quantile bin. The selection ratio for each bin was calculated as follows:

$$SR_{bin} = \frac{Used_{prop} - Avail_{prop}}{Avail_{prop}}$$

where $Used_{prop}$ and $Avail_{prop}$ are the proportion of used and available locations in each quantile bin. Selection ratios were used to categorize habitat quality into the discrete ratings discussed above (i.e., Very Low, Low, Moderate, and High). The bin at which selection ratios switched from negative to positive identified the threshold between Low and Moderate quality habitat. Very Low quality habitat was identified based on the midpoint between the smallest quantile bin and the Low/Moderate quality habitat threshold. Similarly, the midpoint between the Low/Moderate quality habitat threshold and the largest quantile bin differentiated Moderate and High quality habitat. For certain management questions or purposes, it may be adequate to just use two habitat classes—avoided or selected. Subdividing those into the four ratings provides further resolution for certain management questions or objectives. For example, when comparing different

road route options that must traverse an area of 'selected' habitat, potential impacts are expected to be minimized by locating the road in Moderate versus High habitat areas.

RSF frequency distributions were extremely right skewed so that very high RSF values were low in frequency. This issue arises when dealing with RSFs with 'infinitely weighted' available locations, which has become standard practice in recent years (e.g., Muff et al. 2020). In late fall and winter RSFs, the ratio of used to available locations was 1:10 with an additional large weight (i.e., 1,000) assigned to each available location. These large weights effectively reduce RSF predictions to very small decimal numbers and skews their distribution. To ensure that this skew did not underestimate the amount of High versus Moderate quality habitat, all RSF values equal to or greater than the 98th percentile were fixed at that value. Thus, there were effectively 49 quantile bins, in total, because all predictions in the 50th bin were assigned to the 49th bin.

To compare the amount and distribution of selected habitat within the Project RSA (~2,386 km^2) to the broader landscape, the amount of selected habitat was assessed within similar sized polygons across the seasonal ranges. A grid composed of 50 km x 50 km (2,500 km^2) cells was placed over the Yukon extent of the PCH ranges, and the proportion of selected habitat was assessed for each cell.

6.5.1.7 Statistical and Geospatial Software

All statistical analyses were completed in R software for Statistical Computing, version 4.1.0 (R Development Core Team 2020). Package 'mgcv' (Wood 2011) was used to develop and assess non-linearity in response-covariate relationships using generalized additive modelling. Package 'glmmTMB' (Brooks et al. 2017) was used to fit generalized mixed-effects models. In addition to visual assessment of covariate-response relationships, package 'DHARMa' (Hartig 2021) was used to assess simulated model residuals (e.g., goodness of fit, dispersion, outliers, heteroscedasticity). Package 'groupdata2' was used to partition data into training and testing datasets; it was especially useful for partitioning a consistent number of used and available locations among the data folds. All geospatial analyses were completed in R, version 4.1.0 (R Development Core Team 2020), QGIS (QGIS Development Team 2020), and ArcGIS, version 10.7 (ESRI 2020).

6.5.2 RESULTS AND DISCUSSION

6.5.2.1 Habitat Models

The selection of late fall and winter habitat models required an iterative model fitting, testing, and cross-validation process. The appropriate patch size (i.e., 100 m, 500 m, or 1,000 m) of each PFT was selected based on GAM plots to identify which patch size corresponded with the greatest change (slope) in selection. Initial model selection procedures determined that 'full' models, with all possible covariates, were the most parsimonious for late fall (No. 1 in Table 6-4) and winter (No. 1 in Table 6-5) RSFs. However, the 'full' model for late fall did not yield the best predictive performance based on the 5-fold cross-validation procedure. The best performing model for late fall excluded the effects of all PFTs except lichen (No. 3 in Table 6-4; Table 6-6), which yielded a better fit between observed and expected proportions across 10 quantile bins based on regression (i.e., higher R^2; intercepts closer to zero and slopes closer to one), tests of proportions

(i.e., greater number of equivalent observed/expected bins), and spearman rank correlations (i.e., larger correlation coefficients). See Section 5.6.1 for plots and summaries of 5-fold cross-validation results for the selected late fall RSF model. Regressions for each fold had very strong fits (all $R^2 > 0.93$) but did have intercepts that differed from zero and slopes that differed from one. The primary reason for this deviation was a greater number of observed proportions in the largest (10th) quantile bin, whereas all other bins were close to the line of unity (1:1 ratio). Spearman rank correlations were consistently very high (all $r > 0.98$ and $p < 0.001$). The mean number of bins in which observed proportions were no different than expected proportions, across all five folds, equalled 5.2 (low = 4, high = 8).

The best performing model for winter consisted of the full parameterization (No. 1 in Table 6-5; Table 6-7), which yielded a better fit between observed and expected proportions across 10 quantile bins based on regression (i.e., higher R^2; more intercepts closer to zero and slopes closer to one), tests of proportions (i.e., greater number of equivalent observed/expected bins), and spearman rank correlations (i.e., larger correlation coefficients) than any alternative candidate model. See Section 5.6.1 for plots and summaries of 5-fold cross-validation results for the selected winter RSF model. Regressions for each fold had strong fits (all $R^2 > 0.79$) and had intercepts that were no different than zero and slopes that were no different than one. Spearman rank correlations were consistently very high (all $r > 0.98$ and $p < 0.001$). The mean number of bins in which observed proportions were no different than expected proportions, across all five folds, equalled 5 (low = 3, high = 6). In conclusion, both late fall and winter model had a fair agreement between observed and expected proportions and had very high spearman rank correlations, which suggests that these models perform adequately for prediction (e.g., see Johnson and Russell 2014, White and Gregovich 2017, Johnson et al. 2020).

Habitat use varied moderately between late fall and winter. Although selection coefficients were highest for macrolichen cover and elevation in both seasons, the relationships varied somewhat, and the extent of Moderate and High rated habitat was reduced in winter compared to late fall. Selection (positive coefficient) for macrolichen cover, the most relevant plant functional type in either season, was greater in magnitude during winter (Table 6-7) than during late fall (Table 6-6). Though the magnitude of selection for macrolichen varied by ecoregion (i.e., interaction), the best-fitting patch size for the selection of macrolichen was consistently 100 m. However, patch size varied for other plant functional types considered during winter (Table 6-7; e.g., conifer tree cover versus forbs). During late fall, caribou selection (positive coefficients) of vegetation was solely driven by lichen cover. Meanwhile, during winter, caribou tended to avoid (negative coefficients) other PFTs such as conifer trees, forbs, graminoids, deciduous shrubs, and evergreen shrubs. The lack of selection/avoidance of other PFTs during late fall is likely the result of more diverse forage use in late fall than in winter and individual variation in habitat choice. Such variation is consistent with a broad habitat selection pattern at the population-level, which led to the poorer predictive performance of late fall models that included other PFT covers.

Preference of absolute elevation also varied between the seasons. Caribou occupied primarily mid elevations (approximately 750 m) during late fall (Table 6-6) but selected low and high elevations during winter (Table 6-7). Caribou also varied in their proximity to waterbodies >1 ha between seasons. Caribou tended to be closer to such waterbodies (negative coefficient) during late fall but remained farther (positive coefficient)

during winter. The ecological basis for these relationships to waterbodies is unclear, but the covariates were retained in the models because they improved predictive performance.

Coefficients associated with lichen cover were of the greatest magnitude, which suggests that the selection of lichen is the primary driver of habitat selection in late fall and winter. This pattern in vegetation use across both seasons is consistent with what is expected of PCH caribou diet and ecology (Thompson and McCourt 1981, Russell et al. 1993). Late fall and winter diets are mostly composed of lichens (and mosses). Though there is some evidence that caribou may forage on evergreen shrubs and deciduous shrubs during late fall (Russell et al. 1993), this pattern was weak, and these covariates were not included in the final model. Another similarity in selection among seasons was in terms of slope and aspect. Caribou avoided steep slopes (negative coefficients, logarithmic) and selected south- and west-facing aspects, which receive greater solar radiation than east- and north-facing aspects. This pattern could be attributed to productive lichen patches during both seasons and to decreased snow depth due to melt and wind during winter.i

Selection gradients (i.e., the degree of preference/avoidance) were greater during winter than late fall. This is likely because forage was more broadly available across different habitats due to lower snowpacks in late fall and because more locations in the late fall were likely associated with travelling than foraging. Though caribou distribution is broader in winter, there was clearly a stronger preference (positive coefficient) for light macrolichens and a stronger avoidance (negative coefficient) of areas with high cover of conifer trees. Stronger preference and avoidance in winter may result in more concentrated forage on lichen and from snow constraints on caribou distribution.

Temporal patterns of habitat selection also varied between late fall and winter. Habitat selection seemed to be fairly consistent across years in late fall but varied from winter to winter. A very small portion of the overall variance ($\sigma^2 = 0.00021$) in habitat selection could be explained by year effects during late fall. This model contributed little to the overall model likelihood and was penalized for an additional parameter ($AIC_\Delta = 2$); thus, year effects were not included for the late fall model. However, during winter, a year effect explained a sufficient amount of variation ($\sigma^2 = 0.013$) in habitat selection to warrant inclusion in the final model (i.e., $AIC_\Delta = -90.9$ with year effect). Variation among years was likely greater in winter due to the effects of snow across the landscape, which can broadly affect the distribution of PCH caribou and their foraging habits.

Snow accumulation and distribution is invariably an important factor affecting habitat selection by PCH caribou at multiple scales. At fine spatial scales, snow depth, density, and hardness can limit access to terrestrial lichens (Johnson et al. 2001). Although snow depth data were not available, elevation was considered as a suitable surrogate. In the winter RSF, caribou exhibited selection for low and high elevations and avoidance of mid elevations, where snowpacks are often deepest. Indeed, Pedersen et al. (2021) identified a significant correlation ($r > 0.6$) between elevation and snow depth in 33% of winters during their study of another barren-ground caribou herd, the Central Arctic Herd. The amount of snowfall and snowpack at broad spatial scales can cause the PCH to occupy different core wintering regions. For example, PCH caribou occupy the Ogilvie/Hart and Richardson Mountains regions on a rotational basis because these regions receive less snow than adjacent areas (Russell et al. 1993). This pattern is consistent with the current data, whereby GPS-collared PCH caribou occupied different ecoregions at different intensities (i.e., number of individuals and locations) across time.

Though snow depth could not be considered explicitly in habitat models, the variation estimated among years and differences in the use of ecoregions and elevations were considered to partially account for the influence of snow. These variables are considered coarse correlates of snowpack patterns across the landscape (Russell et al. 1993), yet, the exclusion of an explicit snowpack covariate does limit fine-scale predictions of how snow affects caribou resource selection. Ultimately, snow depth is probably the primary, ecologically relevant metric that would supplement the current covariate suite and provide greater insight on winter selection patterns. Available snow covariates were examined and deemed not to be useful. For example, information on snow prevalence, date of the first snow, or snow cover are not inherently useful because caribou (and other ungulates) are not constrained in their movements and foraging by shallow snow. Given these considerations, it was deemed more appropriate to account for the coarser effects of snow depth using ecoregion and elevation rather than using a snow cover that may be misleading both ecologically and mechanistically, resulting in a spurious correlation.

6.5.2.2 Predicted Habitat Distribution

Predicted habitat quality, amount, and distribution depended on the magnitude of resource selection and the distribution of habitat covariates across the landscape (i.e., primarily light macrolichen cover). Predictions from habitat models for late fall and winter were classified into four ordinal habitat quality ratings (i.e., Very Low, Low, Moderate, or High quality). See Section 6.9.2 for plots that demonstrate the switch from negative to positive selection ratios across quantile (two-percentile) bins for late fall (31st quantile bin [60th–62nd percentile]; Attachment Figure 11 and Attachment Figure 12) and winter (30th quantile bin [58th–60th percentile]; Attachment Figure 15 and Attachment Figure 16). Furthermore, Section 6.9.2 provides plots of (a) selection ratios associated with each habitat rating and (b) the proportion of the late fall and winter ranges composed of each habitat rating. In general, Very Low quality habitat had low, negative selection ratios while High quality habitat had high, positive selection ratios. Approximately 60% of the late fall and winter ranges consisted of avoided (Very Low and Low) habitat, and 40% consisted of selected (Moderate and High) habitat.

The distribution of habitat across the landscape differed between late fall (Map 6-4) and winter (Map 6-5) ranges. The proportion of selected late fall habitat in the Project RSA (0.404) was equivalent to the mean proportion in the broader late fall range when accounting for variance in that estimate (Table 6-8). In contrast, the proportion of selected winter habitat in the Project RSA (0.265) was substantially less than the mean proportion in the broader winter range (0.411) (Table 6-8). Though mean estimates of selected habitat in the broader late fall and winter ranges were approximately 0.40, there was considerable variation among the 50 km x 50 km cells used in the analyses. In the late fall range, the lowest and highest proportions of selected habitat were 0.140 and 0.881, respectively. Cells with the lowest proportions were located mostly along the western edge of the late fall range (i.e., high elevations in the North Ogilvie Mountains), and cells with the highest proportions were located mostly along the eastern edge of the late fall range (i.e., Eagle Plains ecoregion transitioning into Richardson Mountains). The lowest and highest proportions of selected habitat in the winter range were 0.106 and 0.764, respectively. Cells with the lowest proportions were located centrally in the winter range (i.e., Eagle Plains ecoregion) and cells with the highest proportions were located mostly along the eastern and southern edge of the winter range (i.e., Richardson mountains and North Ogilvie Mountains).

In the Project RSA, selected late fall habitat was concentrated at mid-elevation plateaus and depended on the amount of lichen cover. For example, a large patch of High quality habitat occurred adjacent (south side) to the Dempster Highway (inset in Map 6-4); this patch occurred on a large mid-elevation plateau, in proximity to waterbodies >1 ha in size, and relatively high amounts of lichen cover. In fact, several portions of the Dempster Highway intersected either Moderate or High quality habitat at mid-elevations and with moderate lichen cover. Across the broader landscape, the greatest amount of selected habitat occurred within the southern extent of the North Ogilvie Mountains ecoregion, the western extent of the British-Richardson Mountains ecoregion, and in large areas at the eastern extent of the Eagle Plains ecoregion (Map 6-4). Avoided habitat primarily occurred at low elevation valley bottoms or high elevations (> 750 m, e.g., at the peaks of British-Richardson Mountains) in areas with low lichen and vegetative cover.

Winter habitat occurred primarily at either valley bottoms with open stunted spruce or high elevations with sparse tree cover and high macrolichen cover. Selected habitat was also distant from large waterbodies and

wet environments containing forbs and graminoids, as well as areas with high cover of deciduous or evergreen shrub. In the RSA, selected habitat was localized in specific regions. For example, a large extent of High quality habitat occurred at the northern extent of the RSA, on the west side of Chance creek (Map 6-5). This area is low in elevation and has relatively high lichen cover. Two other large patches of High quality habitat occur at the southern extent of the RSA, both associated with low elevation and very high lichen cover. Although mid-elevations have relatively lower RSF predictions, in general, certain mid-elevation areas with high lichen cover, such as the areas along the Dempster Highway for late fall habitat are also predicted to offer Moderate or High quality winter habitat (inset in Map 6-4). Across the broader landscape, large extents of selected habitat occurred in the Richardson Mountains, the Ogilvie Mountains, and northern extents of Eagle Plains ecoregion. The greatest amount of avoided habitat (Very Low and Low) also occurred in Eagle Plains due to large areas of recent wildfire and its vast mid-elevation plateaus.

The use of multiple habitat ratings, as opposed to a binary classification (e.g., suitable versus unsuitable), was necessary to retain high resolution information on the distribution of habitat quality. For example, there were stark differences in the amount of lichen cover in areas of Moderate versus High quality habitat, and this can have implications for timing and extent of Project operations. Map 6-6 provides a comparison between winter habitat quality ratings and macrolichen cover in the Project RSA. There is a clear distinction between areas of high versus low macrolichen cover. There are several High quality ratings that occur along circular and N-S oriented ridges at the southwest corner of the RSA. Adjacent areas of similar elevation but with low macrolichen cover, transition from Moderate to Very Low in quality. Since macrolichen cover is the strongest driver of resource selection by PCH caribou during winter, it is important to be able to distinguish these high-value regions for management purposes.

Table 6-8. Proportion of selected (Moderate and High) caribou habitat in the Project RSA relative to the mean (and std. error) of 50 km x 50 km cells covering late fall and winter range extents.

Season	Scale	Proportion of Moderate and High Quality Habitat	Std. Error
Late Fall	Project RSA (2,387 km² total)	0.404	–
	Late Fall Range (88,149 km²) [1] (2,500 km² per cell) – 53 cells total	0.415	± 0.025
Winter	Project RSA (2,387 km² total)	0.265	–
	Winter Range (65,077 km²) [1] (2,500 km² per cell) – 40 cells total	0.411	± 0.026

[1] Late fall and winter ranges were subsampled using 2,500 km² cells (approximately the same size and the RSA) to facilitate estimation of mean and variance.

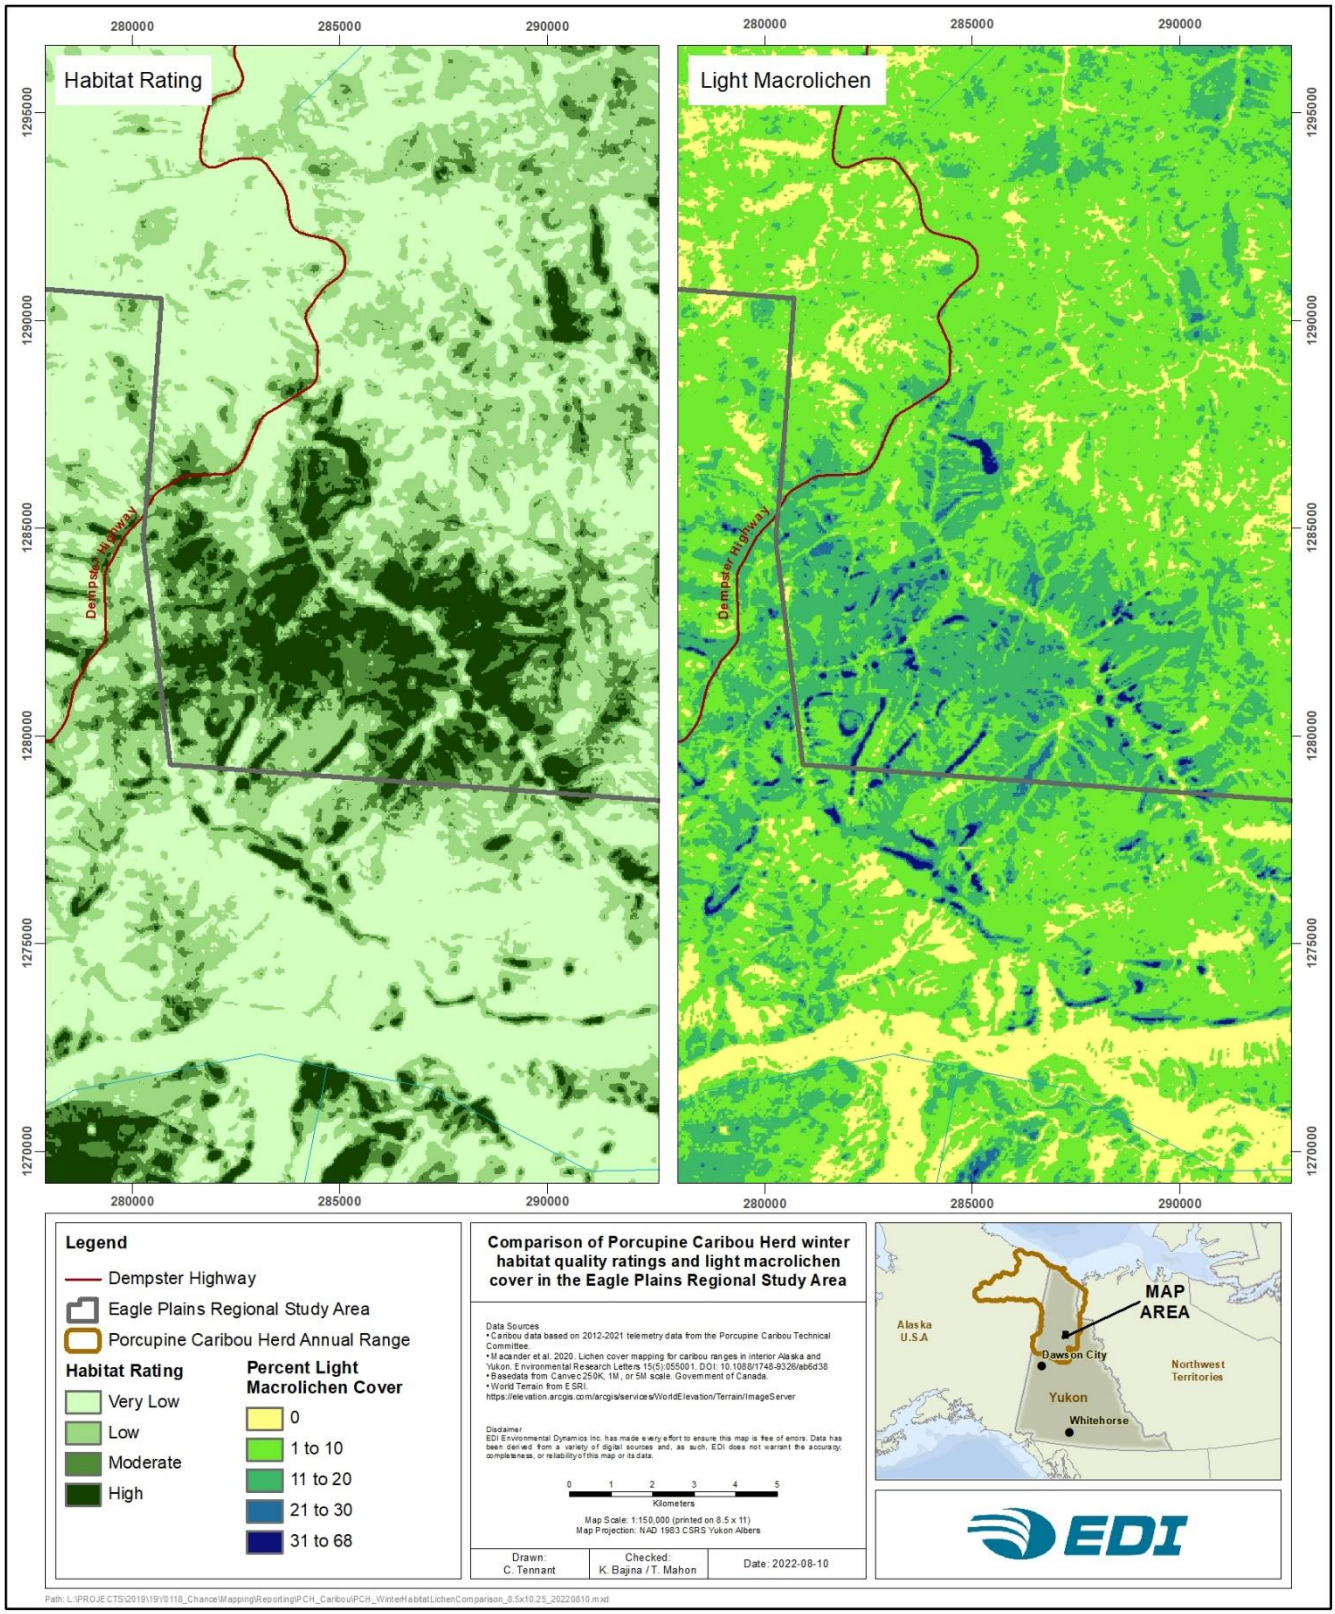


Map 6-6. Comparison of Porcupine Caribou Herd winter habitat quality ratings and light macrolichen cover in the Eagle Plains Regional Study Area.

6.6 MOVEMENT

In addition to habitat selection, movement patterns across the seasonal ranges and within the vicinity of the Project RSA are important to understanding how the PCH may interact with the Project. Metrics such as daily travel rates and duration of residency (i.e., how long caribou spend in an area before moving on) help quantify how caribou use the landscape and how they may react to features, such as the Dempster Highway. In addition to movement metrics, the spatial locations of travel movements can define areas of concentrated movement during migration. To better understand factors affecting PCH caribou movement, two analyses were conducted: (1) calculation of daily movement rates and residency times of caribou in the Project RSA relative to the broader landscape, and (2) delineation of movement paths to assess broad-scale movement patterns and the potential for caribou to interact with the Project.

The PCH typically exhibit movements of several kilometres per day in both late fall and winter. Late fall daily movements (8.7 km/day in the RSA) were substantially greater than those during winter (4.4 km/day in the RSA), and caribou tended to occupy portions of the landscape for shorter periods during late fall than during winter. Caribou residency times in both seasons were two-fold greater in the broader landscape than within the Project RSA, suggesting that, on average, the RSA, is used as more of a transitory area than other portions of the seasonal ranges. The locations and patterns of movement during late fall (i.e., the end of the fall migration period) was variable within and across years and, overall, there was little evidence of dedicated migration corridors. However, in late fall of 2015, several caribou made directed movements along the height of land parallel to the Dempster Highway, from the northeast to the southwest. Although a small number of movements crossed the Dempster Highway, most movements stayed north of the Dempster Highway, potentially reflecting avoidance of the Dempster Highway. However, this series of movements did cross numerous 2D seismic lines, winter roads and a large 3D seismic grid in the RSA.

6.6.1 METHODS

6.6.1.1 Daily Movement Rates and Residency Times

Daily movement rates and residency times were calculated for each radio-collared caribou that occurred in late fall and winter range extents. The locations of each caribou were resampled to obtain one GPS fix per day. Movement rates were calculated as the speed (km/day) travelled between consecutive relocations and residency time was calculated as the number of days within a specified area. Movement rates and residency times were calculated for caribou occurring within the Project RSA (2,387 km^2) and, to compare to the broader landscape, metrics were also calculated within 50 km x 50 km (2,500 km^2) grid cells that covered fall and winter ranges. Means and standard errors of movement rates and residency times were calculated for all 50 km x 50 km cells and compared to mean values in the Project RSA.

6.6.1.2 Migration Movements

Travel routes were delineated by developing occurrence-use polygons that assessed the trajectory of each collared caribou during late fall, 2012-2021. These polygons were created using Brownian bridge movement models (BBMMs), which account for autocorrelated movements in animal relocations and assume that an animal's trajectory follows a diffusion-based (Brownian motion) process (Horne et al. 2007). BBMMs were developed, and kernel density estimation was used to predict 95% utilization distributions (UDs) for each animal, assuming a GPS location error of 100 m and implementing a grid-cell size of 500 m. Analysis was bounded to a 100 km buffer around the RSA to identify spatially relevant movement trajectories. BBMMs and UD polygons were created using the R package 'adehabitatHR' (Calenge 2006).

6.6.2 RESULTS AND DISCUSSION

6.6.2.1 Daily Movement Rates and Residency Times

Mean daily movement rates and residency times varied considerably between late fall and winter and between the Project RSA and the broader landscape. On average, caribou tended to move faster during late fall than during winter, and this was evident both in the Project RSA and across the full late fall range. The movement rates between the Project RSA and the broader landscape were greatest during late fall, i.e., at least a two-fold difference in movement rates outside versus inside the RSA. A similar outcome was evident for residency time inside versus outside the Project RSA. In both seasons, the residency time was at least twice as long outside the RSA than within it (Table 6-9).

Patterns in movement and residency were consistent with what is known about PCH caribou ecology. Caribou are at their most dispersed in both late fall and winter. Except for cows during the calving period, daily movements are lowest in winter and second lowest in late fall (Russell and Gunn 2017). Normally, faster movement rates are associated with shorter residency periods, but this was not the case for the PCH in late fall (Table 6-9). During late fall, caribou in the RSA had slower movement rates but also had shorter residency periods compared to the broader late fall range. A review of the movement trajectories indicates that although travel rates were slower inside the RSA, those paths had greater directional bias (i.e., movement in a single direction) than paths outside the RSA, which exhibited much more tortuosity. These more directed movement paths resulted in shorter residency periods, despite the slower movement rates.

During winter, caribou movement rates inside the RSA were similar to the broader landscape, but, similar to late fall, their residency time inside the RSA was significantly shorter than in the broader late fall range. This suggests that similar to the pattern in late fall, caribou tended to pass through the RSA in winter more quickly than other portions of the broader winter range. This pattern may be explained by the lower predicted habitat quality within the RSA relative to the broader landscape (see Section 6.5.2.2, *Predicted Habitat Distribution*, above). The faster movements and shorter residency times in late fall compared to winter likely reflect the tail end of fall migration movements. Notwithstanding the important differences in movement patterns between late fall and winter, the key results of these analyses are that, in both late fall and winter, PCH caribou (1) travel

several kilometres per day, on average, and (2) the RSA (or similar sized areas outside the RSA) are used for a relatively short portion of the overall season.

Table 6-9. Mean daily movement rates and residency times of the Porcupine Caribou Herd in the Project RSA relative to the mean (and standard error) of 50 km x 50 km cells covering late fall and winter range extents.

Season	Scale[1]	Daily Movement (km/day)		Residency Time (days) [2]	
		Mean	Std. Error	Mean	Std. Error
Late Fall	Project RSA (2,387 km² total)	8.95	± 0.64	4.50 (8.33 %)	± 0.83
	Late Fall Range (88,149 km²) [1] (2,500 km² per cell) – 53 cells total	15.03	± 2.06	7.65 (14.17 %)	± 0.66
Winter	Project RSA (2,387 km² total)	4.02	± 0.64	15.69 (12.86 %)	± 5.11
	Winter Range (65,077 km²) [1] (2,500 km² per cell) – 40 cells total	4.77	± 0.51	25.93 (21.25 %)	± 2.13

[1] Late fall and winter ranges were subsampled using 2,500 km² cells (approximately the same size and the RSA) to facilitate estimation of mean and variance. Estimates of mean and variance within the RSA are derived from differences in rates and residencies of individual caribou.

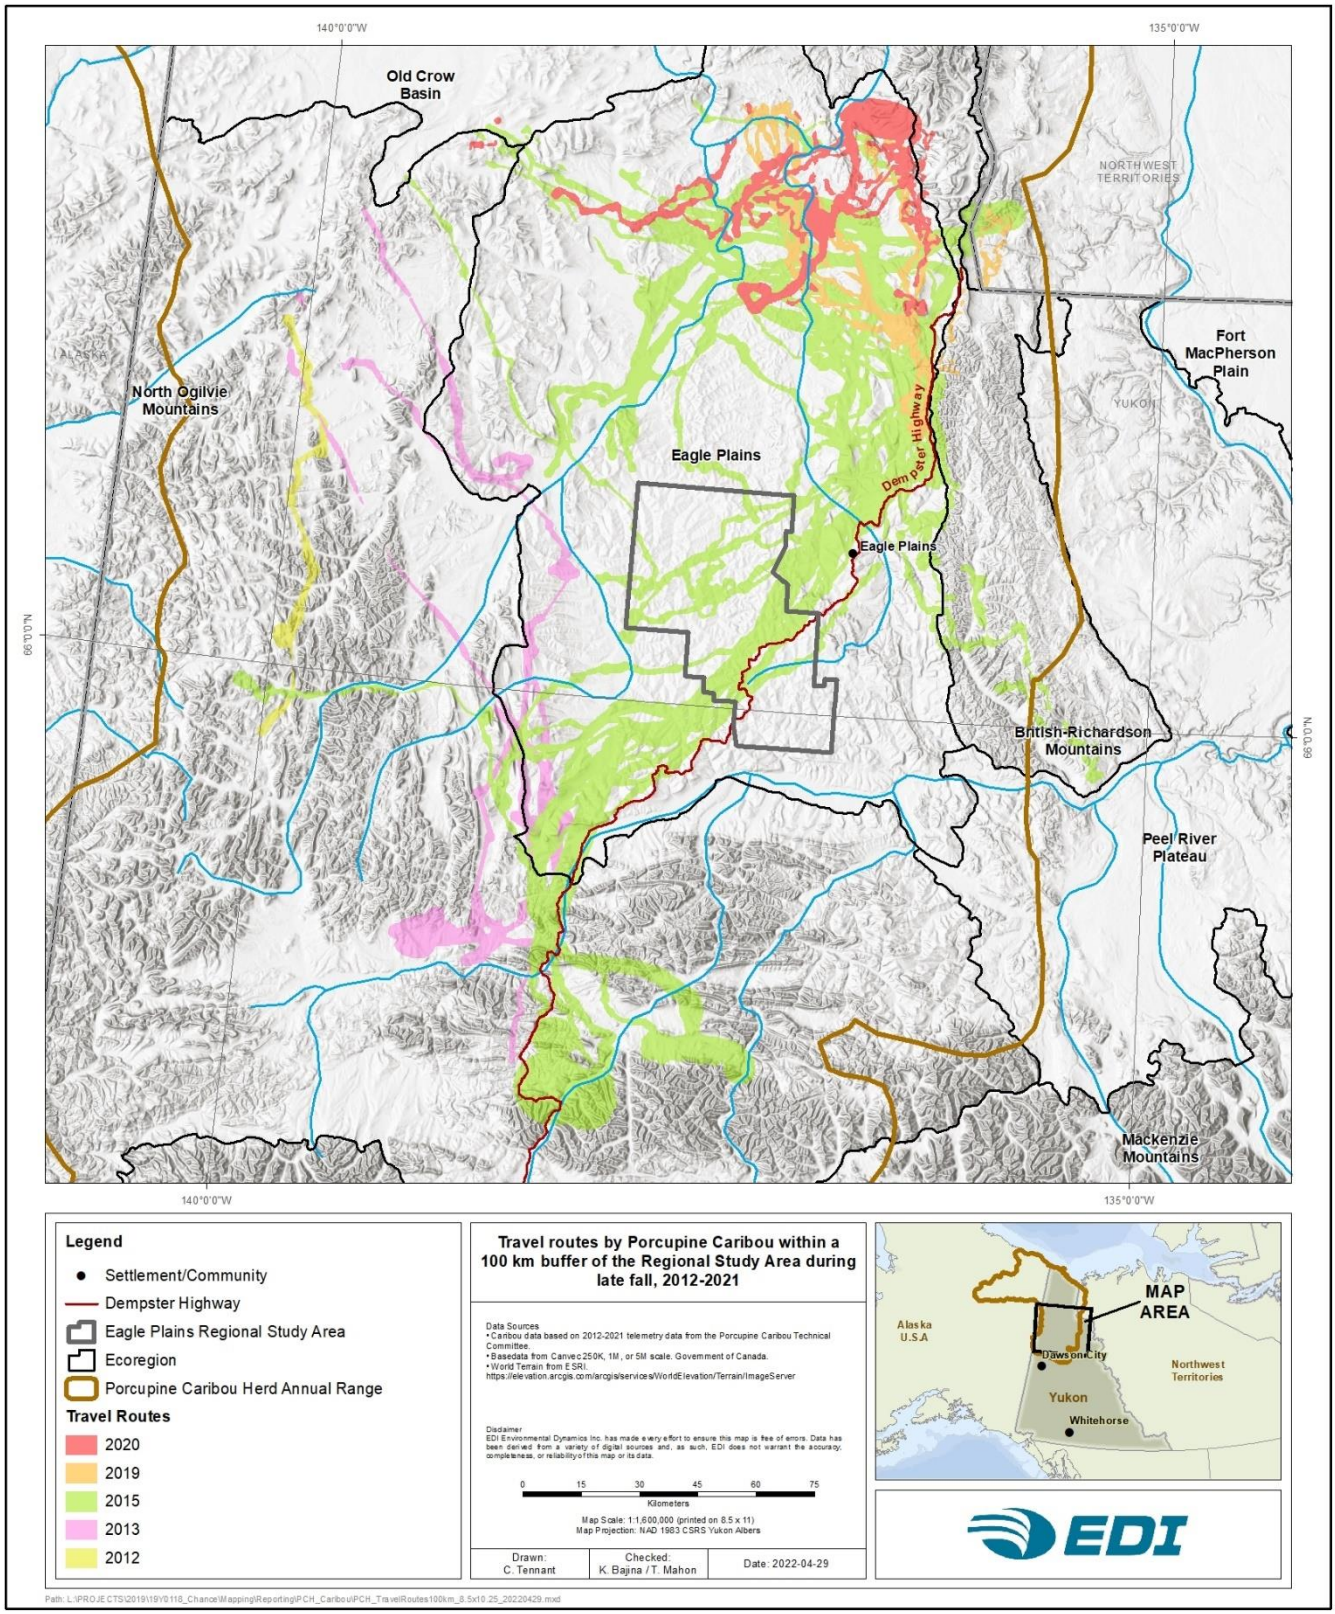
[2] Percent of the season indicated in brackets. Total days: late fall = 54 days, winter = 122 days.

6.6.2.2 Migration Movements

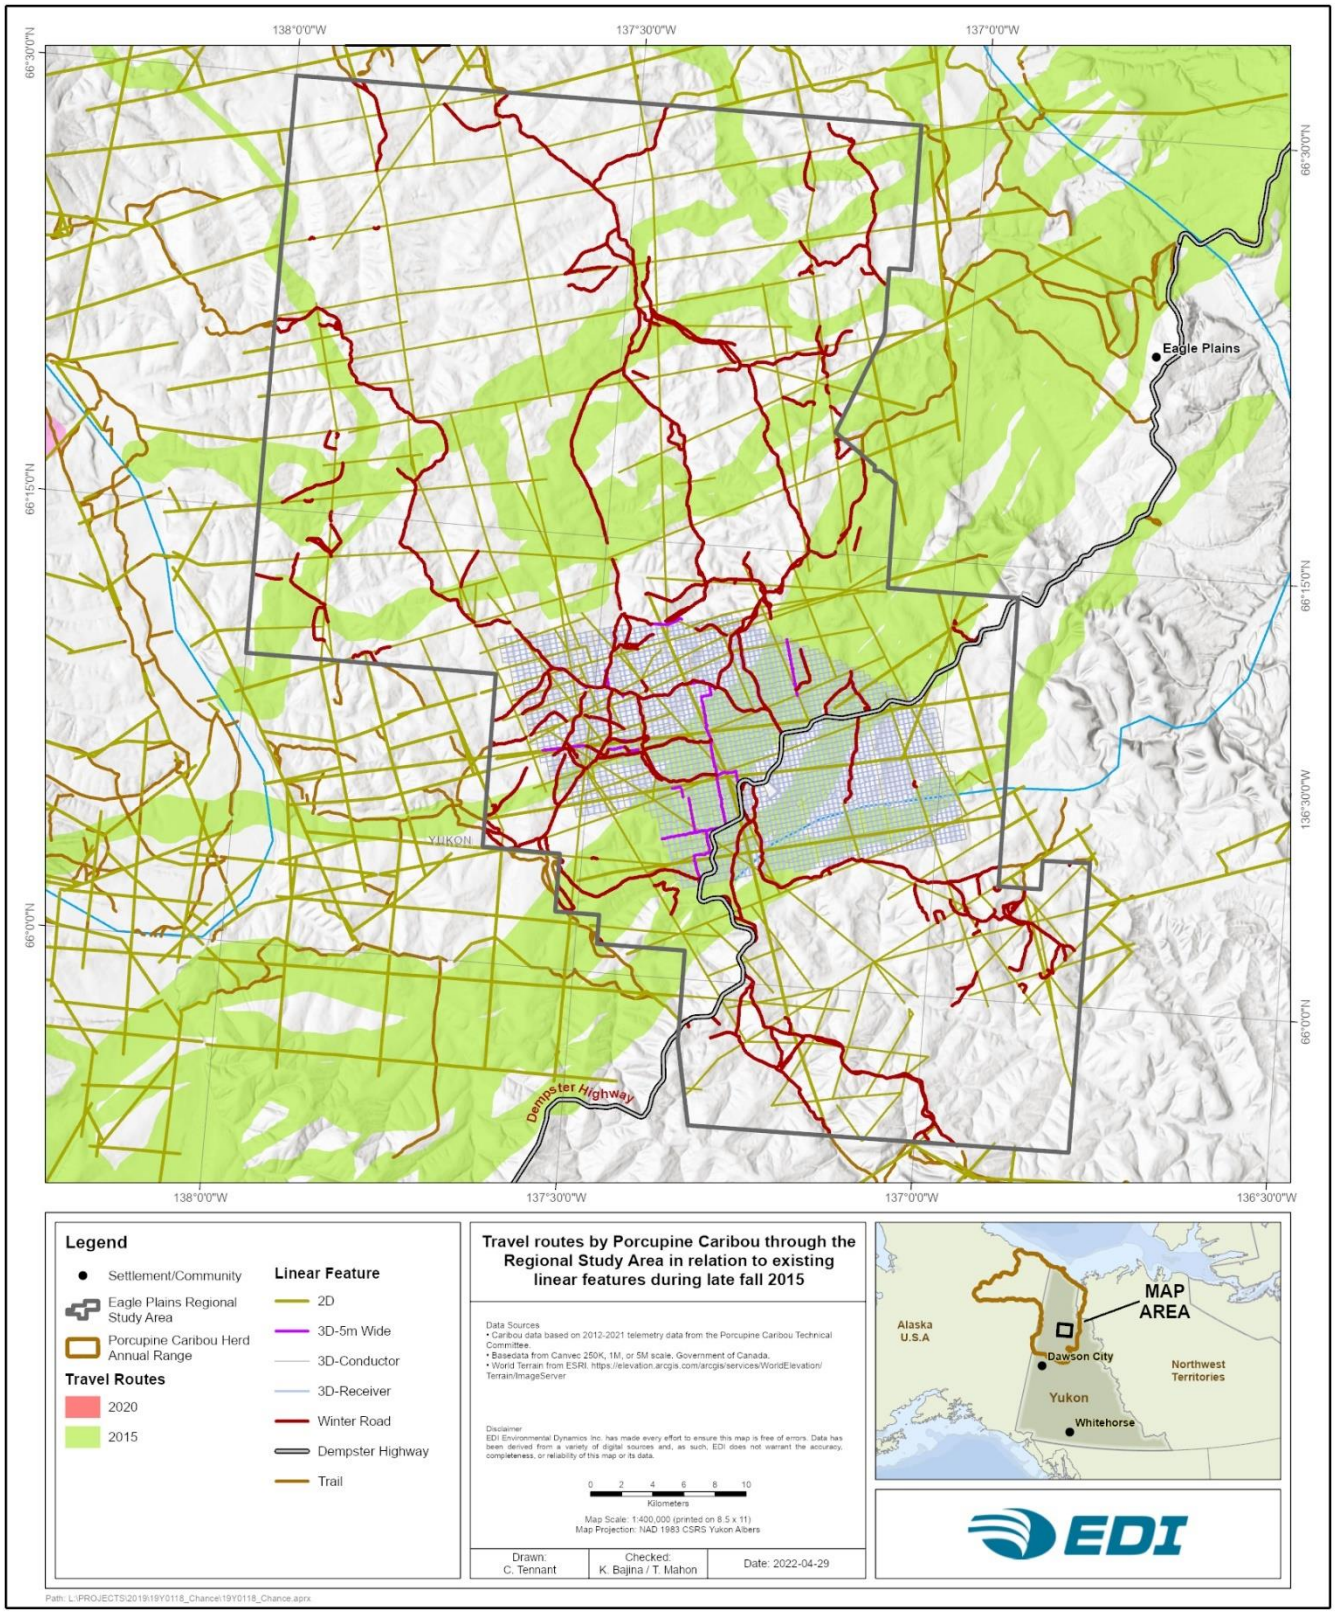
Travel routes through the Project RSA were only evident in late fall of 2015. At that time, 14 caribou travelled from the northeast quadrant of the Eagle Plains ecoregion to either the southwestern portions of that ecoregion or to the North Ogilvie Mountains, along the Dempster Highway (Map 6-7). Although two caribou did cross the highway in the vicinity of the RSA, most of the caribou (12) travelled parallel to the Dempster Highway, along its northwest side, before eventually crossing the highway south of the RSA in the Ogilvie Mountains (Map 6-7). The location of the movement routes in 2015 predominantly northwest of the Dempster Highway was previously noted by Russell and Gunn (2017), who suggested the caribou may have been avoiding crossing the highway. Although this is a valid hypothesis, supported by observations from VGFN elders (Sherry and Vuntut Gwitchin First Nation 1999, p. 288), it is important to note that the set of travel routes in 2015 did eventually cross the Dempster Highway south of the RSA in the Ogilvie Mountains. These crossings may be done at times of lower traffic such as nighttime, as elders had witnessed various unsuccessful attempts of herds to cross the Dempster as vehicles were passing during the day (Sherry and Vuntut Gwitchin First Nation 1999, p. 288). It is also important to note that travel routes in 2015 coincided with a broad, regional height of land (separating the Porcupine and Peel watersheds), which caribou sometimes travel on during migration movements (Russell et al. 1993). On an absolute scale, the height of land along the Dempster Highway, and proximate locations used by caribou as travel routes (~550–650 m), coincide with the mid elevations selected by caribou during fall (see Section 6.5.2.1, *Habitat Models*). The 12 caribou that

paralleled the Dempster Highway in the vicinity of the RSA did cross several inactive winter roads, numerous old 2D seismic lines, and a 350 km² area consisting of one-year-old 3D seismic exploration (Map 6-8).

Inferences about caribou movements are limited by the relatively small numbers of caribou that were collared (<0.1% of the herd annually) and the relatively small number of collared caribou that occurred within the RSA. Collared caribou only occurred in the Eagle Plains ecoregion in half of the years from 2012–2021; however, it is known from local knowledge that caribou occur in the ecoregion in most, if not all years. VGFN elders have discussed to importance of Eagle Plains for caribou winter habitat and noted that if caribou find a good feeding place with many trees, they will stay all winter (VGFN p185). During interviews in the late 1990's, they observed many caribou performing fighting, mating and rutting rituals around Blackstone Flats (Sherry and Vuntut Gwitchin First Nation 1999, p. 188). For the years when collared caribou were present in Eagle Plains, it is unknown how representative the collar locations are of the overall herd. For example, the concentration of travel routes through the RSA in 2015 suggests a potential movement corridor, but the proportion of caribou that is collared is too small to conclude this with confidence. The lack of movements in the same area in any other year does not support the idea that the cluster of movements in 2015 represent a regular travel corridor (but, again, this could reflect the small proportion of caribou collared).



Map 6-7. Travel routes identified for the Porcupine Caribou Herd within a 100 km buffer of the Project Regional Study Area during late fall, 2012–2021.



Map 6-8. Travel routes by Porcupine Caribou through the regional Study Area in relation to existing liner features during late fall 2015.

6.7 RELATIONSHIP TO LINEAR FEATURES

A key issue concerning the PCH is how anthropogenic development may alter caribou distribution, habitat use, and, ultimately, whether changes may influence population demography and access to the herd by First Nations and Inuvialuit harvesters. Linear features are the primary source of disturbance in the Project RSA and the broader Eagle Plains ecoregion. There is uncertainty about how caribou may respond to these features. To better understand the relationship between caribou and linear features, base habitat models were extended to assess the potential for habitat avoidance using a zone of influence (ZOI) framework. The ZOI delineates the area within which caribou behaviour is altered. ZOIs were estimated for three functionally distinct linear feature types (i.e., 2D seismic, winter roads and trails; 3D seismic; and the Dempster Highway). If ZOI estimates are statistically and ecologically significant (i.e., alter the selection of habitat and forage by caribou), they can be used to quantify effective habitat loss (i.e., perceived reduction in habitat quality by caribou due to avoidance) in the Project RSA and Eagle Plains ecoregion.

Statistical ZOIs were determined for 2D seismic lines (including winter roads and trails) in Eagle Plains in late fall and winter. However, confidence in those estimates is relatively low due to several factors. Statistical ZOIs were identified corresponding to 4 km avoidance of 2D seismic lines during late fall and 2 km avoidance of 2D seismic lines during winter. The analysis also identified that the PCH were attracted to the Dempster Highway and 3D seismic areas in both late fall and winter. Sufficient observations were associated with this pattern in relation to the Dempster Highway, but results for 3D seismic areas could be spurious due to a relatively low number of caribou locations in proximity to these features.

Although the analyses determined ZOIs associated with 2D seismic lines (and winter roads and trails), they should be interpreted with caution. (1) The magnitude of the ZOI effects was weak (i.e., including the ZOI effects in the habitat models had little effects on the habitat predictions). (2) Threshold distances estimated from ZOI analyses tend to be very sensitive to spatial and temporal contexts as well as the data and analytical methods used. Estimates of ZOIs can vary dramatically from year-to-year. This can include selecting to be closer to human features in some years and exhibiting dramatic difference in the threshold distances in years when human disturbances are thought to be avoided. The number of caribou locations in this study unevenly distributed with respect to the various linear features both spatially and across years. (3) The pattern of ZOI effects were not consistent with expectations and results from other studies. For example, having a 2 km ZOI for 2D lines and no ZOI for the Dempster Highway is counterintuitive. A previous study estimated a relatively large ZOIs for the Dempster (Johnson and Russell 2014). Based on these factors, it is recommended that these results not be used solely to estimate the effects of linear features on the PCH. Rather, it is recommended that the results be used in conjunction with results from other studies, adapted to the Eagle Plains setting and the ecology of the PCH, to develop a set of ZOIs for assessment and management purposes.

6.7.1 METHODS

A zone of influence framework evaluated the influence of linear features on PCH caribou distribution and habitat selection. Base habitat models developed for late fall and winter were extended by incorporating a 'distance to' covariate for each relevant linear feature and estimating the breakpoint beyond which the likelihood of observing caribou remained unchanged. If a ZOI was present, the likelihood of observing caribou would increase from linear feature footprint until the identified breakpoint. The primary method used to evaluate the presence and magnitude of a ZOI was a segmented regression approach (Boulanger et al. 2012, 2021).

Three functionally distinct types of linear features were considered based on their widths, densities, and extents in PCH fall and winter ranges: (1) 2D seismic, winter roads, and trails; (2) 3D seismic (grid); and (3) the Dempster Highway. The minimum distance between used/available locations and each feature was calculated and treated as a continuous covariate. To limit potential bias in ZOI estimates arising from broad-scale spatial patterns in distribution and habitat selection (see Boulanger et al. 2021, EDI Environmental Dynamics Inc. 2022b), GAMs were used to assess how the distribution of caribou changed at increasing distances from each linear feature type and to identify an 'iteration zone' to test for ZOIs. The iteration zone is defined as the boundary within which caribou distribution and habitat use are minimally affected by broad-scale patterns in climatic (e.g., snowfall) and biotic (e.g., caribou density and forage) processes. Practically, this refers to an initial range of distances (starting at 0 km) where selection is relatively flat (slope = 0) (see Boulanger et al. 2021). For example, during late fall, selection was fairly flat up to 100 km from the Dempster Highway, after which selection decreased sharply (see Attachment Figure 21 in Section 6.9.3). In other cases, such as the relationship to 2D lines during late fall, the slope was substantially greater than zero at very close distances (see Attachment Figure 19 in Section 6.9.3). Selection increased up until approximately 18 km, then sharply decreased until 25 km, and then, once again, sharply increased up until approximately 35 km. Given such non-linearity in the response, the iteration zone was identified within the first major bout of increase/decrease, i.e., within the first 25 km. This approach was taken in each case where a drastic, non-linear selection gradient occurred at very close distances to the linear feature.

Within the iteration zone, several distance thresholds were tested to identify a ZOI. The assumptions were that caribou presence would be reduced and resource selection altered within the threshold distance. We assigned all distances at or beyond the defined threshold the same distance value. For example, if a ZOI distance of 2 km was tested, then all distances up to 2 km retained their values (i.e., numbers ranging from 0 km to 1.99 km), but all distances at or greater than the ZOI were assigned a value of 2 km (e.g., 3 km or 4 km were assigned values of 2 km). A unique model was fit for each threshold tested, and the number of models corresponded to the outer boundary of the iteration zone identified for each linear feature type. In other words, if the iteration zone was deemed between 0 km and 25 km, then 25 models were tested — one for each kilometre interval. The best model, which corresponded with the most likely ZOI, was selected by evaluating the log-likelihoods of all models as a function of the distance thresholds. The highest log-likelihood corresponded with the model with the most statistical support (Boulanger et al. 2012). The magnitude of avoidance was estimated as the odds of caribou occurring at or beyond the ZOI relative to the odds of being on the linear feature (i.e., odds ratio = $e^{coefficient \times ZOI}$).

6.7.2 RESULTS AND DISCUSSION

The influence of linear features on PCH distribution and habitat selection varied between late fall and winter seasons and among functional linear feature types. ZOIs were detected for 2D seismic lines (including winter roads and trails) during late fall (4 km, Attachment Figure 25) and winter (2 km, Attachment Figure 28). These results were derived from analyses that considered only spatially relevant scales (i.e., iteration zones) (see GAM plots for 2D lines in Section 6.9.3). For example, relationships with 2D lines were evaluated only within the Eagle Plains ecoregion because most of these features occurred within this extent. The GAM plots in Section 6.9.3 also demonstrate that, though selection increased/decreased relative to 2D lines, these changes were low in magnitude. For example, within the iteration zones of 2D lines, there was an approximate 0.08 (or 8 %) increase in the probability of selection at far distances from these features. When estimated using a defined threshold, changes in the probability of selection necessarily increased (relative to GAMs) based on the imposed shape of the response (i.e., fitting a linear increase followed by a flat slope at distances equal to and beyond the ZOI). In practical terms, the odds of caribou occurring at distances equal to or beyond the ZOIs for 2D lines are 1.45 (odds ratio = $e^{0.000093 \times 4\ km}$) and 1.27 (odds ratio = $e^{0.00012 \times 2\ km}$) times greater, during late fall and winter, respectively, than the odds of caribou occurring on 2D lines. The ZOIs estimated for 2D lines in the current study were smaller than those previously estimated by Johnson and Russell (2014)—11 km from 1985–1998 and 6 km from 1999–2012 for wells, trails, winter roads, and seismic lines.

Although analysis of 2D seismic lines (including winter roads and trails) did identify statistically significant ZOIs, the results should be interpreted with caution. An important indicator to contextualize these results is whether estimated ZOIs influenced the selection of important habitat components. A comparison of coefficients between habitat models with and without ZOI terms provides a test of the ecological significance of estimated ZOIs (Boulanger et al. 2012). To accomplish this, predictions were made using the estimated ZOIs across the late fall and winter ranges to match the same spatial scale as base habitat models (see Table 6-10 and Table 6-11). During late fall, coefficients associated with macrolichen cover ($\beta_{lichen.base}$ = 0.694 ± 0.029 versus $\beta_{lichen.ZOI}$ = 0.689 ± 0.029) in Eagle Plains were invariant (Table 6-4 versus Table 6-10). Similarly, during winter, coefficients associated with lichen ($\beta_{lichen.base}$ = 1.119 ± 0.018 versus $\beta_{lichen.ZOI}$ = 1.114 ± 0.018) in Eagle Plains, and avoidance of other plant functional types, were consistent (Table 6-5 versus Table 6-11). So, even though ZOIs were determined for 2D lines, the magnitude of those effects was so small that it resulted in marginal changes to the habitat model predictions in both late fall and winter.

No ZOIs were detected for the Dempster Highway during either season. Instead, the segmented regression approach identified an attraction effect, rather than avoidance, for both late fall (9 km, Attachment Figure 27) and winter (11 km, Attachment Figure 30). Thus, caribou were more likely to occur within 9 km and 11 km of the Dempster Highway during late fall and winter, respectively, than beyond those distances. This result contradicts previous work by Johnson and Russell (2014), who identified ZOIs of major roads, including the Dempster Highway, to be as large as 30 km from 1985–1998 and 18.5 km during 1999–2012.

Similar to the results for the Dempster Highway, no ZOIs were determined for 3D seismic lines, but there is high uncertainty associated with those estimates due to the relatively small number of collared caribou that

interacted with the 3D seismic area. Attraction effects were found within 16 km and 4 km of 3D seismic lines during late fall (Attachment Figure 26) and winter (Attachment Figure 29), respectively. As with 2D lines, the magnitude of the attraction effect for Dempster Highway and 3D seismic lines was small relative to base habitat selection. Additionally, considering the potential mechanisms of effects that 3D lines could have on caribou, the apparent attraction of caribou to the 3D seismic lines is likely a spurious result. Based on other studies examining the effects of 3D lines on caribou and their primary predators, wolves, it was expected that the PCH would exhibit a neutral or weak avoidance response to 3D lines due to the potential for facilitated predation to occur.

In addition to the weak effects exhibited by ZOIs relative to base habitat selection, there are other factors that warrant cautious interpretation and use of these analytic results. (1) ZOI estimates and their magnitude of effect can be sensitive to (a) sample sizes and (b) spatial and temporal coverage of the data. Though numerous overall, the data used in this analysis had relatively modest sample sizes near linear features and were unevenly distributed in relation to linear features in Eagle Plains. (2) Caribou can exhibit dramatically different ZOIs from year to year. Collared caribou were only present in modest numbers in 2012/13, 2014/15, 2017/18, and 2018/19, so the data had to be lumped across years to estimate a single ZOI. (3) ZOIs estimated for the PCH in this analysis are substantially smaller than those estimated by Johnson and Russell (2014). The issues associated with these factors are discussed below.

The spatial and temporal context of ZOI studies can influence outcomes. Estimates of ZOIs are a consequence of broad- and fine-scaled space use, and these patterns of distribution can emerge from population demography, biotic interactions (e.g., density-dependent competition or predator-prey interactions), abiotic conditions (e.g., snowfall, forage availability), habitat selection, and potential sources of disturbance (e.g., dust fall, sensory disturbance) (Messier et al. 1988, Johnson et al. 2001, Mahoney and Schaefer 2002, Hinkes et al. 2005, Bowyer et al. 2014, Chen et al. 2017, Boulanger et al. 2021, Pedersen et al. 2021). These sources of variation in space use do not negate the importance of quantifying indirect effects of anthropogenic development, but they do point to underlying issues with the ZOI framework and its utility for management and mitigation. For example, Boulanger et al. (2021) documented ZOI responses by Bathurst caribou to the Ekati-Diavik mine complex (Northwest Territories) that have varied dramatically from year-to-year, which the authors attribute to changes in drought conditions. Similarly, Johnson et al. (2020) found that ZOIs around energy infrastructure (North Slope of Alaska, USA) reduced during periods of high mosquito activity for the Central Arctic Herd (CAH). In these examples, fine-scale changes in caribou space use was primarily driven by selection for areas adjacent to large, open bodies of water: Lac de Gras by Bathurst caribou and the Arctic Ocean by CAH caribou.

Another issue regarding the interpretation of ZOIs is their sensitivity to the data and analytical methods used. For example, Boulanger et al. (2021) found that GPS-collared caribou exhibited 'avoidance' (a ZOI) in only four out of nine years at the Ekati-Diavik mine complex (range = 6–13 km). In five of those nine years, caribou exhibited either no relationship or attraction to mine infrastructure. Additionally, when comparing an overlapping year (2012) between GPS data and aerial survey data for Bathurst caribou, a ZOI was identified using GPS collar data (ZOI = 7.09 km, odds ratio not overlapping zero; see Table 3 in publication) but was not identified using aerial survey data (ZOI = 11.4 km, odds ratio overlapping zero; see Table 4 in

publication). During the data exploration phase of the current study, ZOI results also varied considerably based on different subsets of the PCH data. For example, the estimates of a ZOI around 2D seismic lines (including winter roads and trails) changed by several kilometres when assessing not only different years but different spatial extents (e.g., ecoregions).

The ZOI analysis conducted by Johnson and Russell (2014) for the PCH used a similar approach to the current analysis and other studies, but yielded very different results for seismic lines and major roads. Johnson and Russell (2014) also caution against interpreting their results based on several factors, including a large change in the PCH's population size over their study duration, variation in animal behaviour across the range of development types, and relatively small effect sizes for caribou-disturbance responses. The potential reason for differences between the results in this study and those of Johnson and Russell (2014) are not apparent and may reflect the sensitivity of results to the differences in sample sizes and spatiotemporal patterns in the data used between the two studies. Landscape conditions and land use activities were similar between the two study periods and likely included some of the same data (e.g., winter 2012). Both Johnson and Russell (2014) and the current study dealt with trade-offs in spatial and temporal coverage. Though Johnson and Russell (2014) had data with longer temporal coverage (27 years), these data suffered from poorer spatial resolution associated with larger interval collar fixes (on average, once every seven days), smaller sample sizes (N = 2,127), and coarser habitat variables (i.e., landcover classification). In contrast, the current study used data with shorter temporal coverage (8 years) but had higher spatial resolution associated with collar fixes (on average, one per day), larger sample sizes (N_{fall} = 8,323 and N_{winter} = 13,014), and high resolution habitat variables (i.e., 30 m x 30 m plant functional type percent and digital elevation model). The current study had the advantage of higher spatial resolution, which is especially important for ZOIs, which are, by nature, a spatial phenomenon. A limitation to both this study and Johnson and Russell (2014) is the lack of sufficient interaction between caribou and linear features each year, which prevented the estimation of annual ZOIs.

ZOI analyses, including the analyses in this study, often do not explicitly test specific mechanisms that could be causing caribou to avoid anthropogenic features. It is assumed, correctly or incorrectly, that caribou avoid these areas because they perceive elevated predation risk (Frid and Dill 2002, Semeniuk et al. 2012). This can include avoidance due to direct sensory disturbances associated with the features and learned behaviours that could result in avoidance beyond sensory perception distances (Boulanger et al. 2021). Assuming the ZOIs detected in this study are 'real', potential mechanisms that cause caribou to avoid 2D seismic lines, winter roads, and trails are perceived mortality risk associated with human hunting (Wolfe et al. 2000, Plante et al. 2017) and facilitated predation by wolves (James and Stuart-Smith 2000, Dickie et al. 2017).

Ultimately, the purpose of measuring and testing caribou responses to linear features is to inform management and mitigation. Given the weak effects associated with the ZOIs generated here, and the analytical issues discussed above, it is recommended that these results not be used solely to estimate the effects of linear features on the PCH. Rather, it is recommended that the results be used in conjunction with results from other studies, adapted to the Eagle Plains setting and the ecology of the PCH, to develop a set of ZOIs for assessment and management purposes.

6.8 SUMMARY

The PCH is known for large population aggregations, dramatic population fluctuations, lengthy migrations, and significant cultural and social value to northern Indigenous peoples. Within the NYLUP, the PCH is considered "…*the most significant and culturally important wildlife resource in the planning region.*" Habitat, food supply, predation, hunting, disease and climate range likely play interactive roles as limiting factors to the PCH population. Factors have limited potential to regulate the PCH, individually.

- The potential for food supply, especially lichen, to regulate the PCH is more limited than other barren ground caribou herds because of the PCH's very large annual and seasonal ranges and the diversity of habitats found within those ranges (e.g., including several ecoregions). Overall, the PCH winter range is relatively rich in lichen resources and is comparable to, or better than, those of other herds that winter in taiga regions.
- Predation does not seem to play a role in limiting PCH growth while the herd is at high numbers. One study suggested that the predation rate had to be near twice the observed level to cause the PCH to decline.
- The comprehensive measures within the Harvest Management Plan to monitor and respond to declines in the PCH (i.e., by reducing harvest) provide a solid system to minimize the potential effects that harvesting could have on the herd.

The portion of the PCH annual range that occurs within Yukon is protected by a network of parks, special management areas, conservation areas, wilderness areas, protected areas, ecological preserves, habitat protection areas, and IMA zones within the North Yukon Regional Land Use Plan and the Peel Watershed Regional Land Use Plan. In total, 54% of the annual range of the PCH within Yukon falls within some type of protected area where industrial activity is prohibited, 36% of the annual range occurs within Integrated Management Area zones where development is limited, and 9% of the annual range is not covered by any land management zonation. The Eagle Plains RSA occurs within IMA Zone IV, which permits the highest level of development.

The PCH have historically overlapped the Eagle Plains RSA in the rut/late fall and winter periods. However, the RSA constitutes only a small portion of those ranges — 6.0% of the late fall range and 6.5% of the winter range. The RSA does not overlap with the most frequently used portions of the late fall and winter ranges.

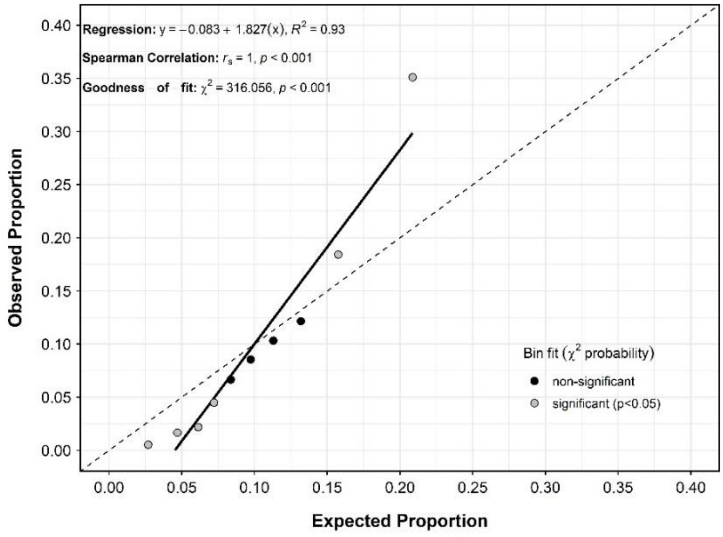
Habitat selection by the PCH in late fall and winter was estimated using resource selection functions. Selected habitats were dependent primarily on the distribution of macrolichen cover. Distance to linear features had a small effect on habitat model predictions. Overall, the strength of selection was greater in winter than late fall, which corresponds to broader movement patterns and use of more diverse habitats by the PCH in fall. In terms of regional habitat distribution, the RSA had similar proportions of selected habitat in fall as the full late fall range; however, the RSA had a much lower proportion of selected habitat in winter compared to the full winter range. Within the RSA, lichen distribution (and caribou use) was strongly affected by extensive recent burns, which had lower lichen cover than unburned areas.

The PCH typically exhibits movements of several kilometres per day in late fall and winter. Late fall daily movements (8.7 km/day in the RSA) were substantially greater than during winter (4.4 km/day). Caribou tended to occupy portions of the landscape for shorter periods during late fall than winter. Caribou residency times in both seasons were two-fold greater in the broader landscape than within the Project RSA, suggesting that, on average, the RSA is more of a transitory area than other portions of the seasonal ranges.

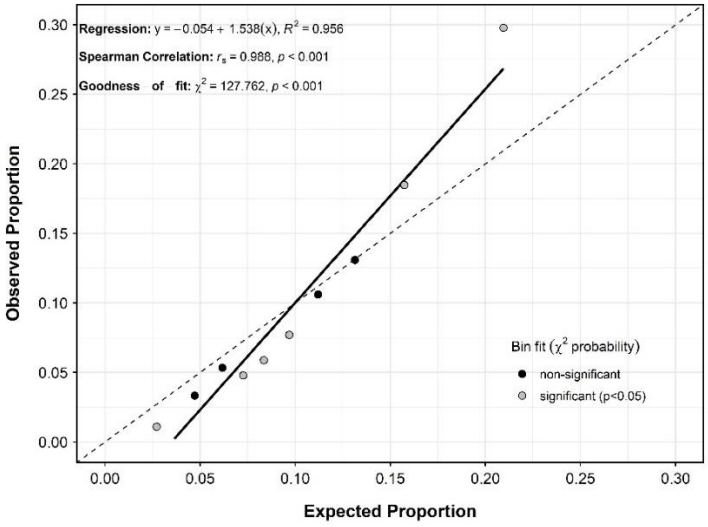
6.9 CARIBOU SECTION ATTACHMENTS

6.9.1 ATTACHMENT 6–A — 5-FOLD CROSS-VALIDATION

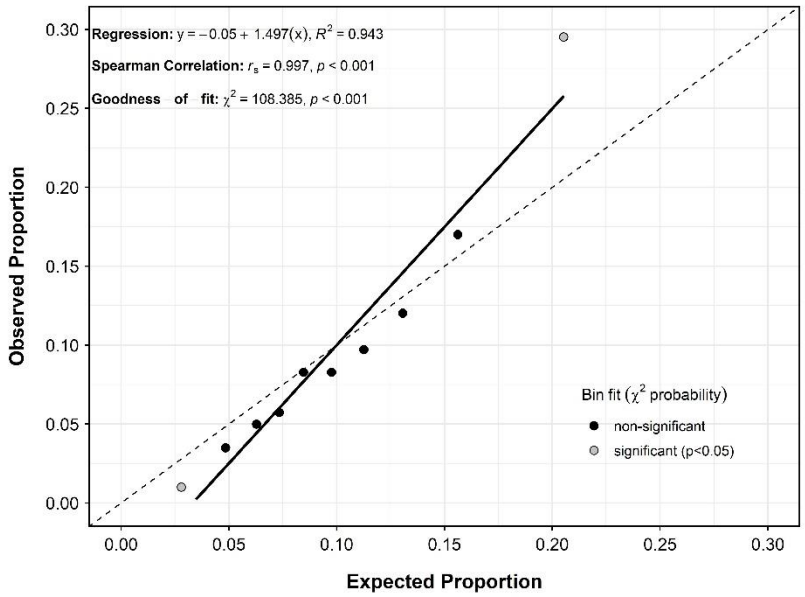
Late Fall



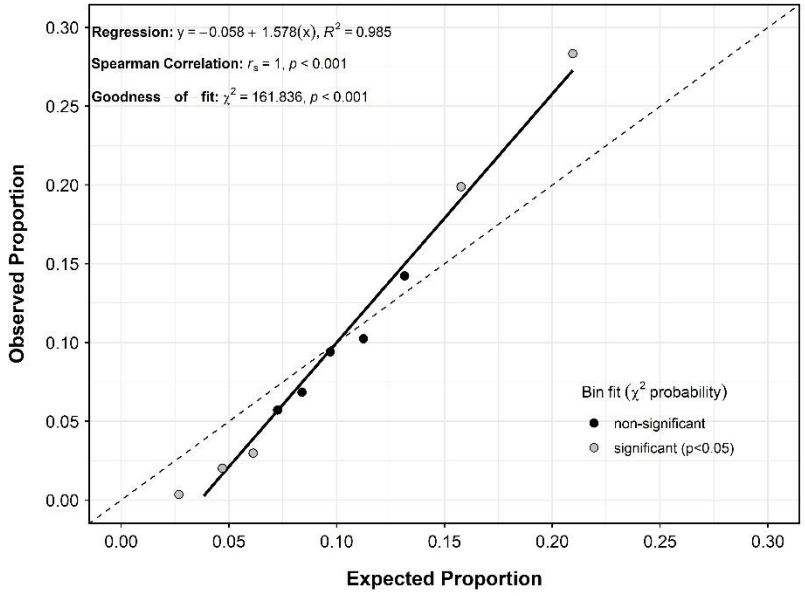
Attachment Figure 1. Cross-validation results comparing expected versus observed proportion of GPS telemetry observations (n = 18,310) of caribou during late fall across 10 quantile bins (Fold 1). Dashed line shows the line of unity (observed = expected). Black line shows the fitted regression; points are either black (not statistically different than expected) or grey (statistically different from expected) for each bin.



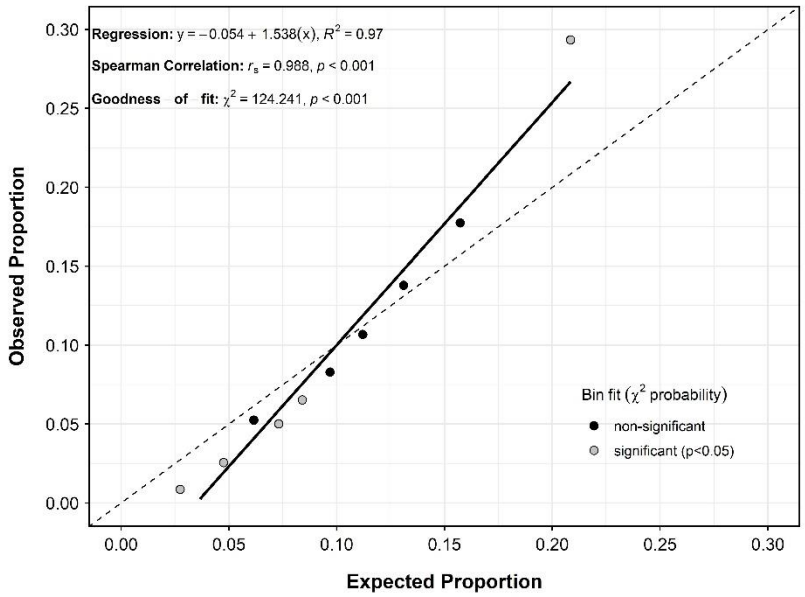
Attachment Figure 2. Cross-validation results comparing expected versus observed proportion of GPS telemetry observations (n = 18,310) of caribou during late fall across 10 quantile bins (Fold 2). Dashed line shows the line of unity (observed = expected). Black line shows the fitted regression; points are either black (not statistically different than expected) or grey (statistically different from expected) for each bin.



Attachment Figure 3. Cross-validation results comparing expected versus observed proportion of GPS telemetry observations (n = 18,310) of caribou during late fall across 10 quantile bins (Fold 3). Dashed line shows the line of unity (observed = expected). Black line shows the fitted regression; points are either black (not statistically different than expected) or grey (statistically different from expected) for each bin.

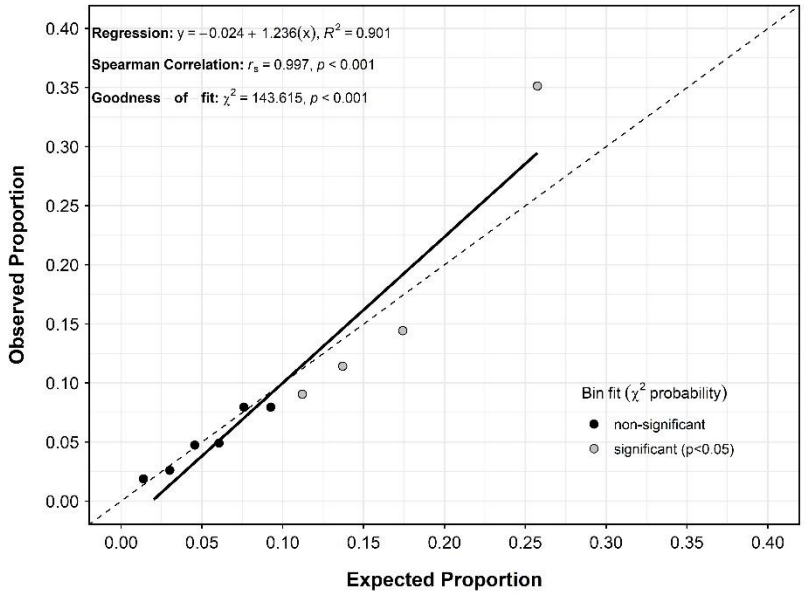


Attachment Figure 4. Cross-validation results comparing expected versus observed proportion of GPS telemetry observations (n = 18,310) of caribou during late fall across 10 quantile bins (Fold 4). Dashed line shows the line of unity (observed = expected). Black line shows the fitted regression; points are either black (not statistically different than expected) or grey (statistically different from expected) for each bin.

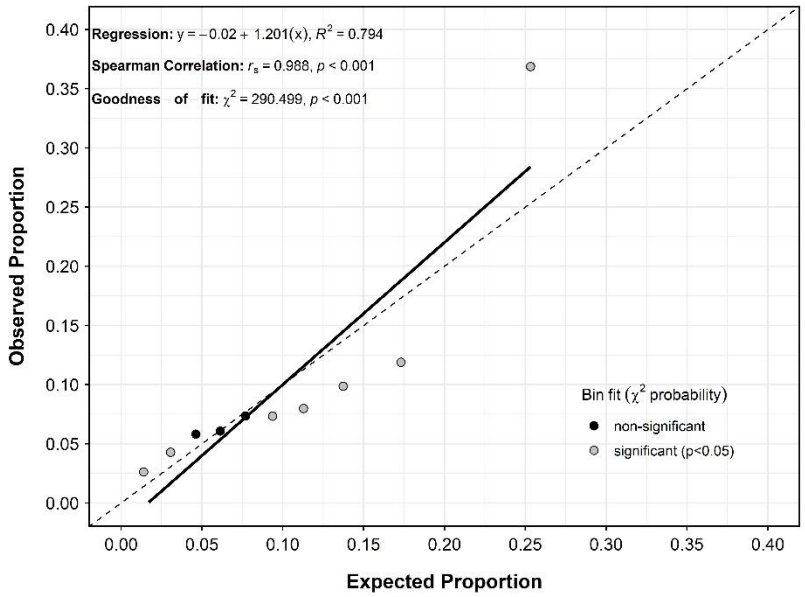


Attachment Figure 5. Cross-validation results comparing expected versus observed proportion of GPS telemetry observations (n = 18,310) of caribou during late fall across 10 quantile bins (Fold 5). Dashed line shows the line of unity (observed = expected). Black line shows the fitted regression; points are either black (not statistically different than expected) or grey (statistically different from expected) for each bin.

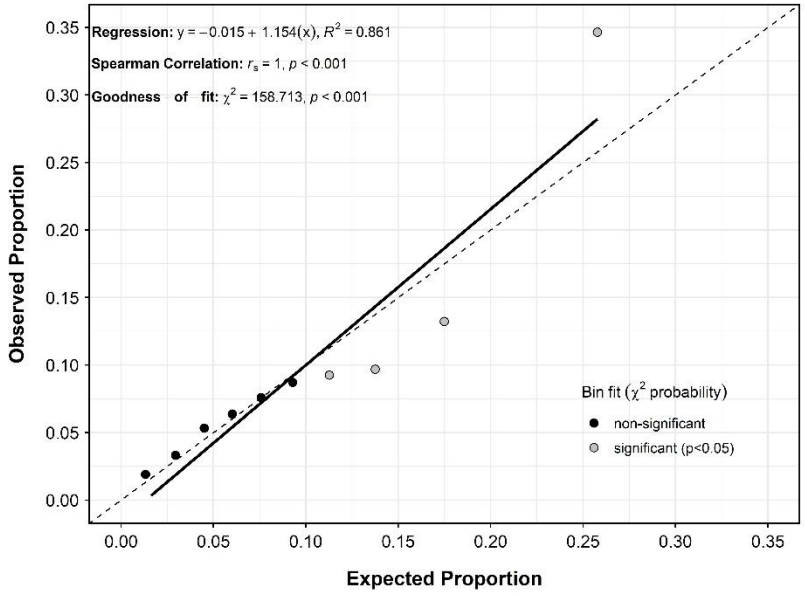
Winter



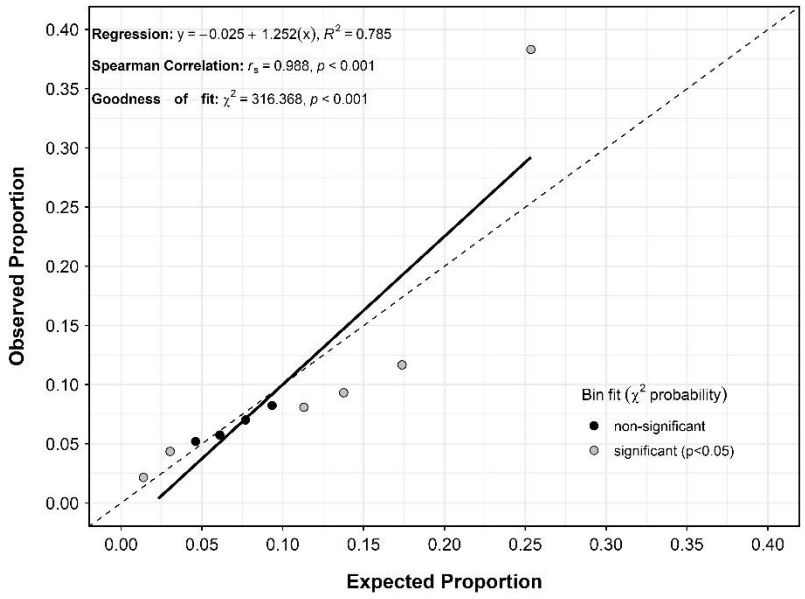
Attachment Figure 6. Cross-validation results comparing expected versus observed proportion of GPS telemetry observations (n = 28,630) of caribou during winter across 10 quantile bins (Fold 1). Dashed line shows the line of unity (observed = expected). Black line shows the fitted regression; points are either black (not statistically different than expected) or grey (statistically different from expected) for each bin.



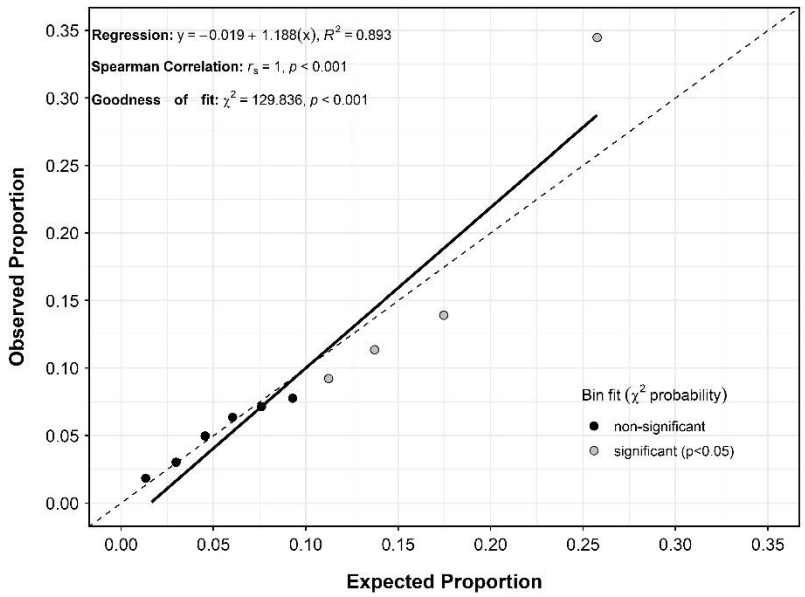
Attachment Figure 7. Cross-validation results comparing expected versus observed proportion of GPS telemetry observations (n = 28,630) of caribou during winter across 10 quantile bins (Fold 2). Dashed line shows the line of unity (observed = expected). Black line shows the fitted regression; points are either black (not statistically different than expected) or grey (statistically different from expected) for each bin.



Attachment Figure 8. Cross-validation results comparing expected versus observed proportion of GPS telemetry observations (n = 28,630) of caribou during winter across 10 quantile bins (Fold 3). Dashed line shows the line of unity (observed = expected). Black line shows the fitted regression; points are either black (not statistically different than expected) or grey (statistically different from expected) for each bin.



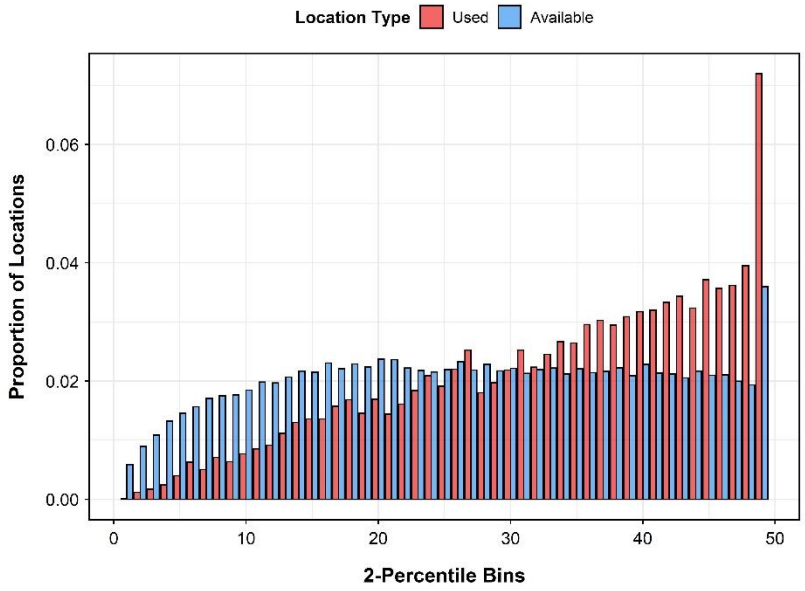
Attachment Figure 9. Cross-validation results comparing expected versus observed proportion of GPS telemetry observations (n = 28,630) of caribou during winter across 10 quantile bins (Fold 4). Dashed line shows the line of unity (observed = expected). Black line shows the fitted regression; points are either black (not statistically different than expected) or grey (statistically different from expected) for each bin.



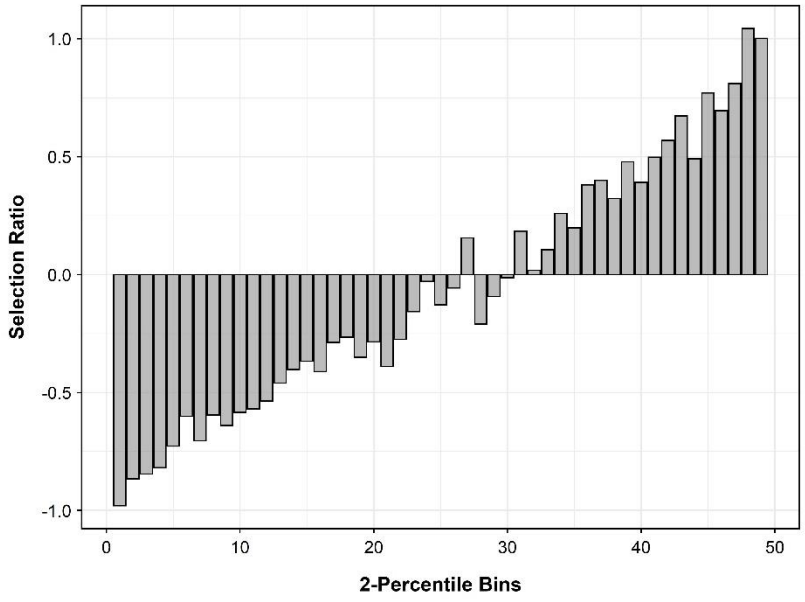
Attachment Figure 10. Cross-validation results comparing expected versus observed proportion of GPS telemetry observations (n = 28,630) of caribou during winter across 10 quantile bins (Fold 5). Dashed line shows the line of unity (observed = expected). Black line shows the fitted regression; points are either black (not statistically different than expected) or grey (statistically different from expected) for each bin.

6.9.2 ATTACHMENT 6–B — SELECTION RATIOS AND HABITAT RATINGS

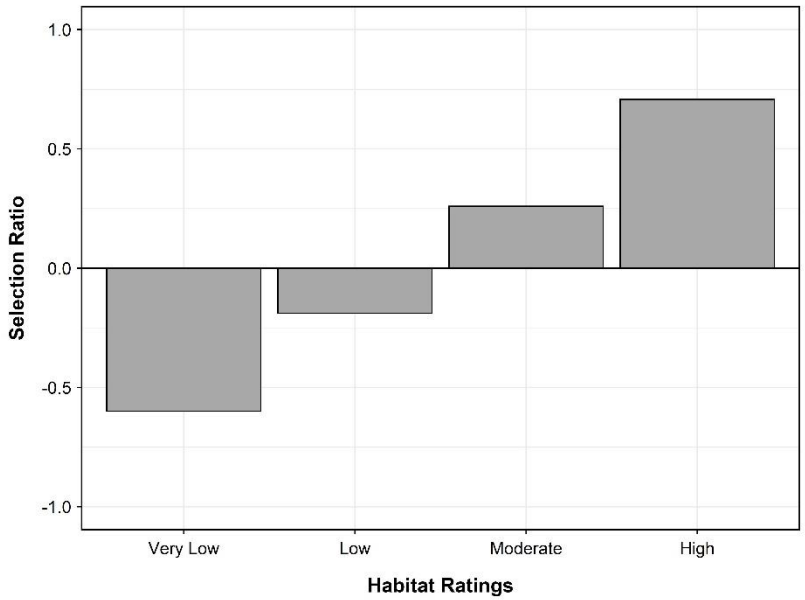
Late Fall



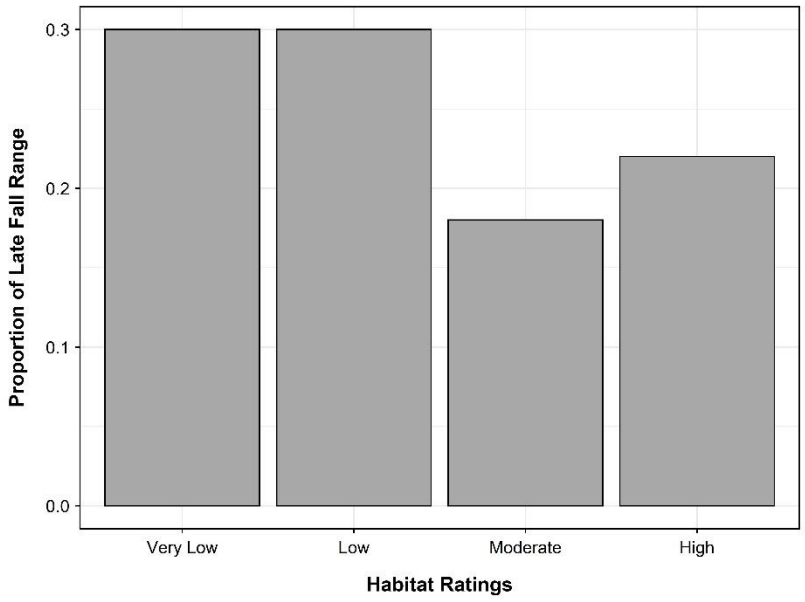
Attachment Figure 11. Proportions of used and available locations across 2-percentile (49 quantiles) interval bins of resource selection predictions during late fall, 2012–2021.



Attachment Figure 12. Selection ratios comparing the proportion of used to available locations across 2-percentile (49 quantiles) interval bins of resource selection predictions during late fall, 2012–2021.

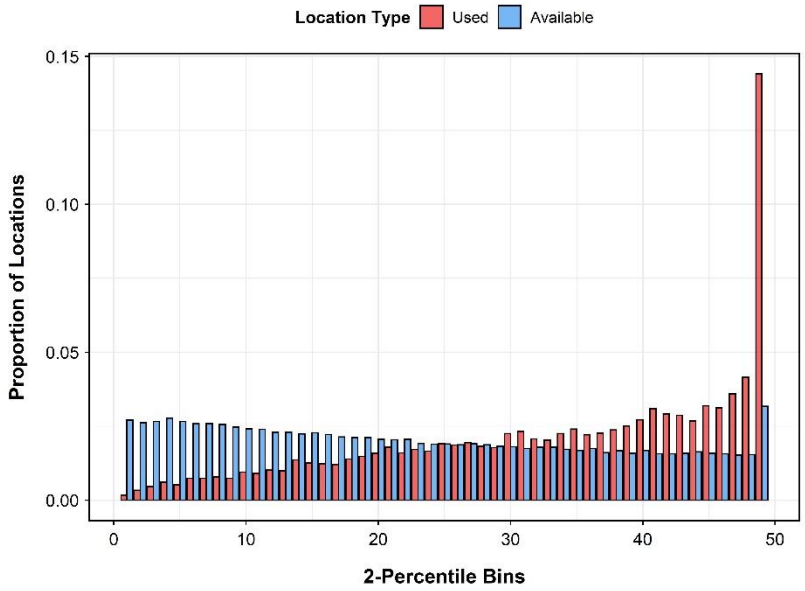


Attachment Figure 13. Selection ratios comparing the proportion of used to available locations across habitat rating classifications during late fall, 2012–2021.

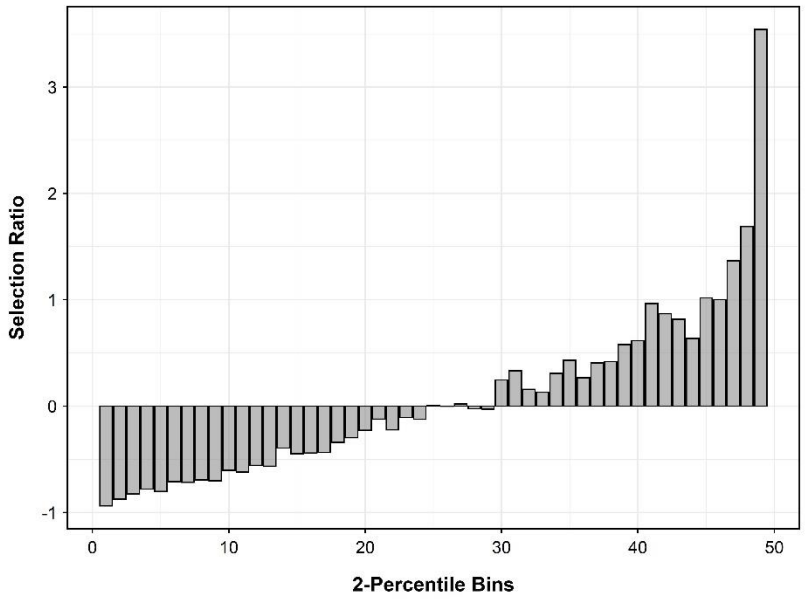


Attachment Figure 14. Proportion of the PCH late fall range composed by each habitat rating classification.

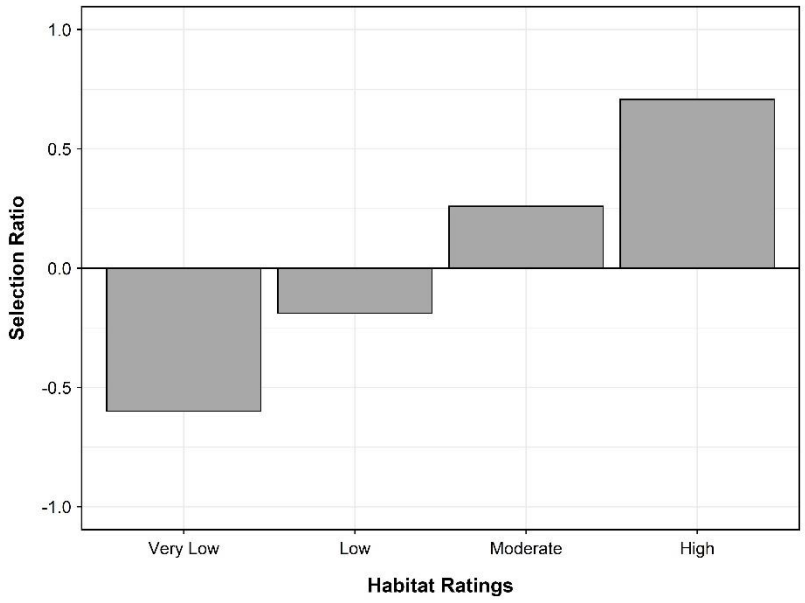
Winter



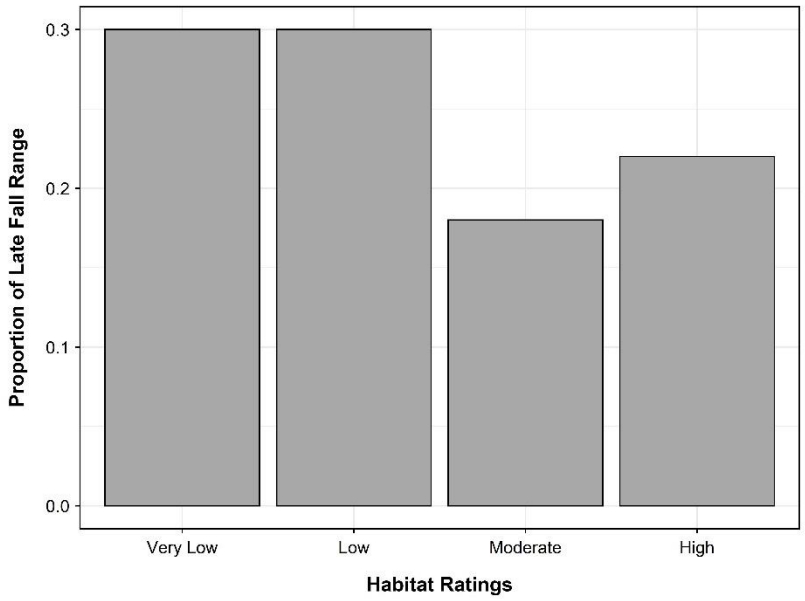
Attachment Figure 15. Proportions of used and available locations across 2-percentile (49 quantiles) interval bins of resource selection predictions during winter, 2012–2021.



Attachment Figure 16. Selection ratios comparing the proportion of used to available locations across 2-percentile (49 quantiles) interval bins of resource selection predictions during winter, 2012–2021.



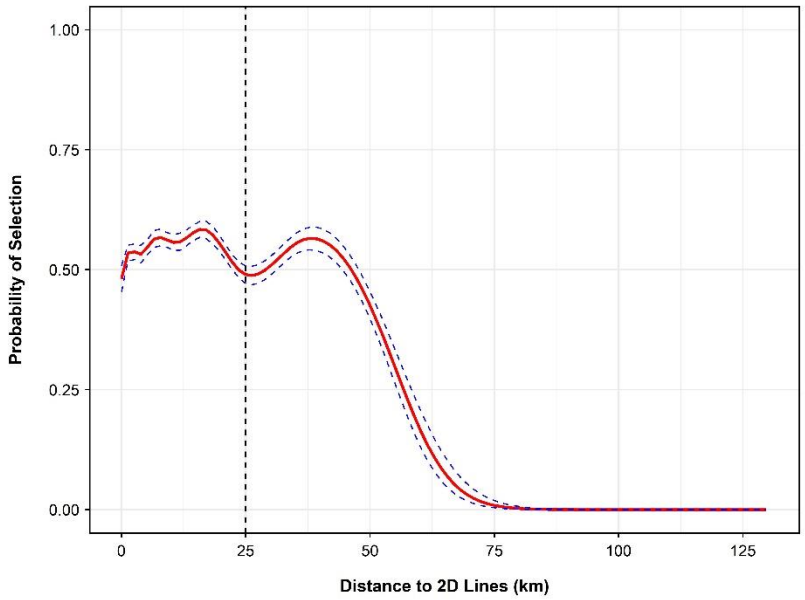
Attachment Figure 17. Selection ratios comparing the proportion of used to available locations across habitat rating classifications during winter, 2012–2021.



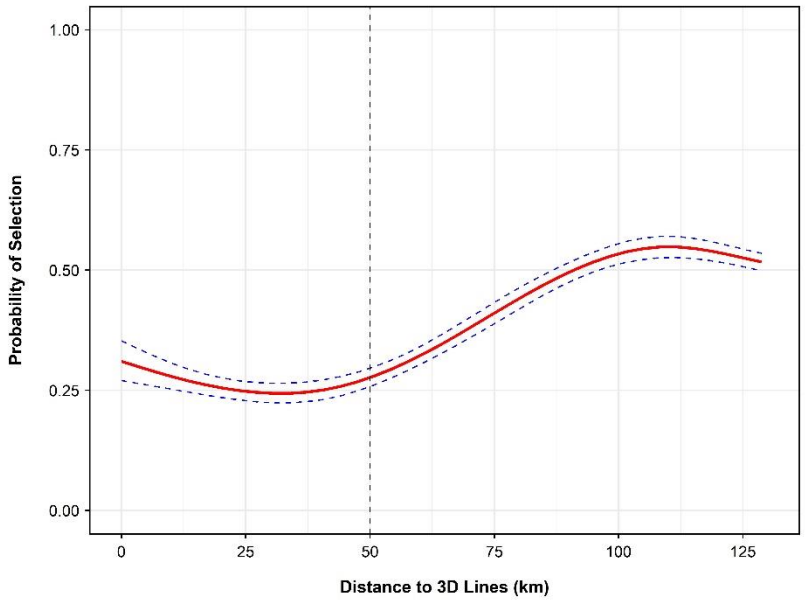
Attachment Figure 18. Proportion of the PCH winter range composed by each habitat rating classification.

6.9.3 ATTACHMENT 6–C — ZONE OF INFLUENCE ANALYSES

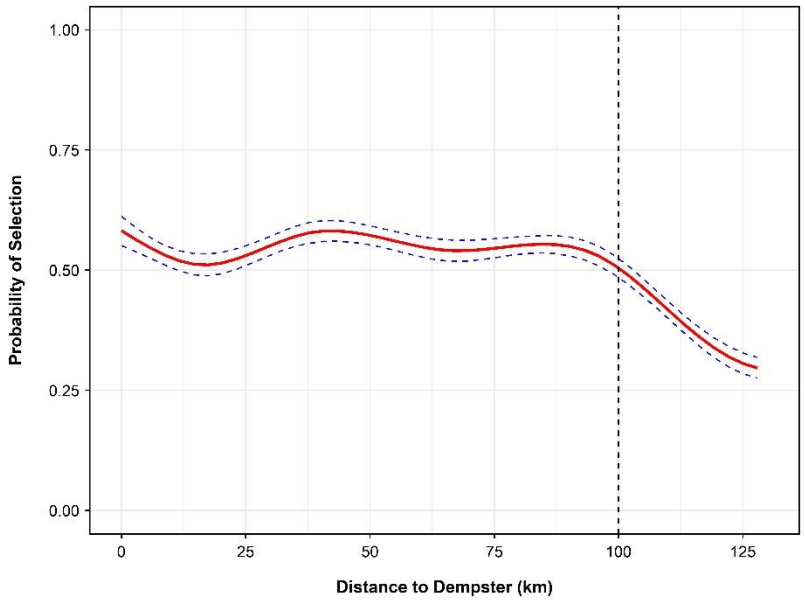
Late Fall



Attachment Figure 19. Marginal effect of distance to 2D seismic lines (including winter roads and trails) on the probability of selection by caribou during late fall (2012–2021) based on a generalized additive model with cubic regression splines. Solid red and dashed blue lines are the fitted mean and 95% confidence intervals, respectively. Vertical dashed line indicates iteration zone cut-off.

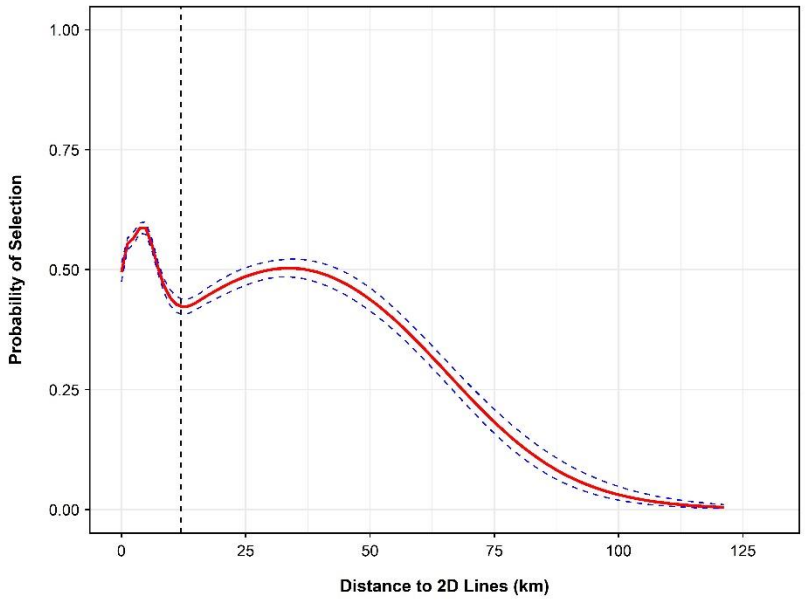


Attachment Figure 20. Marginal effect of distance to 3D seismic lines (single grid in Project RSA) on the probability of selection by caribou during late fall (2012–2021) based on a generalized additive model with cubic regression splines. Solid red and dashed blue lines are the fitted mean and 95% confidence intervals, respectively. Vertical dashed line indicates iteration zone cut-off.

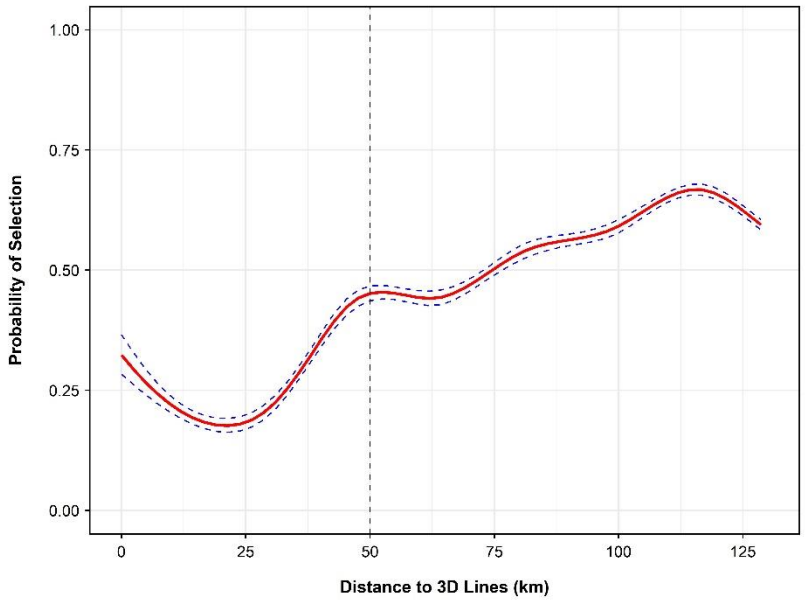


Attachment Figure 21. Marginal effect of distance to the Dempster Highway on the probability of selection by caribou during late fall (2012–2021) based on a generalized additive model with cubic regression splines. Solid red and dashed blue lines are the fitted mean and 95% confidence intervals, respectively. Vertical dashed line indicates iteration zone cut-off.

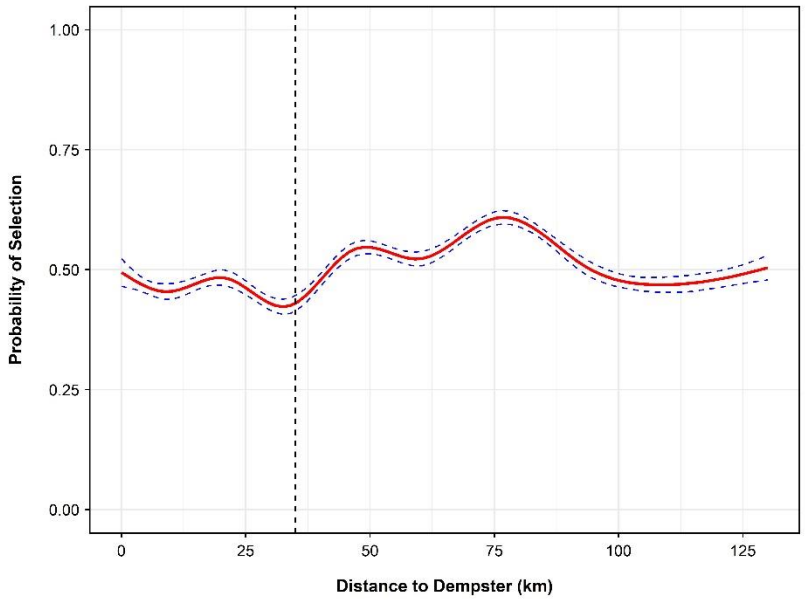
Winter



Attachment Figure 22. Marginal effect of distance to 2D seismic lines (including winter roads and trails) on the probability of selection by caribou during winter (2012–2021) based on a generalized additive model with cubic regression splines. Solid red and dashed blue lines are the fitted mean and 95% confidence intervals, respectively. Vertical dashed line indicates iteration zone cut-off.

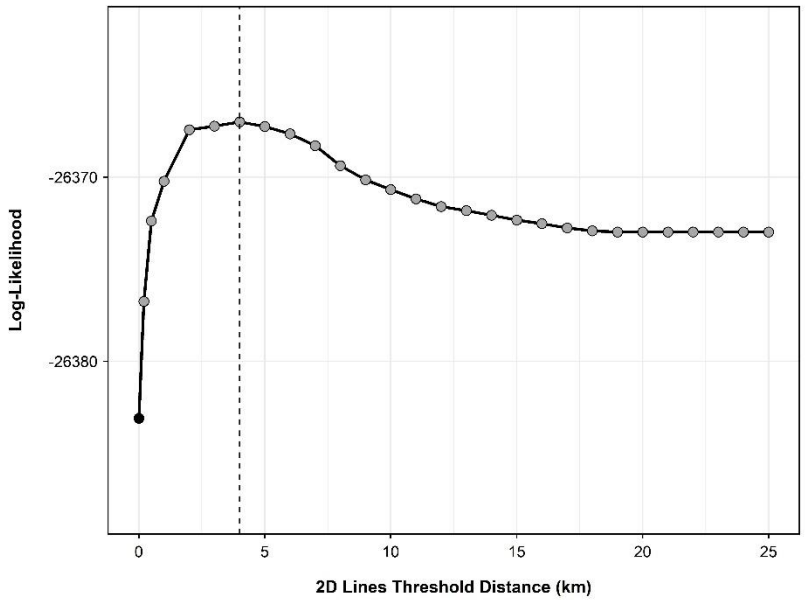


Attachment Figure 23. Marginal effect of distance to 3D seismic lines (single grid in Project RSA) on the probability of selection by caribou during winter (2012–2021) based on a generalized additive model with cubic regression splines. Solid red and dashed blue lines are the fitted mean and 95% confidence intervals, respectively. Vertical dashed line indicates iteration zone cut-off.

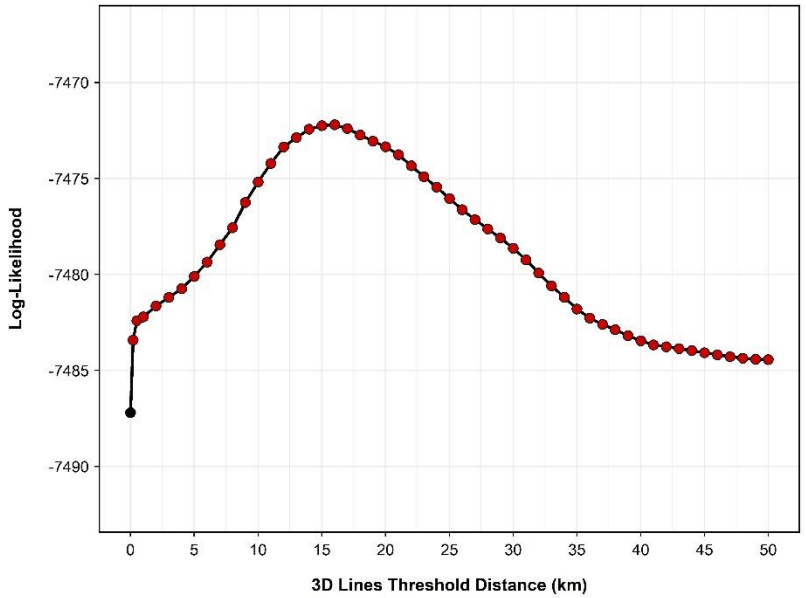


Attachment Figure 24. Marginal effect of distance to the Dempster Highway on the probability of selection by caribou during winter (2012–2021) based on a generalized additive model with cubic regression splines. Solid red and dashed blue lines are the fitted mean and 95% confidence intervals, respectively. Vertical dashed line indicates iteration zone cut-off.

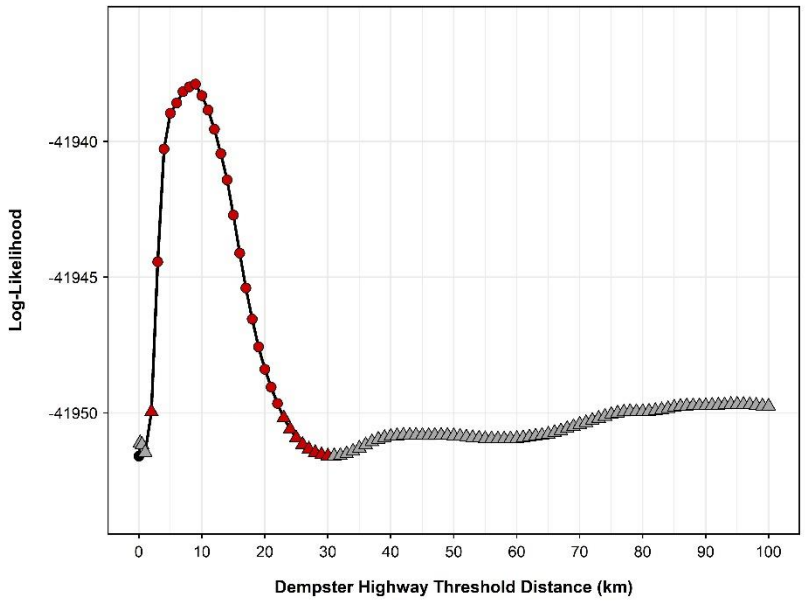
Late Fall



Attachment Figure 25. Segmented regression approach to estimating a zone of influence (ZOI) relative to 2D seismic lines (including winter roads and trails) using GPS collar data from PCH caribou during late fall, 2012–2021. The threshold distance with the highest log-likelihood corresponds with the most likely ZOI. Circles and triangles indicate statistically significant and non-significant ZOI distances, respectively. Grey and red fills indicate positive and negative coefficients, respectively. Vertical dashed line indicates ZOI at 4 km.

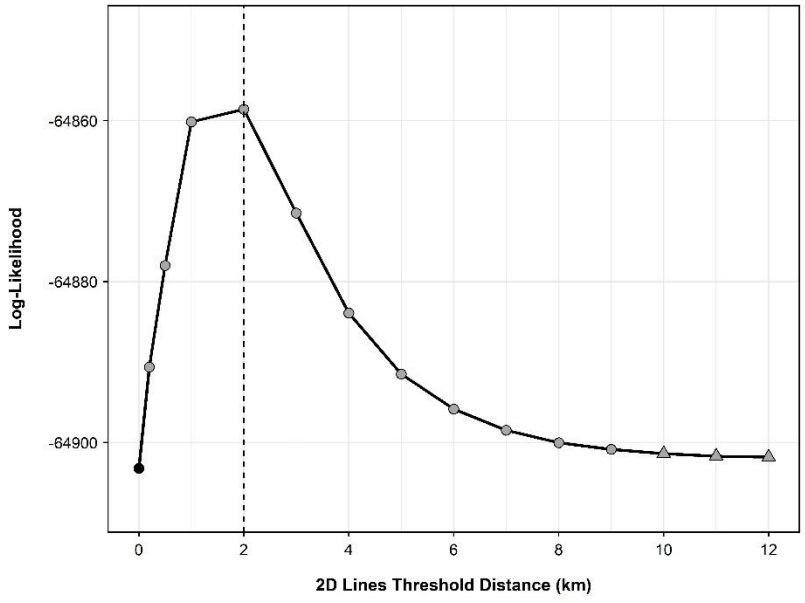


Attachment Figure 26. Segmented regression approach to estimating a zone of influence (ZOI) relative to the lone 3D seismic grid using GPS collar data from PCH caribou during late fall, 2012–2021. The threshold distance with the highest log-likelihood corresponds with the most likely ZOI. Circles and triangles indicate statistically significant and non-significant ZOI distances, respectively. Grey and red fills indicate positive and negative coefficients, respectively.

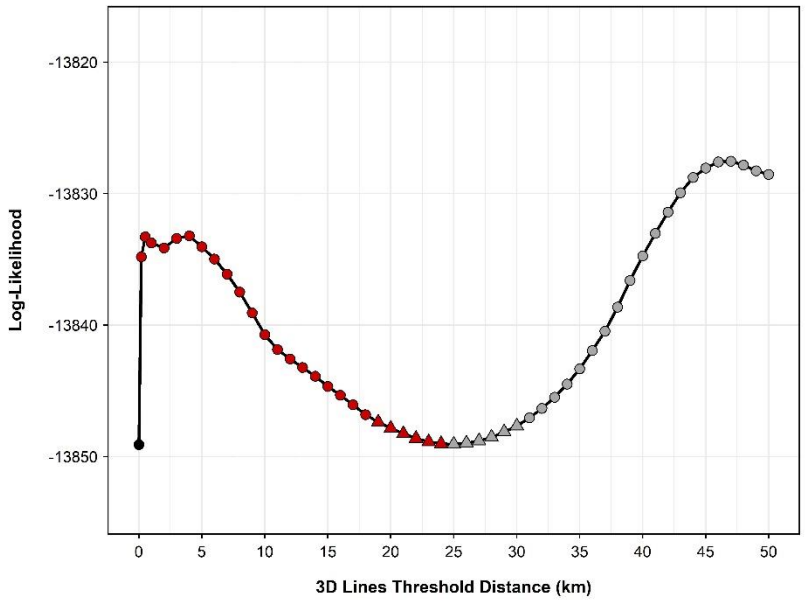


Attachment Figure 27. Segmented regression approach to estimating a zone of influence (ZOI) relative to the Dempster Highway using GPS collar data from PCH caribou during late fall, 2012–2021. The threshold distance with the highest log-likelihood corresponds with the most likely ZOI. Circles and triangles indicate statistically significant and non-significant ZOI distances, respectively. Grey and red fills indicate positive and negative coefficients, respectively.

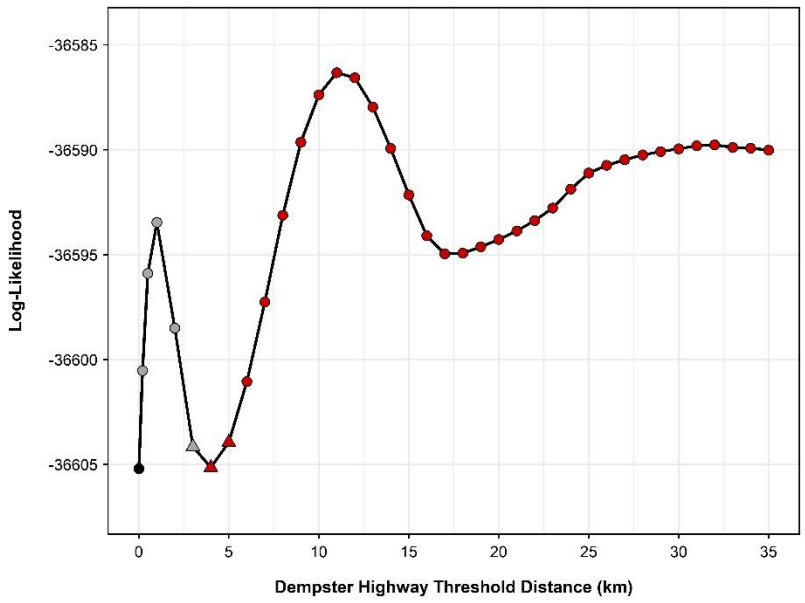
Winter



Attachment Figure 28. Segmented regression approach to estimating a zone of influence (ZOI) relative to 2D seismic lines (including winter roads and trails) using GPS collar data from PCH caribou during winter, 2012–2021. The threshold distance with the highest log-likelihood corresponds with the most likely ZOI. Circles and triangles indicate statistically significant and non-significant ZOI distances, respectively. Grey and red fills indicate positive and negative coefficients, respectively. Vertical dashed line indicates ZOI at 2 km.



Attachment Figure 29. Segmented regression approach to estimating a zone of influence (ZOI) relative to the lone 3D seismic grid using GPS collar data from PCH caribou during winter, 2012–2021. The threshold distance with the highest log-likelihood corresponds with the most likely ZOI. Circles and triangles indicate statistically significant and non-significant ZOI distances, respectively. Grey and red fills indicate positive and negative coefficients, respectively.



Attachment Figure 30. Segmented regression approach to estimating a zone of influence (ZOI) relative to the Dempster Highway using GPS collar data from PCH caribou during winter, 2012–2021. The threshold distance with the highest log-likelihood corresponds with the most likely ZOI. Circles and triangles indicate statistically significant and non-significant ZOI distances, respectively. Grey and red fills indicate positive and negative coefficients, respectively.

EXECUTIVE SUMMARY

The Eagle Plains Exploration Project (the Project) is an oil and gas exploration project located in north Yukon. Chance Oil and Gas Ltd. (Chance) intends to conduct exploratory activities to confirm the quality, quantity, and extent of hydrocarbons over ten years. Work will include seismic exploration and exploratory wells supported by an expanded winter road network. Oil and gas exploration activities create long, narrow clearings through natural vegetation, such as seismic lines and roads, collectively known as 'linear features.' Linear features can be a management challenge because they can affect how people and animals move and plants disperse within a landscape. For example, in southern parts of the boreal forest, linear features appear to affect predator-prey dynamics that can result in increased caribou mortality by wolves. The North Yukon and Peel Watershed Regional Land Use Plans identify mitigations to minimize the potential effects of linear features, including cautionary (0.75 km/km^2) and critical (1.0 km/km^2) indicator levels of linear disturbance.

Intermittent exploration activities in the Eagle Plains area from the 1950s to 2014 have created a network of winter roads, 2D seismic lines, and, most recently, 3D seismic lines in parts of the Regional Study Area (RSA). However, the extent of liner features that currently occur in the RSA, the structural, vegetation, and functional characteristics of different linear feature types, and their degree of regeneration are unknown. EDI Environmental Dynamics Inc. conducted a linear features study to characterize the structural, vegetation, and functional aspects of linear features in the RSA to address these information gaps. The study addressed three objectives: (1) comprehensive mapping and classification of existing linear feature footprints within the RSA; (2) quantification of structural aspects (e.g., widths) and functional aspects (ease of travel and sightlines) of linear features; and (3) quantification of regeneration pathways and structural stages of linear features. This combined information supports assessing potential effects of linear features in the Project application and refinement of mitigation measures for linear features to minimize possible effects.

The linear features inventory was compiled from multiple spatial datasets and was verified and supplemented using satellite imagery in a Geographic Information System. Linear feature densities were estimated for each linear feature type. Estimates were adjusted to account for (i) overlap with open habitats, such as recent burns, where vegetation heights were similar on and off the line, and (ii) for average rates of regeneration determined from field studies.

Site selection used a stratified random design to obtain a representative sample of different feature types across the RSA. Ground and aerial surveys measured specific structural, vegetation, and functional characteristics across the different line types. Measures included width, successional class, structural stage, vegetation composition and height, and sightline distances. A 'walk test' was used to index ease of movement for large mammals. A driving survey documented the visibility of seismic lines from the Dempster Highway (i.e., as an index of potential human access onto the seismic lines). An aerial winter track survey was conducted in March 2020 to assess ungulates' relative use of different linear feature types.

Four primary types of linear features occur in the RSA, totalling 4,269 km: 2D seismic (34%), 3D seismic (51%), winter roads (14%), and the Dempster Highway (1%). The unadjusted linear feature density for the RSA totalled 1.79 km/km^2. After accounting for burns, natural openings and regeneration, the adjusted linear

feature density for the RSA totalled 0.52 km/km², below the cautionary and critical indicator levels in the North Yukon and Peel Watershed Regional Land Use Plans.

Structural, vegetation, and functional characteristics differed substantially among linear feature types. 3D seismic accounts for the largest extent of linear features in the RSA and had the narrowest widths and limited functional effects (e.g., the proportion of features used by ungulates in the winter was less than a third of the rates of use on 2D and winter roads). Winter roads had the widest average widths and the greatest functional effects except for the Dempster Highway. However, a substantial portion (39%) had also regenerated into or past the Tall Shrub stage (which this study suggests may be the best criterion for functional recovery). Most 2D lines had substantial vegetation regeneration, resulting in the shortest average sightlines and slowest movement speeds. However, ungulates still appeared to select them to travel on during winter.

Except for the Dempster Highway, where walking speeds were near twice the rate of other linear feature types, there was relatively little difference in movement rates among linear feature types and control areas. The density of shrubs and trees primarily limited movement rates. 2D lines, which had the highest density of shrubby regeneration, had the slowest average movement rates. For other linear feature types, the combination of vegetation regeneration on linear features and the naturally open nature of most adjacent undisturbed areas did not convey a substantial increase in movement rates on linear features compared to undisturbed areas.

Sightline distances on 2D lines and winter roads were also affected mainly by the degree of vegetation regeneration. Where regeneration was limited, sightlines on 2D lines and winter roads regularly exceeded 150 m. On 3D lines, which have not had enough time since their creation for vegetation to regenerate to the height that restricts vision, sightlines were limited by meanders purposely constructed to reduce sightlines. The meanders employed on 3D lines were also effective in reducing the detectability of the lines from the Dempster Highway. In the blind test, where observers did not know the location of the 3D lines, only 5% (4 out of 74) crossings were spotted. With a map showing the crossing locations, only two additional 3D lines were detected.

These results provide information to assess the potential effects of linear features in the Project application and refine mitigation measures.

ACKNOWLEDGEMENTS

EDI Environmental Dynamics Inc. (EDI) completed the work within the traditional territories of the Vuntut Gwitchin First Nation (VGFN), First Nation of the Na-Cho Nyäk Dun, and the Tetlit Gwich'in Council (Secondary Use Area). Tyrel Kassi, a VGFN citizen, played an active role in the field components of the project. We thank him for his diligence and shared perspectives during the project.

AUTHORSHIP

1 INTRODUCTION

1.1 PROJECT OVERVIEW

The Eagle Plains Project (the Project) encompasses a 2,386 km² area in north-central Yukon, approximately 605 km north of Whitehorse and 40 km south and west of Eagle Plains hotel, along the Dempster Highway (Map 1-1). The Project occurs within the Eagle Plains petroleum basin, north of the Ogilvie River and west of the Richardson Mountains. The basin contains proven natural gas and oil reserves (Peel Watershed Planning Commission 2019), including 4.6 billion m³ of gas and 3.2 million m³ of oil (Hannigan 2014).

The Regional Study Area (RSA) has had intermittent periods of oil and gas exploration since the 1950s. That activity has developed winter roads, seismic lines, and exploratory wells across parts of the current RSA. Approximately 40 exploration wells have been drilled at Eagle Plains. Eight wells are maintained in suspended status, and the remaining wells have been plugged and abandoned. Seismic exploration has included approximately 10,000 km of two-dimensional (2D) lines (mainly before 1985), and about 325 km² of three-dimensional (3D) seismic was conducted in 2013–2014 (Northern Cross (Yukon) Ltd. 2014).

The current exploration program will build on past exploration to better define the extent, amount and quality of oil and gas deposits. Under the current program, Chance Oil and Gas Ltd. proposes conducting additional 3D seismic over large extents of the RSA and drilling up to 30 exploratory wells. Depending on the drilling program results, extended flow testing over several months may be conducted at a subset of the wells to determine the quantity and quality of the oil and gas deposit. The existing winter road network will be expanded to support the seismic and drilling programs. Most work is expected to be conducted in the winter (e.g., seismic line clearing and drilling); however, seismic recordings and extended flow testing may also occur during summer.

Oil and gas exploration activities create long, narrow clearings through natural vegetation, such as seismic lines and roads, collectively known as 'linear features.' Linear features can be a management challenge because they can affect how people and animals move and plants disperse within a landscape. For example, in southern parts of the boreal forest, linear features appear to affect predator-prey dynamics that can result in increased caribou mortality by wolves. The North Yukon and Peel Watershed Regional Land Use Plans identify mitigations to minimize the potential effects of linear features. The Plans also include cautionary (0.75 km/km²) and critical (1.0 km/km²) linear density indicator levels.

1.2 PURPOSE AND OBJECTIVES

Intermittent exploration activities in the Eagle Plains area from the 1950s to 2014 have created a network of winter roads, 2D seismic lines, and, most recently, 3D seismic lines in parts of the RSA. However, the extent of liner features that currently occur in the RSA, the physical and functional characteristics of different linear feature types, and their degree of regeneration are unknown.

EDI Environmental Dynamics Inc. (EDI) conducted a linear features study to characterize the physical and functional aspects of linear features in the RSA to address these information gaps. The three objectives of this study were to: (1) conduct comprehensive mapping and classification of existing linear feature footprints within the RSA; (2) determine physical aspects (e.g., widths) and functional aspects (ease of travel and sightlines) of linear features; and, (3) quantify regeneration pathways and stages of linear features. The combined information forms the basis for assessing the potential effects of linear features in the RSA and refining mitigation measures for linear features.

1.3 STUDY AREA

The RSA for the Eagle Plains Project is approximately 2,386 km² (238,566 ha), centred in the Eagle Plains Ecoregion in north Yukon (Map 1-1). The area consists of subdued topography of rolling hills and sloping plains. The RSA is centred on a major watershed divide (denoted by the location of the Dempster Highway), with the northwestern two-thirds of the RSA draining into the Porcupine River watershed to the north, via Chance Creek, and west, via McParlon Creek and the Whitestone River. The southeastern third of the RSA drains into the Peel River watershed via Dalglish Creek.

Development in the RSA and the surrounding Eagle Plains is low. The Dempster Highway is the primary vehicle access corridor, running from approximately Dawson City, Yukon in the south to Inuvik, Northwest Territories in the north, and transiting the RSA. The Eagle Plains settlement is on the Dempster Highway, approximately 40 km northeast of the RSA and includes the Eagle Plains Hotel and the Government of Yukon's Highway Maintenance camp. The Eagle Plains area has had intermittent periods of oil and gas exploration since the 1950s. That activity has created winter roads, seismic lines, and exploratory wells across parts of the RSA. Approximately 40 exploration wells have been drilled at Eagle Plains. Eight wells are maintained in suspended status, and the remaining wells have been plugged and abandoned. Approximately 10,000 km of 2D lines have been developed across the Eagle Plains Ecoregion, mostly between 1961 and 1984 (Access Consulting Group and EBA Engineering Consultants Ltd. 2001, GEOTIR 2014). More recently, approximately 2,200 km of 3D LIS exploration was conducted in a 325 km² area between November 2013 and April 2014 (GEOTIR 2014). This 3D exploration grid is near the centre of the RSA, spanning north and south of the Dempster Highway.

1.3.1 REGIONAL ECOLOGICAL SETTING

The Eagle Plains Ecoregion is a 20,400 km² portion of the Taiga Cordillera Ecozone in north Yukon between the Richardson and Ogilvie Mountains. Unlike much of the mountainous Taiga Cordillera, most of the Eagle Plains Ecoregion occurs as low altitude rolling topography between 300 m and 600 m above sea level (masl), with few scattered peaks above and around 1,000 masl (Ecological Stratification Working Group 1995). Most of the ecoregion is unglaciated terrain, with surficial features formed due to permafrost and frozen ground-related processes, including thermokarst subsidence, soil creeps, cryoturbation, solifluction, and active layer detachment slides on shale (Yukon Ecoregions Working Group 2004).

The Eagle Plains Ecoregion experiences moderate precipitation, with annual amounts around 400 mm. Most precipitation falls as rain throughout the summer, averaging 50 to 80 mm per month, June through August. Precipitation is lighter through September to April and falls as snow, with average winter snowpacks of 80 cm peaking in April. The climate is strongly affected by latitude, with extended winter conditions from October to early May. There is a substantial variation in seasonal temperatures in the Eagle Plains, with cool short summers and long cold winters. Average winter temperatures are between −30°C and −25°C, with extremes as low as −60°C. Average summer temperatures are around 13°C, with extremes as high as 30°C. Due to the northern latitude, this region experiences continuous sun above and below the horizon, in summer and winter, respectively.

Most of the Ecoregion, including the northeast portion of the RSA, drains north into the Yukon River via the Whitestone, Porcupine and Eagle rivers. That part of the RSA includes the headwaters of the Eagle River and several other tributaries of the Porcupine River, along with the Chance and McParlon Creek subdrainages of the Whitestone River. The southeast corner of the Ecoregion drains east to the Mackenzie River via the Peel, Wind and Ogilvie Rivers. Dalglish and Enterprise creeks flow directly into the Peel River. The few lakes in the Ecoregion are generally oxbow or thermokarst lakes (Yukon Ecoregions Working Group 2004). Several wetland complexes are associated with larger creeks in the RSA.

The Eagle Plains Ecoregion is within the continuous permafrost zone where permafrost can be found up to 200 m thick. The Eagle Plains Ecoregion is dominated by the Cryosolic soils that occupy much of the northern third of Canada, characterized by near-surface permafrost. Turbic Cryosols predominate, exhibiting patterned ground formations and hummocks, and are often associated with open stands of black spruce (*Picea mariana*), tamarack (*Larix laricina*) and birch (*Betula* spp.). The active permafrost layer in these ecosystems generally ranges between 20 cm and 90 cm below the surface. The active layer depth is generally deeper directly under hummocks and shallower under inter-hummock areas (Yukon Ecoregions Working Group 2004).

The RSA is entirely within the Subarctic Bioclimate Zone (Environment Yukon 2014). Vegetation in the RSA is characterized by open-canopy, spruce-dominated habitats where permafrost and short cool growing seasons limit tree growth and often result in stunted, disclimax vegetation communities (Environment Yukon 2016). Hummocky, black and white spruce (*Picea glauca*) woodlands with well-developed shrub communities are common in upland areas. White spruce and ground lichens increase in abundance in well-drained sites. Areas with low slope gradients and fine-textured soils often have ground cover dominated by cottongrass tussocks beneath a shrub layer of birch, black spruce, Labrador tea (*Rhododendron groenlandicum*), and occasionally tamarack (*Larix laricina*) (Yukon Ecoregions Working Group 2004).

Forest fires are a common disturbance agent in the region, and burns of various ages occur throughout the RSA. Fires increase the depth of the active permafrost layer and changes in soil moisture and productivity, affecting vegetation regeneration and resulting in terrain disturbances, such as slope failures and erosion. Regenerating burns are dominated by shrubs, such as scrub birch (*Betula glandulosa*), willows (*Salix spp.*) and alder (*Alnus spp.*), with Alaskan paper-birch (*Betula neoalaskana*) often the first tree species to colonize burn areas. As burns regenerate into young and mature forest, black and white spruce typically become the dominant forest species. Residual Alaskan birch in spruce-dominated stands often defines the extent of old burns (Yukon Ecoregions Working Group 2004).

Mammal diversity is relatively low in the Eagle Plains Ecoregion due to its northern location and low productivity. Voles (*Microtus* spp., *Myodes* spp., *Phenacomys* spp.), American marten (*Martes americana*), ermine (*Mustela erminea*), and red fox (*Vulpes vulpes*) are common smaller mammals. Wolves (*Canis lupus*), wolverines (*Gulo gulo*), and both black and grizzly bears (*Ursus americanus* and *U. arctos*.) are present at low densities. Moose (*Alces alces*) inhabit the region year-round. The RSA overlaps a small portion of the winter range of the Porcupine caribou herd (PCH), a subpopulation of the barren-ground caribou (*Rangifer tarandus granti*). The PCH is an iconic species in north Yukon, with high cultural, social, economic, and ecological values. The PCH's population has been increasing over the last several decades and is currently estimated to consist of 202,106 to 234,808 caribou (Caikoski 2017, Porcupine Caribou Technical Committee 2018). The PCH is known to occupy portions of the Eagle Plains Ecoregion in fall and winter when they tend to occur in smaller groups over a larger area than during other seasons.

1.3.2 REGIONAL LAND USE PLANNING

The RSA overlaps four First Nation Traditional Territories. Most of the RSA is within the Traditional Territory of the Vuntut Gwitchin First Nation. The southeastern portion is in an area of overlapping Traditional Territories of Vuntut Gwitchin First Nation, the Tetlit Gwich'in Council, the First Nation of Na-cho Nyäk Dun, and Tr'ondëk Hwëchin. Although the RSA is located outside of any First Nation Settlement Lands, it does abut Vuntut Gwitchin First Nations Settlement Lands on parts of its east and southwest borders. Each First Nations government has provided input to, and approved of, the Regional Land Use Plan(s) on their Traditional Territory under the respective First Nation Final Agreements.

1.3.2.1 North Yukon Regional Land Use Plan

The RSA lies mainly within the North Yukon Planning Region and is subject to the North Yukon Regional Land Use Plan (NYRLUP) (Map 1-1). The NYRLUP was created to protect the natural and cultural resources of the region while allowing sustainable economic development opportunities (Vuntut Gwitchin Government and Yukon Government 2009). It provides management direction for using public and settlement lands based on four principles: sustainable development, precautionary principle, conservation, and adaptive management. The NYRLUP divides the Planning Region into 23 land management units classified into three categories: protected area, integrated management area (IMA), and community area. IMAs are further classified into four zones: Zone 1 (lowest development), Zone II (low development), Zone III (moderate development), and Zone IV (highest development). IMA zones are classified based on the area's sensitivity to landscape disturbance, ecological and cultural values, risk of significant impacts, and level of acceptable change. The RSA is a Zone IV IMA with lower ecological and cultural values in a moderately sensitive biophysical setting. Subsequently, Zone IV IMAs allows for the highest development level to occur.

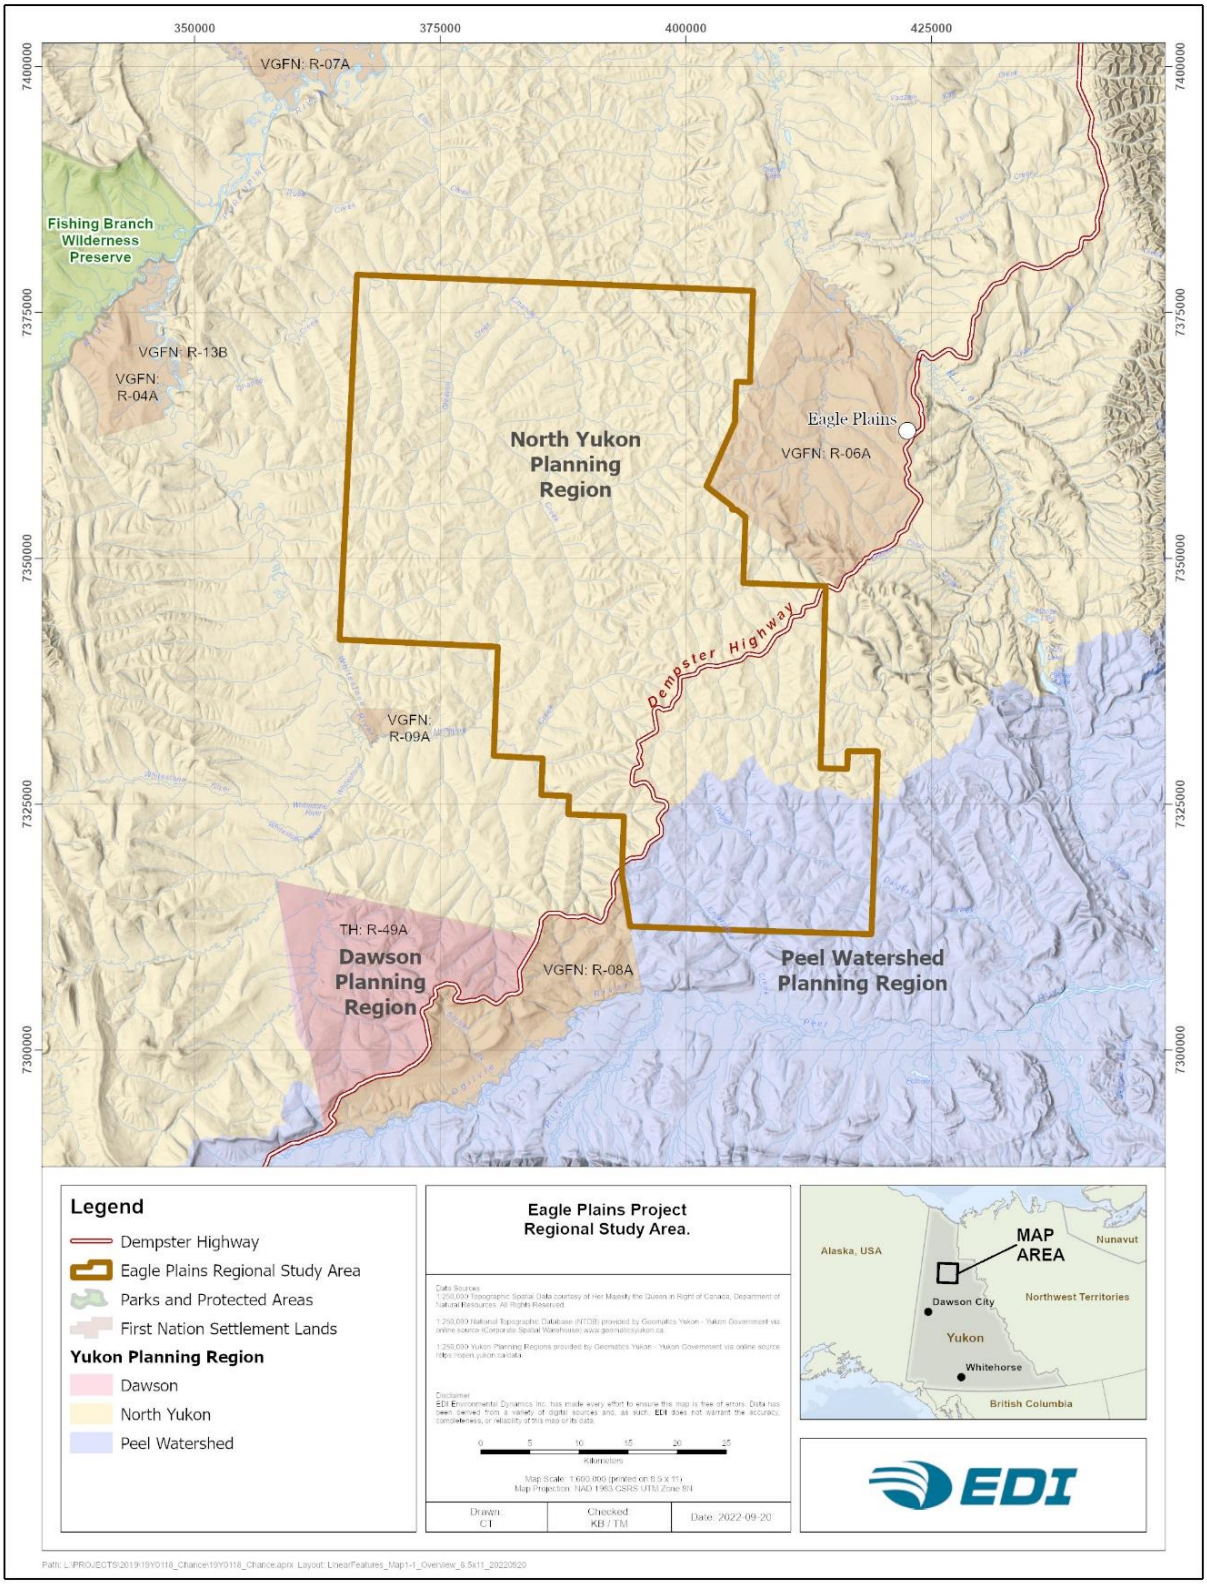
The NYRLUP encourages results-based management and uses cumulative effects indicators to determine if goals and objectives are met. Results-based management allows for innovation and creativity in land-use strategies and approaches. The two cumulative effects indicators included in the NYRLUP are direct surface disturbance and linear density. The NYRLUP guidelines for Zone IV IMAs are 0.75–1.0% surface disturbance and 0.75–1.0 km/km² linear density (Vuntut Gwitchin Government and Yukon Government 2009).

However, as surface disturbances and linear features reach a level of functional recovery and become part of the continuous landscape, they can be subtracted from the total amount of disturbed area (Vuntut Gwitchin Government and Yukon Government 2009). The NYRLUP suggests using a height of 1.5 m for woody vegetation in forested areas, as vegetation above this height would likely no longer allow for travel or access by humans or wildlife and is, therefore, considered functionally recovered. Activities considered exempt from functional disturbance restrictions are (1) new linear features less than 1.5 m wide; (2) land-use activities that occur on frozen water bodies; (3) winter work with no required clearing of trees; and (4) winter work that uses existing disturbances and linear features.

1.3.2.2 Peel Watershed Regional Land Use Plan

The southeastern corner of the RSA lies within the Peel Watershed Planning Region (PWPR) and is subject to the Peel Watershed Regional Land Use Plan (PWRLUP) (Peel Watershed Planning Commission 2019) (Map 1-1). Like the NYRLUP, the PWRLUP was established to provide management direction and ensure long-term sustainable development in the Planning Region. The PWRLUP was founded on three main themes: environmental protection, social considerations, and economic development. It follows a similar framework as the NYRLUP. The PWPR is divided into 16 Landscape Management Units (LMU), which each share similar ecological characteristics, planning issues, and management intent. Each LMU is categorized by a land-use designation system. Conservation Areas are managed to protect ecological and cultural resources, while IMAs are 'working' landscapes where new development and surface disturbance may be allowed. IMAs are further classified into Zones, which correspond to the level of allowable development with comparable justification as the NYRLUP. The RSA is part of LMU 7 (Dalglish Creek), classified as an IMA Zone IV, allowing for the highest level of development.

Like the NYRLUP, the PWRLUP encourages results-based management and uses the same cumulative effects indicators, surface disturbance and linear density to inform decisions. The PWRLUP cautionary and critical indicators are identical to those of the NYRLUP: 0.75–1.0% surface disturbance and 0.75–1.0 km/km² linear density. As surface disturbances reach a level of functional recovery and no longer enable travel or access by wildlife and people, they can be subtracted from the total amount of disturbed area. The PWRLUP suggests using a 1.5 m woody vegetation height as a threshold for functional recovery in forested or shrubland areas. In areas dominated by low-growing vegetation, a feature could be considered functionally recovered when covered by native species roughly the same height and composition as the surrounding vegetation. To be considered as "functionally recovered," features must have similar sediment and run-off compared to background levels, roughly match original contours, and have no human-brought materials on the site. Exceptions to the linear density calculation are identical to those outlined in the NYRLUP.



Map 1-1. Eagle Plains Project Regional Study Area.

2 BACKGROUND

The term "linear feature" refers to any narrow, linear clearings of vegetation on the landscape. They include roads, seismic lines, power lines, and pipelines. Seismic lines are the dominant linear feature class in northern Canada, accounting for approximately 46% of all linear features in the Canadian boreal region (Pasher et al. 2013). Seismic exploration detects underground oil and natural gas reservoirs by analyzing sound waves reflected from the underlying geology (Yukon Energy Mines and Resources 2006). Sound waves are emitted by detonating small charges in a series of drilled shot holes (up to 20 m deep) or by vibrating a heavy metal plate on the ground's surface using a truck-mounted vibrator (Yukon Energy Mines and Resources 2006). Both methods require cleared travel corridors for equipment transportation, which results in a network of seismic lines across the landscape where seismic exploration has occurred.

Until the late 1990s, conventional 2D was the primary form of seismic exploration used in North America. 2D seismic lines were created using bulldozers to clear all vegetation in straight swaths, approximately 5–10 m wide in their earliest form. These wide, straight lines were necessary to enable large, heavy equipment movement. This process resulted in significant physical disturbance, often removing most surface vegetation and roots and the top layer of soil (Bliss and Wein 1972). Progressive improvements in 2D seismic exploration methods reduced the environmental impact, such as clearing in winter instead of summer and raising and adding mushroom shoes to the bulldozer blade to reduce soil disturbance. Despite these improvements, many of the 2D seismic lines created in the 1960s and 1970s in northern Canada remain disturbed, with little evidence of ecological recovery (Lee and Boutin 2006, van Rensen et al. 2015).

3D seismic exploration provides more accurate subsurface geological structure data than 2D technology. 3D seismic exploration techniques were developed in the mid-1990s, and their use became widespread in the early 2000s (Dabros et al. 2018). At the same time as the transition to 3D, the seismic industry was transitioning to smaller and more specialized equipment that reduces cost, improves efficiency and reduces environmental impacts. Modern seismic equipment and methods typically use what is referred to as Low Impact Seismic (LIS) methods that minimize line widths and site disturbance and compaction. Typical 3D seismic lines are 2–3 m wide, constructed in 100–500 m spaced grids, and follow meandering rather than straight routes. There have been substantial improvements in the equipment used for 3D seismic line creation: low ground pressure mulchers, lighter equipment, ATV-mounted equipment, mushroom shoes and smear blades, and 'envirodrills' greatly reduce physical and vegetation disturbance (Dabros et al. 2018). These methods often leave the ground vegetation intact and only remove trees and tall shrubs, reducing overall disturbance and facilitating faster regeneration. The location of the seismic line can be adjusted on the fly in the field to minimize impacts, such as avoiding the cutting of large trees.

Continuous advancements in seismic exploration technology have improved geophysical accuracy while simultaneously reducing environmental impact. Numerous studies have examined the effects of linear disturbances on soil, hydrology, vegetation, regeneration, and wildlife responses (see Dabros et al. 2018 for a comprehensive review). Although the bulk of literature focuses on 2D seismic lines, as they have been part of the landscape for over 60 years, there have been several recent studies investigating the effects of LIS and 3D seismic lines (e.g., Kemper and Macdonald 2009a, Kansas et al. 2015, Golder Associates 2016).

Linear features have been associated with various environmental effects, including permafrost thaw, soil compaction and rutting, increased soil moisture and pooling, altered snow cover, temperature and wind patterns, and varied vegetation and wildlife responses (Dabros et al. 2018). In addition to the immediate loss of vegetation, linear features can create extensive edge effects, facilitate non-native or disturbance-induced species establishment, alter species composition, and positively and negatively affect wildlife (Dabros et al. 2018).

One of the most extensively studied effects of linear features in the southern boreal forest is the indirect effects that linear features can have on mortality risk to woodland caribou (*R. tarandus caribou*). Linear features can result in complex effects on populations dynamics that include (i) increases in secondary prey (moose and deer), which elevate wolf populations (apparent competition) and (ii) more efficient hunting by predators along linear features (facilitated predation) (Wittmer et al. 2007, Latham et al. 2011, Dickie et al. 2017a, Keim et al. 2019b, 2021). Research has also documented the responses of birds to linear features (Bayne et al. 2005, Machtans 2006, Lankau et al. 2013), bears (Tigner et al. 2014, Finnegan et al. 2018), and furbearers (Tigner et al. 2015).

Most studies investigating impacts and recovery of seismic lines and other linear features were conducted in southern boreal forest ecosystems (i.e., Boreal Plains Ecozone; e.g., Lee and Boutin 2006, Kansas et al. 2015, van Rensen et al. 2015, Dickie et al. 2017a). There are fundamental differences in the climate, vegetation communities, wildlife communities, and ecological processes in taiga ecosystems that may result in different patterns and responses to linear features. For example, regeneration patterns of linear features in taiga ecosystems over permafrost can follow different successional trajectories than those of southern boreal regions (Simpson 2008). The few studies that have examined linear features in taiga regions have found similarities and differences to southern studies revegetation (Kemper and Macdonald 2009, Dabros et al. 2018). One of the key objectives of this study was to collect local information from Eagle Plains that can be used to better contextualize or adapt the findings from other studies to the Eagle Plains Project.

3 METHODS

A GIS analyses and field surveys were conducted to characterize linear features within the RSA. The inventory of linear features in the RSA was developed in a GIS by compiling available spatial data and then verifying and updating that against satellite imagery. Field studies quantified the width, vegetation characteristics, ecological function (line-of-sight, large mammal ease of movement assessment), and visibility of lines from the Dempster Highway.

3.1 LINEAR FEATURES INVENTORY

The inventory of existing linear features in the RSA was developed in a GIS by compiling available spatial data and then verifying and updating that against satellite imagery. A preliminary linear feature database was first developed that was used to support field surveys (described below in this section). A second step linked the field data to the linear feature database and conducted a more thorough review and verification process using satellite imagery to produce a final linear feature dataset for the RSA (see details in section 3.5.1).

Linear feature spatial data were obtained from the following sources:

- Yukon Government Energy, Mines and Resources "Oil and Gas Seismic Lines" dataset (a combination of less detailed National Energy Board data pre-1999 and the more detailed company-submitted data post-1999) (Yukon Government 2019)
- Natural Resources Canada CanVec "Roads," "Trails," and "Cut Lines" 1:50,000 scale datasets (Natural Resources Canada 2019)

The two datasets were merged into one dataset of all linear features documented in Yukon and clipped to the RSA. Key attribute data included (if available) the linear feature type (i.e., 2D and 3D seismic lines, winter roads, trails, Dempster Highway), width, year of establishment, and data source. This preliminary linear feature dataset was compared against satellite imagery at a (minimum) 1:10,000 scale to verify its accuracy. Any linear features that did not correspond with features visible in satellite imagery were either corrected or deleted based on satellite imagery interpretation. In the case of duplicate features across datasets, the 'best' data were attributed to a single feature by considering the spatial accuracy and the amount and accuracy of attribute data, as assessed against satellite imagery. Where duplicate widths occurred in the two source datasets, the wider width was retained.

3.2 LINEAR FEATURE CHARACTERISTICS SURVEY

Field studies quantified the width, vegetation characteristics, line-of-sight, and large mammal ease of travel assessment across the linear feature types identified from the GIS inventory. One aspect of the field study was to compare vegetation, line-of-sight, and ease of movement on the linear features to undisturbed areas adjacent to the cleared lines. Three types of surveys collected data for the linear feature study: ground surveys

(finest level of detail), air surveys (medium level of detail), and air calls (coarsest level of detail). EDI crews collected field data between July 28 and August 8, 2019.

3.2.1 SITE SELECTION

All ground surveys and aerial surveys occurred at predetermined, random sites. Sample sites were selected using a clustered, random sampling approach. This approach balanced obtaining a random, representative sample across linear feature types with survey efficiency (i.e., without clustering sites, the travel time between points would have been substantially greater and resulted in smaller sample size). Survey sites were drawn from 5,000 points distributed randomly across the set of mapped linear features (minimum spacing of 200 m between points). Each point was randomly assigned a unique number.

Each survey cluster included options for both ground and air surveys. For ground surveys, the cluster used a 2 km radius designed to accommodate approximately four ground survey sites, intended to be surveyed within a half-day of work (and close enough so crews could walk between sites). The objective was that two ground clusters could be surveyed by a crew each day. For air surveys, a 4 km radius was used that generally provided at least ten random survey site options. The objective for air survey clusters was that they could be surveyed while transiting between ground survey clusters.

Survey sites were selected via a two-stage process. The first stage was randomly drawing 100 points from the 5,000-point dataset. These points defined the survey clusters and served as actual survey sites. In this first stage, site selection was stratified to obtain an approximately equal sample across 2D, 3D and winter roads. This overweighted sampling of 2D and winter roads, relative to their extents in the RSA, but those features had the highest uncertainty in terms of their widths, vegetation characteristics, and functional characteristics. Stratification was necessary to obtain sufficient sample sizes across these less-common features. The second site-selection stage selected additional random points from the 5,000-point dataset in proximity to the first point, using the 2 km radius for ground surveys and the 4 km radius for aerial surveys.

The RSA was divided into 10 work areas to implement the sample design, each corresponding to a day of surveys. Each day the survey crew selected clusters to survey using the ascending order of the random identification number of the first point used to define each cluster. Similarly, points within each cluster were prioritized in ascending order of the random identification number. Normally, at least two ground clusters and two air clusters were sampled each day. However, that varied somewhat depending on the number of sample sites available in each cluster and the availability of the helicopter.

3.2.2 LINEAR FEATURE CHARACTERISTICS AND SURVEY METHODS

3.2.2.1 Linear Feature Characteristics

A range of structural, vegetation, human use, and functional characteristics was assessed in the field. A list of the various characteristics examined, with a description of each, is provided in Table 3-1. Successional classes and structural stages of vegetation are defined in Table 3-2 and Table 3-3, respectively.

Table 3-1. Description of physical, ecological and function characteristics assessed in the Eagle Plains linear feature study.

Parameter	Description	Survey Measured [1]
Plot location	Latitude and longitude using WGS 1984, measured by Garmin GPS units to ~4 m accuracy.	G, AS, AC
Linear feature type	Dempster Highway, winter road, 2D, 3Dc (conductor lines), 3Dr (receiver lines), and 3D5 (3D lines used both for seismic and local equipment/vehicle travel.	G, AS, AC
Linear feature width	During ground surveys, measured to the nearest 0.05 m and replicated four times. During aerial surveys, they were visually estimated to the nearest 1 m.	G, AS
Percent mulch	Percent cover of mulch (wood chips) on the seismic line, estimated to the nearest 1% using visual estimates. In areas with dense trees or large shrubs, the thick mulch layer produced during line clearing can hinder vegetation regeneration.	G, AS
Successional class	Refers to the successional trajectory of vegetation regeneration on the linear feature. Includes normal, magnified, stagnated, retrogressive, no succession, or recent disturbance class following Simpson (2008)[1].	G, AS, AC
Burn status	Burnt or not burnt; based on visual assessment (i.e., burned trees, charred ground vegetation).	G, AS, AC
Structural stage	Categorical descriptor of the dominant vegetation life form in the plot following the *Field Manual for Describing Yukon Ecosystems* criteria (Environment Yukon 2017). Structural stage categories are defined in Table 3-3.	G, AS
Height and species of tallest vegetation	Measured to the nearest 0.1 m for the tallest vegetation layer, approximated by the 90th percentile height to exclude extreme heights of individual plants.	G
Cover and species of dominant trees	Percent cover was recorded to the nearest 1% if less than 10%, and to the nearest 5% if over 10%. One or two dominant tree species were recorded.	G, AS
Cover and species of dominant shrubs	Percent cover was recorded to the nearest 1% if less than 10%, and to the nearest 5% if over 10%. Up to five co-dominant shrub species were recorded. Ground shrubs were excluded.	G, AS
Ecosite	Ecosite was recorded using Predictive Ecosystem Mapping (PEM) Units, available at the time of the survey. However, separate vegetation surveys indicated that the accuracy of the PEM mapping was poor, and ecosites were not used in subsequent analyses.	G
Permafrost activity/degradation	Present or absent. Additional comments (i.e., type of activity, percent cover) were recorded if applicable.	G
Wildlife trails	Present or absent. If present, rated as poorly, moderately, or well defined.	G
Potential for Off-Highway Vehicle (OHV) passage	Present or absent. Based on professional judgment, a 4x4 side-by-side is summer, considering obstructing vegetation, ground conditions (e.g., wetlands, peatlands), and graminoid tussocks.	G, AS
Signs of human activity	Present or absent. If present, applicable comments were recorded.	G
Ground disturbance	Percent cover of visibly disturbed ground. If present, type and additional descriptive comments were recorded.	G

[1] G=Ground Survey, AS=Aerial Survey, AC=Air Call.

[2] Between 2006 and 2008, Yukon Government, Department of Energy, Mines, and Resources investigated the recovery status of linear features in the Eagle Plains, British Mountains, and Peel River Plateau Ecoregions (Simpson 2008). They found that linear features typically regenerated into one of six categories: normal succession, magnified succession, retrogressive succession, successional stagnation, no succession, and recent disturbance (Table 3-2).

Table 3-2. Descriptions of successional classes on linear features in the Eagle Plains area (following Simpson 2008).

Successional Class	Description
Normal succession	Vegetation is similar to the adjacent undisturbed area but often in an earlier seral stage. E.g., often young trees surrounded by early successional shrubs and forbs. The disturbance was likely limited to removing trees and shrubs, with little to no disturbance to soil or permafrost.
Magnified succession	Vegetation on the feature is taller than the adjacent undisturbed area. Deciduous species often dominate tree and shrub layers, but a similar pattern was also observed for coniferous trees on some sites. The response is likely due to increased site productivity (including increased soil moisture, nutrients, and temperature) due to soil disturbance or increased depth to permafrost. Most frequently, but not exclusively, observed in burns.
Retrogressive succession	Sites are typically moss or sedge-dominated (rarely forb or low shrub), with high moisture content, often including standing water (i.e., micro wetlands), that contrast to upland conditions in adjacent undisturbed areas. The condition appears to result from permafrost melting and water pooling associated with vegetation removal and removal/compaction of the peat layer and mostly associated with winter roads.
Successional stagnation	Vegetation is typically dominated by graminoids or shrubs and not progressing to more advanced successional stages. Disturbance to soil or permafrost is likely. The ground may have been compacted. Almost exclusively associated with winter roads.
No succession	No ecological differences between the linear feature and adjacent undisturbed areas except that there is no or very little tree or shrub regeneration on the line, other than what was left after creation of the feature. Disturbance appears to be limited to the removal of trees and shrubs, with little to no disturbance to ground vegetation, soil, or permafrost.
Recent disturbance	Newer seismic line where successional patterns could not be determined. Features in this class were most likely trending to 'normal succession' or 'no succession', but the degree of regeneration was too limited to classify confidently.

Table 3-3. Structural stage categories used in ground and air surveys for the Eagle Plains linear feature study.

Structural Stage Code	Structural Stage Name	Description
1	Non-vegetated	Very recent disturbance (e.g., fire or flood) and no vegetation or less than 5% vegetation.
2	Sparse/Cryptogram	Either the initial stages of primary succession or a cryptogram community maintained by environmental conditions (e.g., bedrock, talus). Sparse tree, shrub and herb cover. Either sparsely vegetated overall (low cover of vascular plants and cryptograms, if present) or dominated by cryptograms.
2a	Sparse	5–10% vegetation cover.
2b	Bryoid	Bryophyte-dominated.
2c	Lichen	Lichen-dominated.
3	Herb	Early successional stage (e.g., post-fire forest succession) or a herb community maintained by environmental conditions or disturbance. Vegetation is dominated by herbs, although if the site overall is sparsely vegetated, herb cover can be low as long as herbs characterize the vegetation. Trees and shrubs are usually sparse or absent; however, shrub cover and stature (compared to herb cover and stature) determine whether the site is considered herbaceous.
3a	Forb-dominated	Includes non-graminoid herbs and ferns.

Structural Stage Code	Structural Stage Name	Description
3b	Graminoid-dominated	Includes grasses, sedges, reeds, and rushes.
3c	Aquatic	Floating or submerged plants dominate.
3d	Ground shrub-dominated	Dominated by dwarf woody species such as kinnikinnick (*Arctostaphylos uva-ursi*) or dwarf willows.
4	Shrub	Early successional stage of a forest or a shrub community maintained by environmental conditions or disturbance. Dominated either by shrubby vegetation, including tree seedlings or saplings; or, if sparsely vegetated overall, dominated by shrubs, which characterize the community as a shrubland.
4a	Tall Shrub	Dominated by woody plants >2 m tall with diameter at breast height (dbh) ≤7 cm.
4b	Low Shrub	Dominated by woody plants <2 m tall.
5	Treed: Pole/Sapling	Trees >2 m tall and with dbh >7 cm, typically densely stocked. Self-thinning and vertical structure are not yet evident in the canopy. Younger stands are vigorous (usually >15 to 20 years old); older stagnated stands (up to 100 years old) are also included; time since disturbance usually <40 years; up to 100+ years for dense (5,000–15,000+ stems per ha) stagnant stands.
6	Treed: Young Forest	Self-thinning has become evident and the forest canopy has begun to differentiate into distinct layers. A more open stand than at the pole/sapling stage.
7	Treed: Mature Forest	Trees established after the last stand-replacing disturbance have matured; a second cycle of shade-tolerant trees may have become established; shrub and herb understoreys become well developed as the canopy opens up.
8	Treed: Old Forest	Stands of old age with complex structure; patchy shrub and herb understoreys are typical; regeneration is usually of shade-tolerant species with a composition similar to the overstorey. Fire-maintained stands may have a single-storey appearance.
9	Treed: Very Old Forest	Very old stands with complex structures, abundant large trees, snags and coarse woody debris (CWD); snags and CWD occurring in all stages of decomposition; stands are comprised entirely of shade-tolerant overstorey species, with well-established canopy gaps.

3.2.2.2 Survey Methods

Three types of surveys assessed linear feature characteristics: ground surveys (finest level of detail), air surveys (medium level of detail), and air calls (coarsest level of detail). The reason for using different survey types was to maximize the sample size obtained, recognizing that the ability to collect certain types of data, or the level of measurement precision, decreased from ground surveys to aerial surveys to air calls. The characteristics that were measured during each survey type are noted in Table 3-1. Surveys were conducted between July 28 and August 8, 2019.

Ground surveys collected the most information and had the highest measurement precision of the three survey methods. All parameters listed in Table 3-1 were recorded. Field measurements generally followed methods in *Field Manual for Describing Terrestrial Ecosystems* (BC MFLNRORD and BC MOE 2010) with parameter specific details noted in Table 3-1. Photographs were taken of representative on-line and off-line plots.

Air surveys collected moderate resolution data on linear features. Air surveys efficiently collected a larger quantity of more generalized data than ground surveys. The subset of parameters recorded for aerial surveys is noted in Table 3-1. The survey methods generally followed procedures outlined for helicopter-based 'visual checks' in *Standard for Terrestrial Ecosystem Mapping in British Columbia* (Resources Inventory Committee 1998). Data were collected by hovering in a helicopter approximately 30 m over the sample sites for approximately three minutes while field crews recorded data for the reduced set of variables. Like ground surveys, relevant data were collected for both on-line and off-line plots. Photographs were taken at representative air survey plots (Attachment A).

Air calls collected data at the coarsest resolution of the three survey types, and no off-line data were collected. The data collected during air calls were limited to linear feature type, successional class, and burn status. Air calls were opportunistically conducted when EDI crews were flying through the RSA and linear features were encountered.

A fundamental aspect of the field study was to compare linear feature characteristics to adjacent undisturbed areas. Hence, field surveys included paired on-line and off-line plots at each sample site (excluding sites assessed via air calls). Off-line plots were located 50 m off the linear feature, with the direction off the feature selected randomly at each site using a coin toss. Data collected for each sample site were recorded on tailored survey forms (Attachment B).

3.2.2.3 Line-of-Sight and Ease of Travel

In addition to the structural and vegetation measures noted above, line-of-site and ease-of-movement were assessed as functional characteristics of the linear features at each ground plot. The sightline, measured to the nearest metre, was calculated as the farthest line that could be sighted using a range finder at the height of 1.5 m off the ground. Two measurements were recorded, one in each direction along the linear feature. Sightline measurements were repeated using the same bearings in the off-line plot.

Ease of travel was assessed using a 'walk test,' as Keim et al. (2019a) described in a study assessing the functional recovery of linear features. They found that ease of travel, as measured by a walk test conducted by human researchers, positively correlated with the intensity of use by several wildlife species. One EDI crew member timed themselves to the nearest second for the walk test while walking an approximately 75 m transect, measured to the nearest metre using a hip chain. This walk test was repeated in both the on-line and off-line plots, the paired transects spaced in parallel, approximately 50 m apart. The same observer conducted both walk tests to minimize observer bias at each site.

3.3 VISIBILITY OF LINEAR FEATURES FROM THE DEMPSTER HIGHWAY

One of the management concerns associated with seismic exploration is that seismic lines create travel routes that humans use. The probability of human use of seismic lines to access the surrounding landscape likely increases if the seismic line is visible and accessible from roads. The intersections of seismic lines and winter roads with the Dempster Highway are the primary locations where this could originate. Driving surveys were conducted along the 47 km section of the Dempster Highway within the RSA to determine the number and

type of linear features that could be located and accessed by the public from the Dempster Highway. Two types of surveys were conducted: a blind search where the location of the linear features was unknown and a 'map search,' where the observers had a map of the linear features that showed where they occurred. Both surveys were conducted on August 8, 2019.

The blind search approximated the proportion and type of linear features that the public could locate and access without prior knowledge of their locations. An EDI field crew drove along Dempster Highway at 35 km/h and attempted to identify linear features by visual inspection alone, unaware of where they intersected the highway. When a linear feature was identified, the crew stopped to record the following parameters:

- linear feature type;
- sight line distance;
- evidence of human use;
- evidence of wildlife use; and
- potential for OHV passage.

Photographs were taken, and relevant comments were recorded for each linear feature intersection where applicable.

The map search was a targeted search designed to approximate the proportion and type of linear features the public could spot from the Dempster Highway with prior knowledge of their locations. Using a map of linear features present in the RSA, an EDI field crew drove along the Dempster Highway, slowing to 10 km/h and attempting to identify the linear features when passing a point where the map showed they intersected the highway. When a linear feature intersection was reached, the crew recorded whether the line was visible or not and the parameters listed above for the blind search where a line was detected.

3.4 WINTER TRACK SURVEY

An aerial survey was conducted to assess the relative frequency of use of different liner feature types by ungulates and humans in late winter (March 2020). The survey consisted of 11 transects spanning the width of the RSA. Three of the transects were established parallel to the Dempster Highway at 50 m, 1 km and 5 km off the highway. The remaining transects were spaced approximately 5 km apart across the remainder of the RSA.

Before the field survey, each transect was established in a GIS. Each intersection with a linear feature was given a unique identification point and used to generate a field form (i.e., with a row for each linear feature intersection). The field survey involved flying along each transect and recording the presence of ungulate tracks or human tracks (e.g., snowmobile tracks) at each linear feature that was traversed. Surveys were conducted via helicopter at approximately 70 km/h, 50 m above the ground, with one navigator/data recorder and one primary observer. The surveyors classified tracks to species and counted the number of unique tracks. However, overlapping tracks and dustings of new snow made track identification and counts uncertain in over

half the detections. Therefore, analyses defaulted to the simple presence/absence of ungulate tracks. The primary metric examined was the proportion of linear features with ungulate tracks.

The original survey plan was also to count tracks in undisturbed areas between linear features. However, tracks were so numerous that surveying the entire area between linear features would have required substantially reducing the aircraft speed. This would have reduced the number of transects that could have been surveyed. As a compromise, field crews subsampled the area between lines by surveying an approximate 200 m band of an undisturbed area adjacent to each linear feature.

In conjunction with winter fish habitat assessments, the transects were surveyed over six days (March 7–13, 2020). Each day, one or two transects were surveyed while transiting to/from the study area. No track-erasing snowfalls occurred during the survey period. Snow depths ranged from 65 to 80 cm.

3.5 DATA PREPARATION AND ANALYSIS

3.5.1 SPATIAL DATA

The project generated two primary spatial datasets — a point database corresponding to all field survey sites and the linear feature database. The Linear Feature Survey Point Database (ArcGIS point feature class) contains all location-specific (point coordinate) field data collected at sample sites in summer 2019. Several fields were added to this database based on calculations and spatial joins (e.g., year of linear feature establishment and most recent fire). Paired on-line and off-line plot data were recorded as part of the same sample site coordinate.

The Linear Feature Inventory (ArcGIS polyline feature class) is a compilation of all documented linear features within the RSA, verified by comparing the preliminary linear feature inventory to aerial and satellite imagery and ground-truthing results.

Several modifications were made to improve the accuracy and detail of the Linear Feature Inventory:

- Linear features were classified into the following categories:
  - 2D (historical seismic lines, typically >3m wide),
  - 3D5 (including 4–5 m wide 3D lines that were used for both seismic and local vehicle/equipment travel);
  - 3Dc (3 m wide 3D seismic conductor lines);
  - 3Dr (2 m wide 3D seismic receiver lines);
  - winter roads (any trails or limited use roads used by vehicle or equipment, generally wider than 5 m and often with an obviously curving path); and,
  - Dempster Highway.
- Overlapping features (within a 3 m tolerance) were addressed according to the following rules:

- If two linear features of the same or unknown age overlapped, the wider feature was saved and the narrower feature deleted.
- If two linear features of the same or unknown width overlapped, the more recent feature was saved and the older feature deleted.
- If a 3D line overlapped with a 2D line, both lines were saved. This is because the older 2D lines were often still evident on the landscape in some state of regeneration, as were the 3D lines. However, both were saved since it was unknown at what state each line was in (i.e., if the 2D line was still evident, or only the 3D line, or both in varying states of regeneration). This occurred for 33 km of linear features within the RSA.

The preliminary linear feature inventory within the RSA was compared against a recent high-resolution satellite or aerial imagery (generally, 0.5–1 m resolution) at a 1:10,000 (or finer) scale to verify the accuracy of the source data. Any features that were visibly offset from georeferenced imagery were corrected to match the imagery.

Some older (1960s and 1970s) 2D seismic lines included in the source databases did not appear in satellite imagery. These 2D lines were compared against the imagery along the length of the feature to search for any sign of linear disturbance and then cross-referenced with field surveys conducted along the line, if present. These unverified linear features were classified as 'not applicable' and excluded from analysis if there was no evidence of linear disturbance along the feature's length in the imagery, which could often be verified with associated surveys noting that the feature was 'not present,' 'not visible,' or 'completely regenerated.' Unverified linear features were retained if there was evidence of linear disturbance along any feature's length in the imagery or if associated surveys had noted that the feature was present and in some state of regeneration, even if the feature was not visible in the imagery. A total of 199,473 m of erroneous or regenerated linear features were deleted from the linear feature inventory within the RSA.

Some linear features were visible on the imagery that had not been included in any of the source databases. In these cases, the linear features were manually digitized and classified into linear feature types based on visual assessment and attributes of adjacent connecting features, if present. Digitized linear features were assigned a year if they were obviously a continuation of a documented feature or if they were surrounded by features of the same type and year. Otherwise, the year was not included. High-resolution imagery was not available for the southernmost portion of the RSA (approximately 25 km by 15 km). This area was compared against lower quality Google Earth imagery, but this was not detailed enough to detect undocumented linear features if any existed (Google Earth 2019). However, existing linear features were verified using this method. A total of 202,945 m of linear features were digitized within the RSA.

After the Linear Feature Inventory was verified and corrected to be consistent with imagery and field observations, it was spatially joined to the Linear Feature Survey Point Database. In cases where the survey point did not correspond with any nearby linear feature, or if a linear feature was deleted (following the methods described above), the data were retained in the survey point database, but the linear feature type was updated to 'not applicable' and excluded from data analysis. Ten survey plots were identified as 'not applicable' and excluded from analyses; thus, the corrected sample size for survey plots is n = 210.

3.5.2 FIELD DATA

After completing field sampling, data forms and field notes were reviewed for completeness and accuracy during an internal data quality-assurance process. All associated digital photographs and GPS coordinates were reviewed to correspond to the appropriate field plots. A summary of field plots by linear feature type and survey type is provided in Table 3-4. All recorded data were entered into MS Excel databases (Microsoft 2019). Spatial data were uploaded to the ArcGIS platform (ESRI 2019).

Field-collected data were summarized primarily using Excel spreadsheets (Microsoft 2019). More detailed statistical analyses were performed on select data using R Statistical Software (R Development Core Team 2020). For example, the variation in ease of travel and vegetation cover as a function of linear feature types, burn history, successional stage, or ecosite were explored. During formal analyses, standard assumptions of normality and homogeneity of variance were assessed, and variance-covariance structures were applied to model heterogeneity (of residuals) if required. For instance, the sightline distance (m) was fourth-root transformed to meet normality. In certain models, random effects were included to account for variance among different subjects. For example, observers were included as a random variable to account for observer bias (i.e., a random intercept model; package "nlme", Pinheiro et al. 2016). Corrected Akaike's Information Criteria (AICc) scores were used to compare sets of candidate models. Models with the lowest AICc score were selected because they yielded the best balance (parsimony) between explained variance and level of complexity.

Table 3-4. The number of sites surveyed using ground surveys, air surveys, and air calls for each linear feature type in the Eagle Plains RSA.

Linear Feature Type	Survey Type			
	Ground Survey	Air Survey	Air Call	Total
2D	31	32	44	107
3D-5m wide	5	0	0	5
3D-Conductor	26	3	0	29
3D-Receiver	23	1	0	24
Winter Road	18	17	8	43
Dempster Highway	2	0	0	2
Not Applicable	3	2	5	10
Total	108	55	57	220

3.5.3 LINEAR FEATURE DENSITY CALCULATION

Linear feature densities were calculated in two ways: (1) using the total linear feature extents, and (2) adjusting the extents to account for (a) lines through 'open' habitats, such as wetlands and recent burns, where the vegetation on the line did not differ from vegetation off the line, and (b) functionally recovered linear features such as 2D lines from the 1960s and 1970s that had advanced regenerated at least to the Tall Shrub structural stage. Adjustments were determined by intersecting the Linear Feature Inventory with a recently developed

Ecological Landscape Classification (ELC) map of the RSA (a companion Eagle Plains Project baseline report). The ELC map documented the type and structural stage of vegetation communities across the RSA. The extent of linear features in open habitats was determined by the lengths of linear features overlapping Low Shrub, Herb and Bryoid structural stages in the ELC maps. This includes seral habitats regenerating from burns and ecosystems that are maintained in those stages over time, such as wetlands and shrub-carrs. The extent of regenerated linear features was determined by integrating the proportion of regenerated lines observed from the field surveys (e.g., 61% for 2D lines) with the length of lines through non-open vegetation types in the ELC map. Adjustments were applied to generate functional linear feature densities for each linear feature type individually (i.e., to compare the relative extents of different feature types) and combined to provide an overall density for all linear feature types. For example, the linear feature density for 2D lines was calculated by starting with the total length of 2D lines in the RSA, reducing that by the length of lines through open vegetation types, then reducing the remaining extent by the average proportion of 2D lines that were observed to be regenerated, and then dividing the remaining total length of lines by the extent of the RSA.

4 RESULTS

4.1 LINEAR FEATURE INVENTORY AND DENSITIES

A total of 4,269 km of linear features were mapped and verified in the RSA (Map 4-1, Table 4-1). Winter roads and 2D seismic occur in varying densities across much of the RSA. The extent of 3D seismic is limited to the one area straddling the Dempster Highway in the centre of the RSA.

The total linear feature density in the RSA was 1.79 km/km², based on a total length of 4,269 km and the RSA area of 2,386 km². 3D seismic lines accounted for approximately half of the total length of linear features in the RSA, 2D seismic lines accounted for about one-third, followed by winter roads and the Dempster Highway (Table 4-1). Adjusting for open habitats (i.e., areas in structural stages Low Shrub, Herb, and Bryoid) and vegetation regeneration[1] resulted in substantially lower densities of 0.52 km/km² (Table 4-2). Relatively large extents of recent wildfires were the greatest factor reducing linear feature densities. The relative proportions of the different linear feature types were similar after adjustments, though the proportion of 3D increased and 2D decreased. This was mainly due to the greater degree of vegetation regeneration on 2D lines, consistent with their age since disturbance.

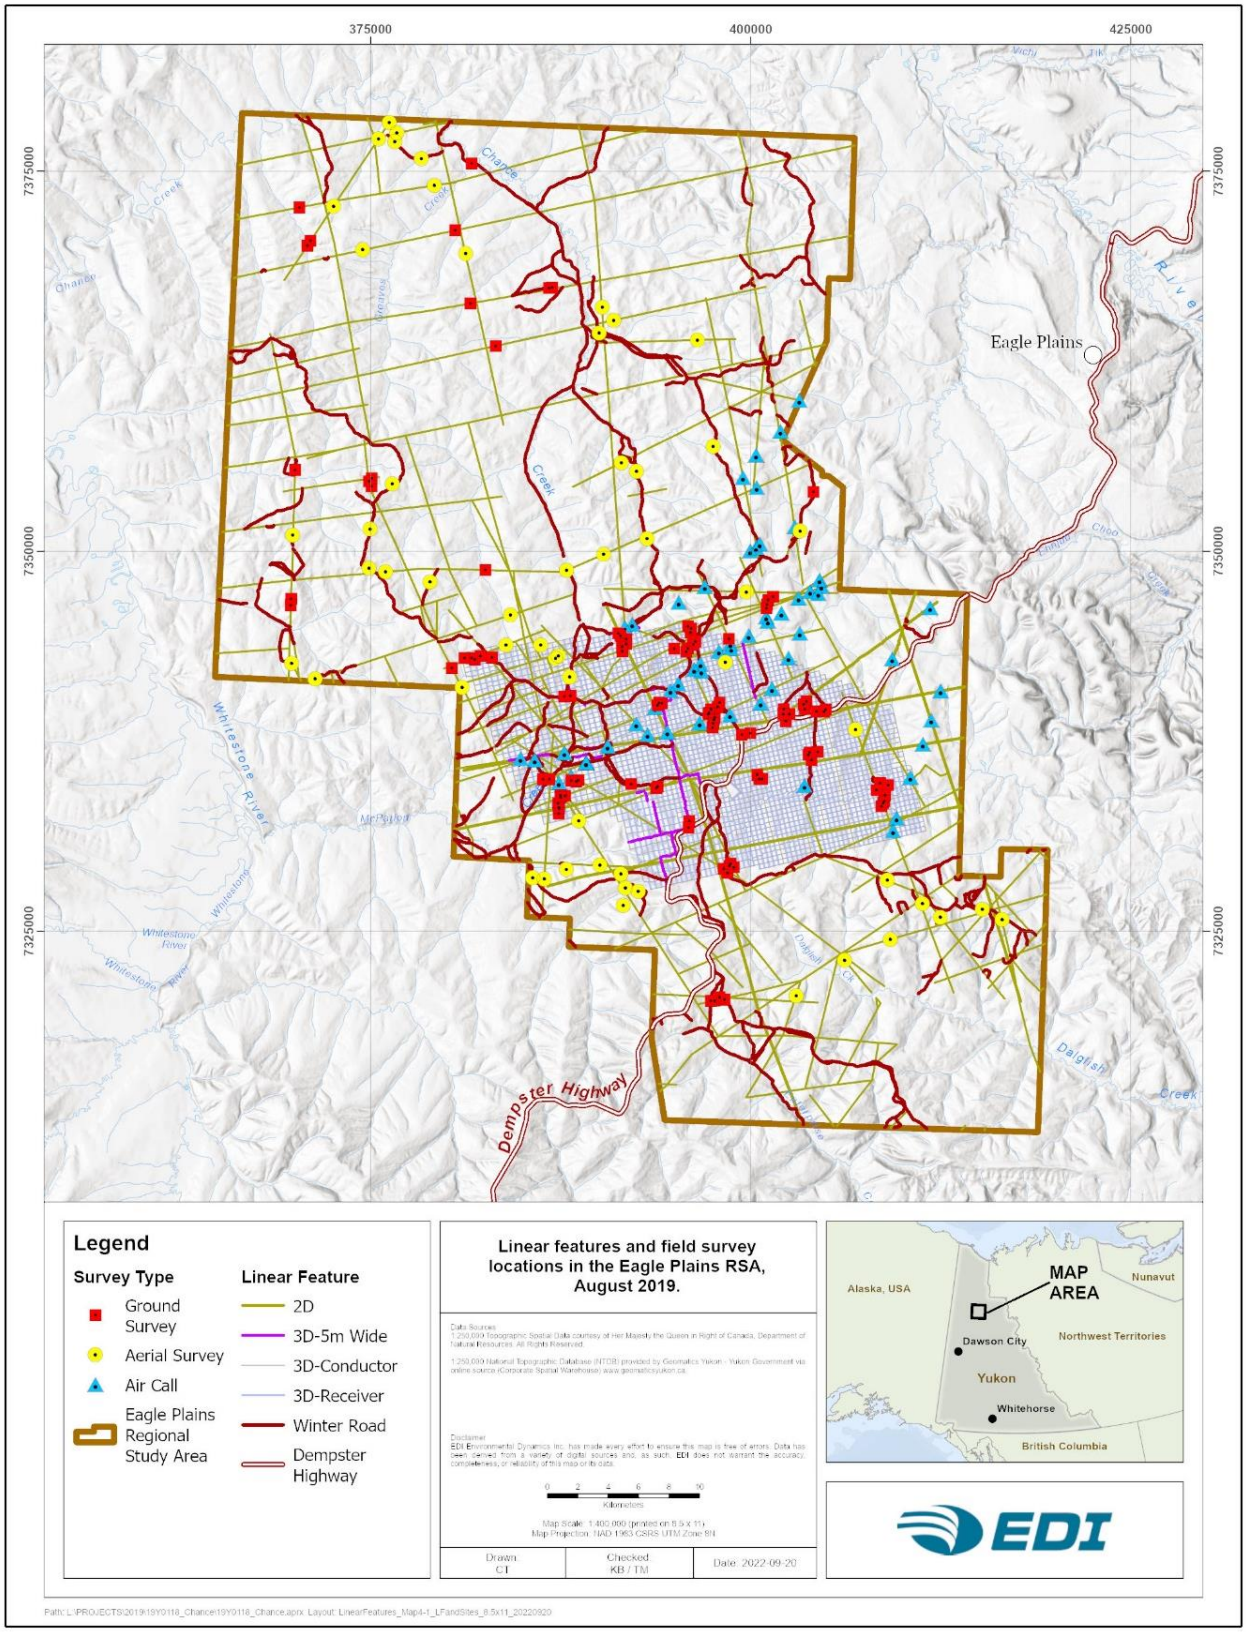
Table 4-1. Summary of total length and density of linear features documented in the Eagle Plains RSA.

Linear Feature Type	Total Length (km)	The Proportion of Total Length	Linear Feature Density (km/km²)
2D	1,452	34%	0.608
3D (combined)	2,165	51%	0.907
3D-5m wide	48	1%	0.020
3D-Conductor	1,189	28%	0.498
3D-Receiver	928	22%	0.389
Winter Road	596	14%	0.250
Dempster Highway	47	1%	0.020
Unknown	8	<1%	0.003
Total	**4,269**	**100%**	**1.788**

[1] See Section 5.5 Functional Recovery of Linear Features for details about vegetation regeneration criteria.

Table 4-2. Summary of total effective length and density of linear features in the Eagle Plains RSA adjusted for open habitat and vegetation regeneration.

Linear Feature Type	Total Length (km)	Proportion of Total Length	Linear Feature Density (km/km²)
2D	289	23%	0.121
3D (combined)	750	60%	0.314
3D-5m wide	21	<1%	0.009
3D-Conductor	401	32%	0.168
3D-Receiver	328	26%	0.138
Winter Road	171	14%	0.072
Dempster Highway	26	<1%	0.011
Unknown	8	<1%	0.003
Total	1,243	100%	0.521



Map 4-1. Linear features and field survey locations in the Eagle Plains RSA, August 2019.

4.2 LINEAR FEATURE CHARACTERISTICS

4.2.1 LINE WIDTHS

Line width varied by linear feature type. Mean line widths ranged from 1.96 m for the narrowest line type (3D receiver lines) to 33.75 m for the Dempster Highway (Table 4-3). Standard error around mean estimates were smallest for 3D seismic lines, which were cleared in the same season using the same equipment and methods, and greatest (by a large margin) for winter roads. The average difference in widths between 3D conductor (wider) and 3D receiver lines was 1.2 m.

Table 4-3. Widths of different linear feature types in the Eagle Plains RSA.

Linear Feature Type	n	Minimum mean width (m)	Maximum mean width (m)	Overall mean width (m)	Standard Error (m)
2D	107	3.97	8.5	5.42	0.11
3D-5m wide	5	5.30	6.40	5.68	0.22
3D-Conductor	29	2.50	4.80	3.17	0.13
3D-Receiver	24	1.63	2.53	1.96	0.04
Winter Road	43	2.53	17.97	7.42	0.66
Dempster Highway	2	33.00	34.50	33.75	0.75

4.2.2 MULCH COVER

Mulching of woody vegetation is common during seismic line clearing activities and was used in the 2013/14 3D program. In areas with thick tree or shrub cover, mulching can create a thick blanket of wood chips that inhibits vegetation regeneration (Golder Associates 2016). There was no evidence that this was an issue with any of the seismic lines within the RSA. On average, the percent cover of mulch was <1% on all line types.

4.2.3 HUMAN USE

No sign of human use was detected along linear features during the summer ground surveys (e.g., OHV tracks, ruts, water crossings, vegetation trampling/scarring, tree blazes, trap sets, garbage, and campsites), except for the two sites on the Dempster Highway.

On average, 42% of on-line sites were deemed passable to an OHV (a 4x4 side-by-side) during summer, considering obstructing vegetation, ground conditions (e.g., wetlands or peatlands), and the presence of graminoid tussocks (Table 4-4).

Table 4-4. Proportion of survey sites deemed passable to OHV in summer across different linear feature types in the Eagle Plains RSA.

Linear Feature Type	No. Survey Sites	% Passable
2D	55	9%
3D-5m wide	5	80%
3D-Conductor	29	59%
3D-Receiver	24	75%
Winter Road	29	55%
Dempster Highway	2	100%
Total	144	42%

4.2.4 SUCCESSIONAL CLASSES

Linear features surveys in the Eagle Plains RSA observed five of the six of the successional classes documented by Simpson (2008): normal succession, magnified succession, stagnated succession, no succession, and recent disturbance (Figure 4-1) (Attachment A). No retrogressive succession sites were observed at official survey sites. However, a small number of retrogressive sites were incidentally observed on winter roads while travelling through the RSA.

Most sites surveyed (79%) were undergoing normal succession. The next most common successional class was magnified succession, occurring in 11% of sites, followed by stagnated succession, occurring in 5% of sites. All 3D seismic lines surveyed followed a normal successional trajectory, except for one site that was classed as recently disturbed. Magnified succession was most common in 2D seismic lines (21%), while stagnated succession was most common in winter roads (19%). Successional classes were defined as 'not present' if the linear feature was not present in the field or had regenerated to a stage that was not discernable from the adjacent areas. The Dempster Highway was classified as recently disturbed due to the regular maintenance of the road.

Fire history appeared to influence some successional classes. Magnified succession was more common at burnt sites (19 burnt versus 5 unburnt). In contrast, stagnated succession was more common at unburnt sites (3 burnt versus 7 unburnt). Sites on a normal successional trajectory did not appear to have any relationship to burnt status. The remaining successional classes were too uncommon to draw any conclusions.

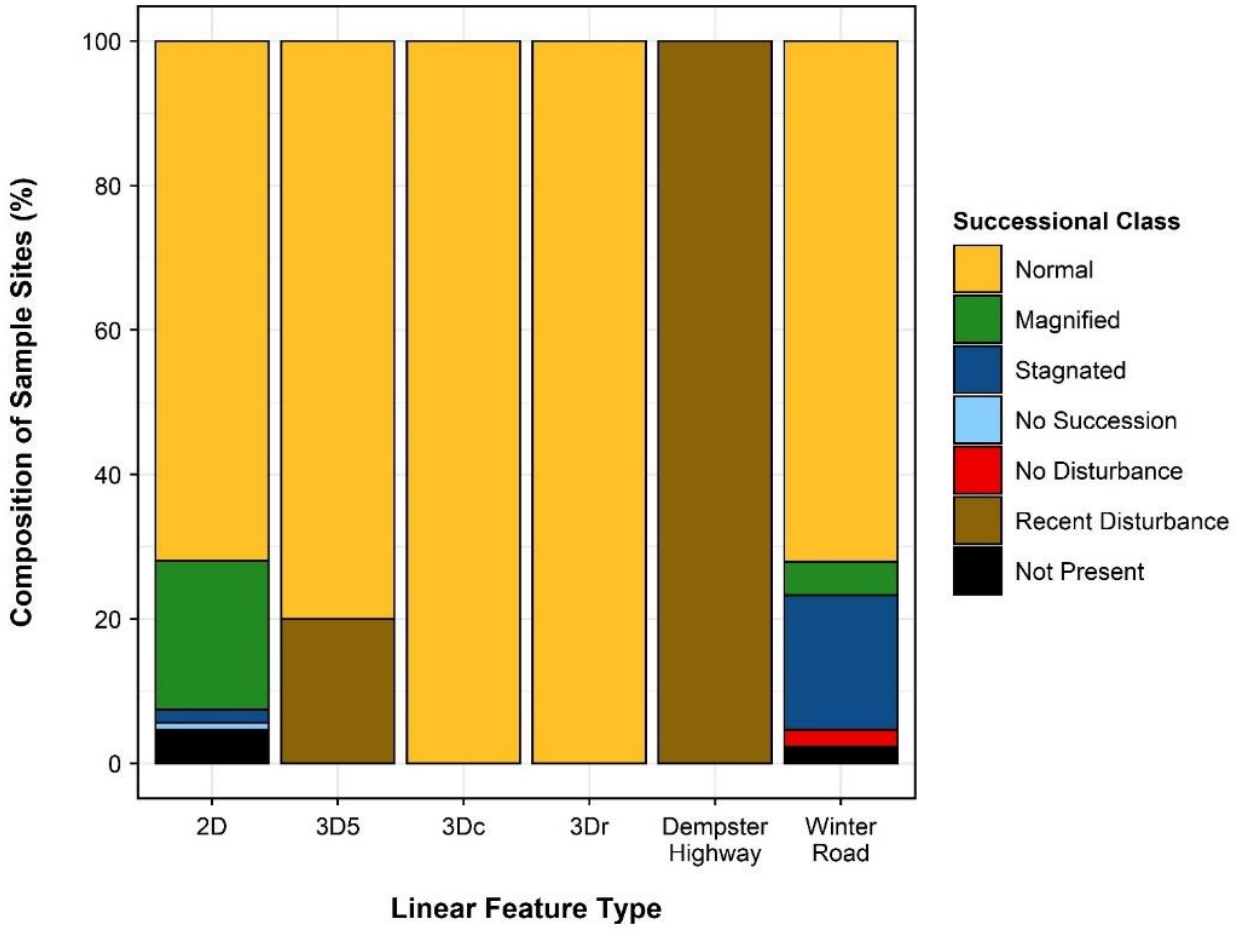


Figure 4-1. Summary of successional classes observed across different linear feature types in the Eagle Plains RSA.

4.2.5 STRUCTURAL STAGE

Most linear features were in a Low Shrub (56.1%) or Tall Shrub (29.0%) structural stage. However, the distribution of structural stages varied substantially across linear feature types (Table 4-5). Although herbaceous and forested stages occurred at some on-line plots, they were not common (less than 5%each). Nearly all forested structural stages were observed on 2D seismic lines and winter roads, reflecting the long time since they were created. Tall Shrub stages were almost twice as frequent in 2D seismic lines than any other linear feature type. Conversely, 83% of 3D linear features were in the Low Shrub structural stage, with most of the remaining in the Tall Shrub stage. The differences in structural stages between 2D and 3D lines appear to be primarily due to the time since disturbance. Winter roads were less consistent in their structural stages; herbaceous, shrubland and forested stages were all observed with moderate frequency. The two Dempster Highway plots were the only non-vegetated stages recorded.

Off-line plots were also mostly in Low Shrub and Tall Shrub stage, but they also included a higher proportion of Young Forest and Mature Forest compared to on-line plots (Table 4-5; Photos A-15 to A-20 in

Attachment A). For off-line plots, the Low Shrub sites were mostly burned areas, and the Tall Shrub sites were mostly stunted, open-canopy, black spruce forest 2–8 m tall.

Fire had a strong effect when comparing structural stages between paired on-line and off-line plots (Figure 4-2). The top two charts in Figure 4-2 show that the pattern of structural stages for burnt areas was very similar between on-line and offline plots. The bottom two charts show that the pattern of structural stages differs substantially between on-line and offline plots in unburnt areas. In unburnt areas, off-line plots had much lower numbers of sites in Low Shrub and much higher numbers of sites in Young Forest and Mature Forest than on-line plots. For burnt areas, the on-line and off-line plots at the same site were the same structural stage in 72% of cases, and within one structural stage of each other 91% of the time (e.g., Tall Shrub vs Pole Sapling). For areas that were not burnt, the on-line and off-line plots at the same site were the same structural stage in only 29% of cases. These results demonstrate that in the absence of fire, pronounced differences between linear disturbances and the surrounding community are evident in both recent (3D) and legacy (2D and winter road) linear feature types. But following a fire, the vegetation structure on-line and off-line are likely to be similar (Photos A-22 to A-24 in Attachment A).

Table 4-5. Vegetation structural stages observed on different linear feature types as a proportion of all plots sampled (n = 156) in the Eagle Plains RSA.

Linear Feature Type	No. Sites	Structural Stage[1]								
		Non-vegetated	Bryoid	Herb	Low Shrub	Tall Shrub	Pole-Sapling	Young forest	Mature forest	Old Forest
2D	62	0%	0%	2%	37%	47%	2%	8%	3%	2%

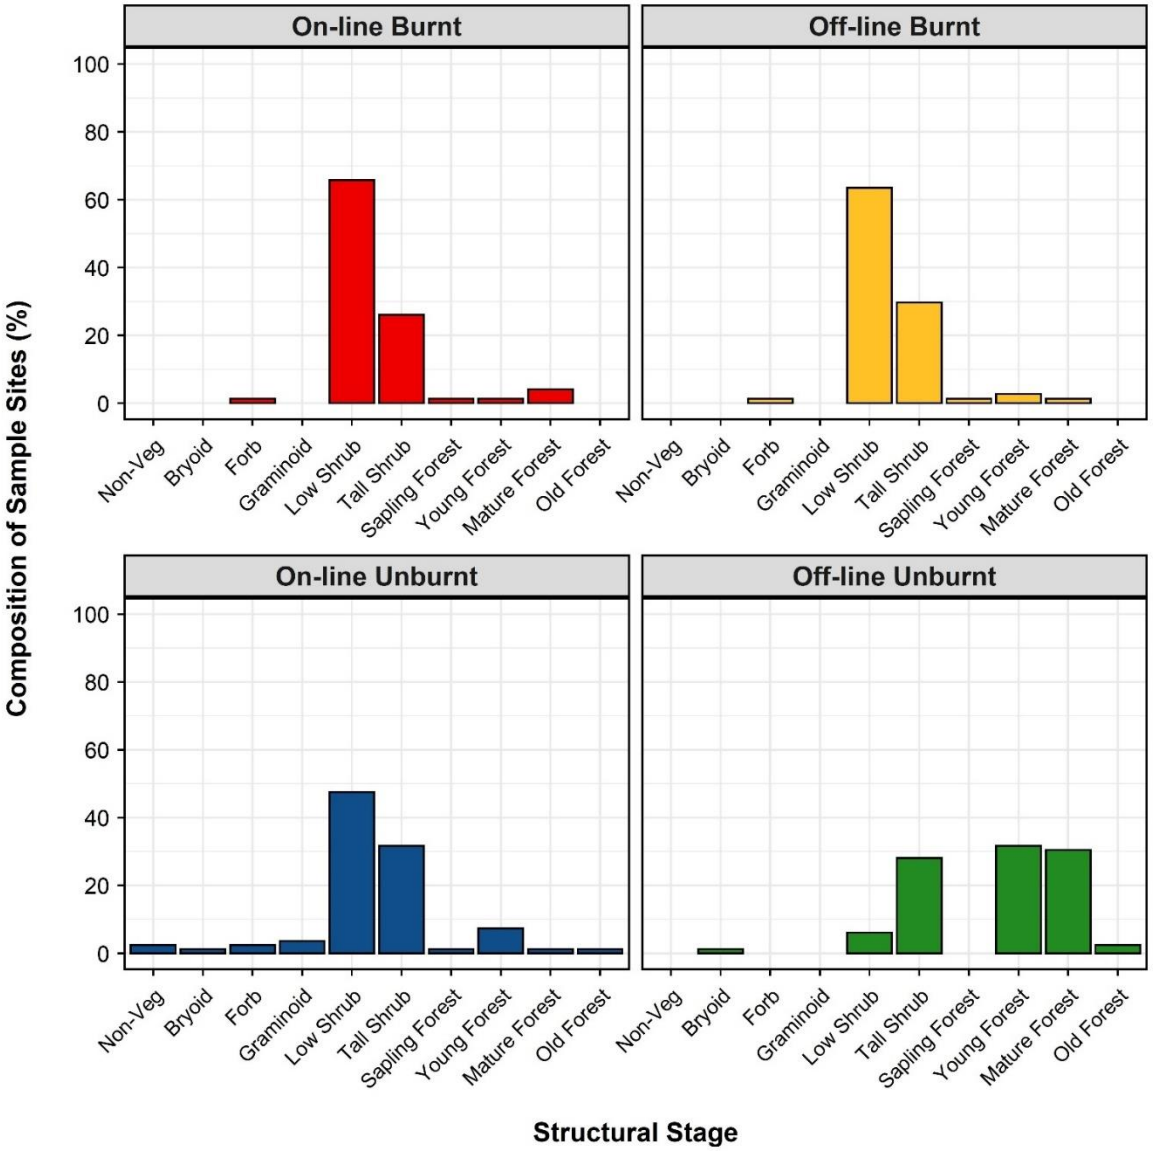

Figure 4-2. Comparison of structural stages on linear features to off-line plots in burnt and unburnt areas, in the Eagle Plains RSA.

4.2.6 VEGETATION HEIGHT

Based on the similarity of patterns in vegetation composition and structure, linear feature types were combined into two groups for assessment of patterns in height: (i) 2D and winter roads and (ii) 3D. A wide range of vegetation heights was recorded at both on-line and off-line plots in the RSA, from 0.3 m to 16 m. Collectively, off-line plots had a normal distribution of vegetation heights between 0 m and 4 m, and then a scattered distribution across heights up to 16 m (Figure 4-3). Plots with ≥4 m tall vegetation accounted for approximately 40% of all off-line reference plots.

In comparison, recovering 2D seismic lines and winter roads shared a relatively uniform distribution between 0 m and 4 m but with a peak occurring at vegetation heights measuring 1.5–2 m tall (Figure 4-4). Only 21% of 2D and winter roads contained dominant vegetation ≥4 m, and only 5% were ≥8 m tall. 3D seismic lines were rarely composed of vegetation ≥2 m, and most of the vegetation (67%) recovering on 3D lines was less than 1 m (Figure 4-5). This is very different from the off-line undisturbed height distribution. However, 3D lines were all only five years old at sampling, and shorter vegetation was expected.

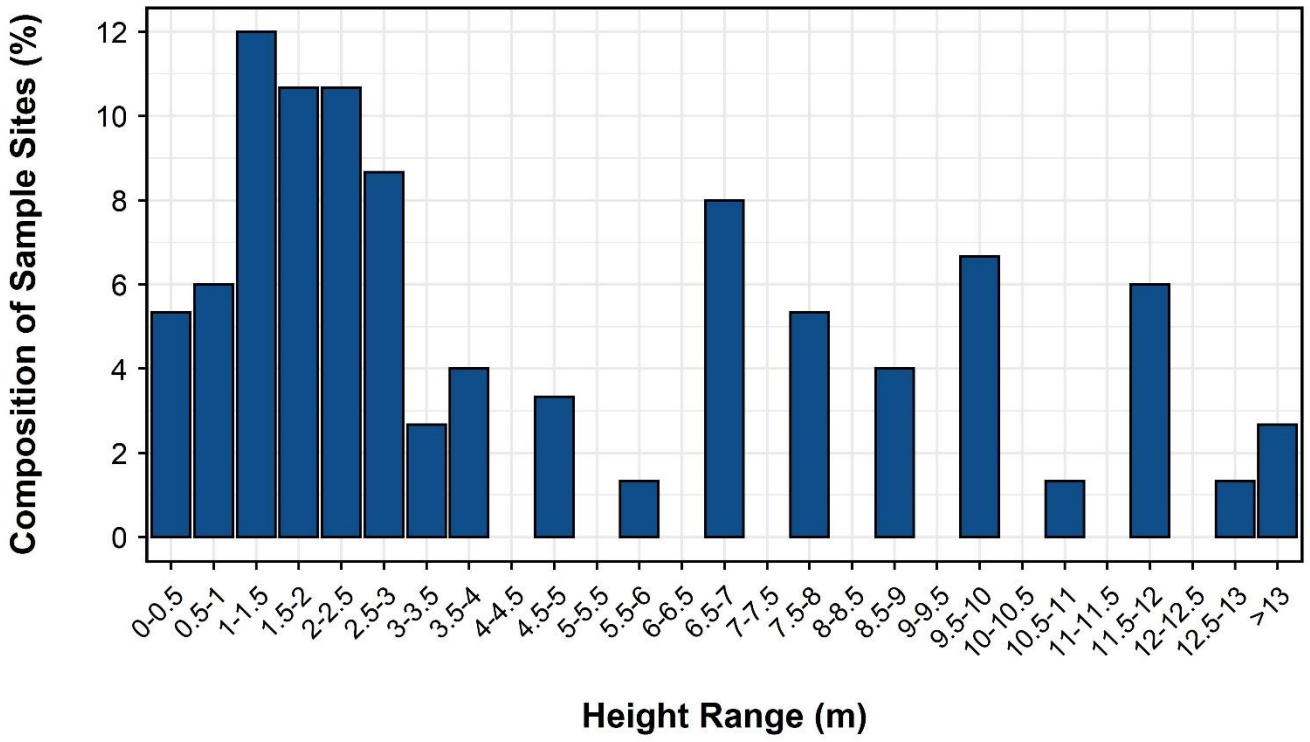

Figure 4-3. Vegetation height distribution of off-line reference plots in the Eagle Plains RSA.

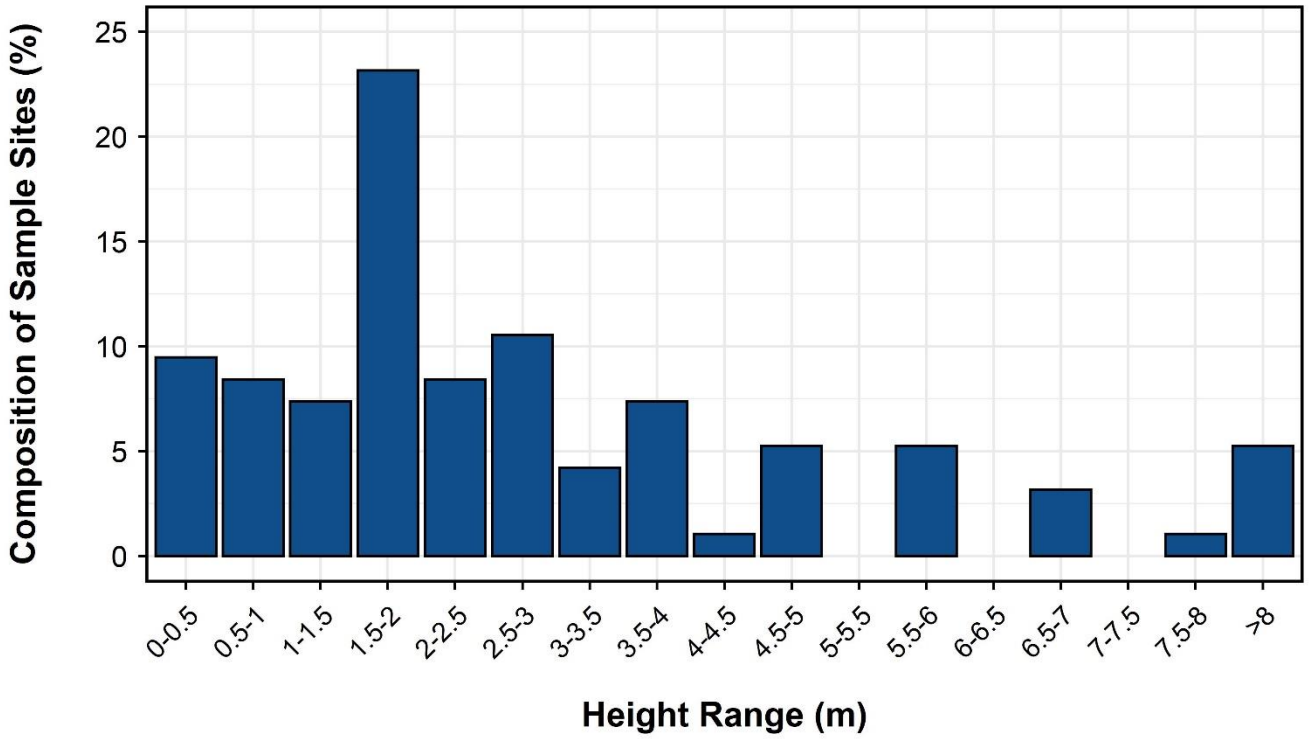

Figure 4-4. Vegetation height distribution of on-line 2D and winter road plots in the Eagle Plains RSA.

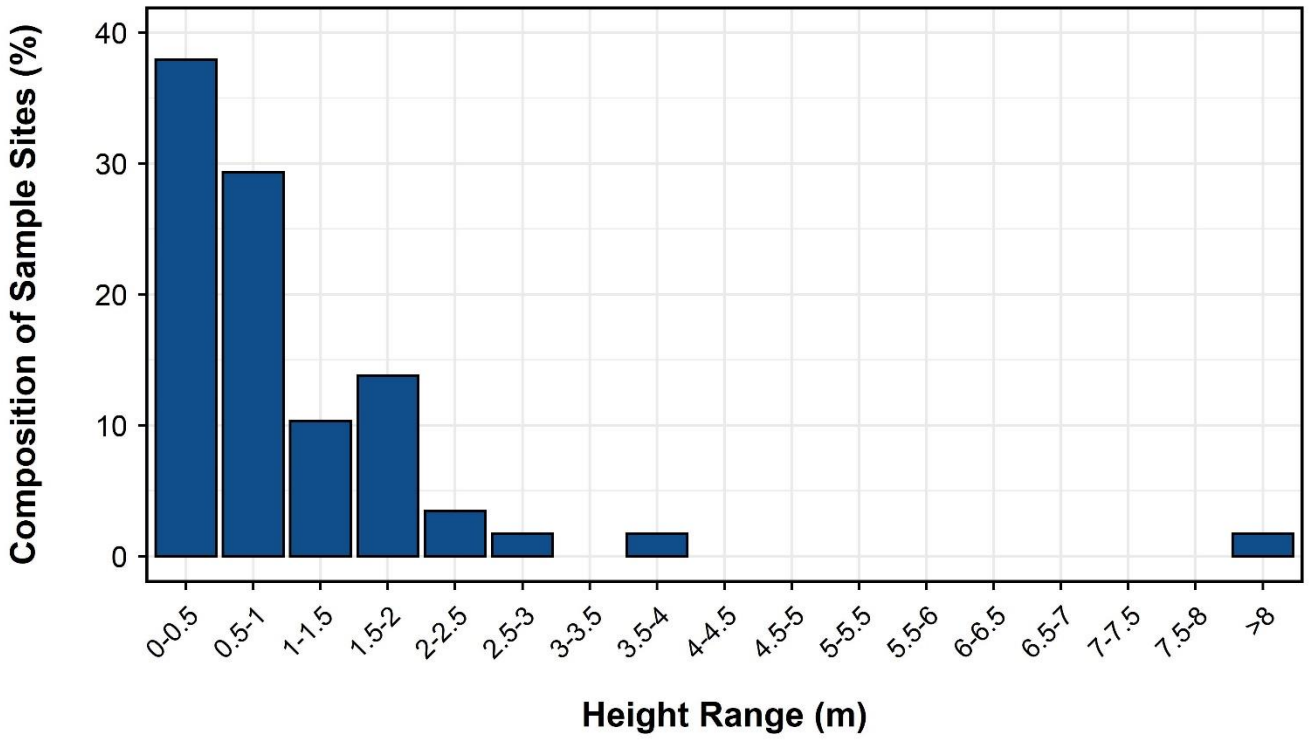

Figure 4-5. Vegetation height distribution of on-line 3D plots in the Eagle Plains RSA.

4.2.7 VEGETATION COVER

Tree and shrub cover varied between linear feature types and burn status (Table 4-6). Generally, tree cover was low on undisturbed reference plots (mean tree cover of 8% on unburnt and 2% on burnt sites). This is typical of the taiga cordillera landscape — forests are generally stunted and sparse due to poor nutrient regime and continuous permafrost conditions (Smith et al. 2004). Of the on-line plots, tree cover was greatest on 2D seismic lines and burnt winter roads (5% to 8%) and lowest on 3D seismic lines and the Dempster Highway (0%), regardless of burn status. This is likely due to the recently disturbed 3D seismic lines that are too young for trees to have re-established. Burnt 2D seismic lines and winter roads had greater tree cover than unburnt lines.

Shrub cover was much greater than tree cover overall. Shrub cover was typically 30–40% on unburnt off-line plots and 40–50% on burnt off-line plots. Shrub cover was highest on 2D seismic lines (~54%), regardless of burn status. Shrub cover was moderate on winter roads (38–45%) and lowest on unburnt 3D seismic lines (8–22%). Burnt 3D seismic lines had approximately twice as much shrub cover as unburnt 3D lines.

Table 4-6. Summary of the mean tree and shrub cover (%) between on-line and off-line, and burnt and unburnt plots surveyed in the Eagle Plains RSA.

Linear Feature Type	Burn Status	Mean Tree Cover (%)		Mean Shrub Cover (%)	
		On-line	Off-line	On-line	Off-line
2D	Burnt	7.0	3.5	54.0	36.0
	Unburnt	5.5	13.4	53.2	32.8
3D5	Burnt	0.0	0.3	41.7	60.0
	Unburnt	0.0	0.5	7.5	42.5

	Unburnt	1.3	4.0	37.5	32.3
Dempster Highway	Unburnt	0.0	1.0	0.0	37.5

4.2.8 LINE-OF-SIGHT AND EASE OF TRAVEL

Line-of-sight (sightline) distance was examined primarily as a function of line type; however, vegetation height (the primary factor affecting sightlines) was also examined for on-line and off-line plots for each linear feature type using multiple linear regression. Mean sightlines varied significantly by linear feature type (Table 4-7, $F_{4,187} = 3.3$, $P = 0.01$). For reference, the average sightline distance for offline controls was 46.7 m. This relatively far distance reflects the open stand structure on most sites in the region. Burn status had little influence on sightlines (e.g., burnt off-line=50.2 m, unburnt offline=43.6 m). 2D lines had the shortest average sightline distances at 41.2 m. This was mainly due to the advanced stage of regenerating vegetation on the lines. Where regenerating vegetation was limited, sightline distances on 2D lines frequently exceeded 150 m.

On 3D lines, the time since clearing was too recent for regenerating vegetation to obscure sightlines. Instead, sightline distances on 3D lines were generally controlled by bends in the lines, which were specifically designed as mitigation measures to reduce sightlines. For 3D lines, sightline distances decreased from 3D5 to 3Dc to 3Dr lines. The reduction in sightline distances resulted from differences in line width and the average distance between bends across the feature types.

The regression analysis also found a significant interaction between on-line versus off-line occurrence and vegetation height ($F_{1,187}$ = 13.0, P = 0.0004), whereby on-line plots had, on average, more negative slopes than off-line plots. In other words, sightlines at on-line plots decreased more drastically than off-line plots with each incremental increase in vegetation height. This is consistent with the qualitative observations of field crews that the regenerating vegetation on lines was thicker than the vegetation off lines.

Similar to sightline distances, determining differences in ease of travel among line type the primary factor of interest for the walking speed tests. However, burn status, and the percent cover of trees and shrubs were expected to be the most important explanatory variables related to walk speeds, so they were included as secondary variables using a mixed-effects linear regression. Walking speeds across linear feature types and the differences between on- and off-line plots within linear feature types varied significantly (Table 4-8, $F_{5,170}$ = 3.4, P = 0.006). However, the magnitude of the difference between on-line and off-line plots was modest. Even the Dempster Highway only conveyed a 35% increase in walking speed over off-line plots. Other researchers, in other areas, often observed walk speeds on linear features were often at least twice as fast as off-line transects (Keim et al. 2019a).

Notwithstanding the modest magnitude of faster walking speeds on-lines, there were clear patterns in walking speed differences across linear feature types. 2D lines were the one feature type where walking speeds were slower on lines than off lines. This reflected the thick, shrub stage vegetation that had regenerated on most 2D lines, which impeded travel (similar to the effect that regenerating vegetation had on sightline distances in the previous section). Walk speeds decreased across the other feature types in relation to line width and the degree to which ground cover was levelled or compacted.

Statistical analyses indicated that both burn status ($F_{1,170}$ = 17.85, P < 0.0001) and percent cover of shrubs and trees (hereafter woody vegetation; $F_{5,170}$ = 5.29, P = 0.0002) affected walking speeds, both on and off lines. On average, walk speeds in burns were approximately 10% slower than in unburnt areas. This is partly related to thicker woody cover in most burns, which hinders walking speed because of the time it takes to push through or walk around it. Walking speeds significantly decreased, on average, by 0.04 (CI = 0.02–0.06) km/h and with every 10% increase in the percent of woody cover off-line and 0. 11 (0.07–0. 15) km/h on 2D lines.

Table 4-7. Average sightline distances along different linear feature types in the Eagle Plains RSA.

Linear Feature Type	n	Average Sightline Distance (m)	Comments
2D	30	41.2	Sightlines are frequently reduced by regenerating vegetation >1.5m tall
3D-5m	5	105.6	Has fewer bends than 3Dc and 3Dr
3D-Conductor	26	75.9	Sightlines limited by bends in lines; too recent for regenerating vegetation to impede sightlines
3D-Receiver	23	60.2	Sightlines limited by bends in lines; too recent for regenerating vegetation to impede sightlines

4.3 VISIBILITY OF LINEAR FEATURES FROM THE DEMPSTER HIGHWAY

Overall, the blind search identified 11 of 100 possible linear feature intersections with the Dempster Highway (Table 4-9). Five of the features were roads that were classified as winter roads in the GIS inventory, but most (four) were actually short, all-season roads leading to gravel pits or well sites. Two of the observed features were human truck/OHV trails that led to camp sites 100–200 m off the Dempster Highway, and four were 3D seismic lines. The map search detected two more 3D lines, one 2D line, and one old winter road. The 2D line and the old winter road had regenerated into Young Forest structural stages. Excluding the four short secondary roads into gravel pits and well sites, and the two human trails, only 8% of linear features that intersected the Dempster Highway were visible during the two driving surveys.

Only 6 of the 74 3D lines that crossed the Dempster were detected. The combination of construction design (i.e., creating a bend in the 3D line adjacent to the highway) and regenerating vegetation in the right-of-way made it difficult to detect the 3D lines. Evidence of human use (e.g., packed vegetation, tire tracks, rutting, garbage, campfire remnants, tree stumps, or tree blazes) was observed on four of the short, all-season roads

and the two trails. No evidence of human use was noted on any of the 2D or 3D seismic lines, or the three winter roads (including the Chance and Blackie winter roads). However, some types of human use do not leave sign during the snow-free season (e.g., snowmobile use in the winter).

Table 4-9. Summary of linear features identified and intersecting the Dempster Highway during a blind search test.

Linear Feature Type	No. Features Intersecting the Dempster	No. (%) Observed Blind Search	No. (%) Observed Map Search	Total No. (%) Observed	OHV Accessible	Sign of Human Use
2D	18	0 (0%)	1 (6%)	1 (6%)	0	0
3D	74	4 (5%)	2 (5%)	6 (8%)	4	0
Secondary Roads	8	5 (63%)	1 (13%)	6 (75%)	5	4
Trail	n/a	2 (n/a)		2	2	2
Total	100	11 (11%)	4 (4%)	15 (15%)	11	6

4.4 WINTER TRACKS

In total, 462 linear features were surveyed for winter tracks over 358 km along the 11 transects. No human sign was observed on any linear features, except the Dempster Highway. Ungulate tracks were frequently observed travelling along linear features. The proportion of linear features with tracks decreased with decreasing linear feature widths, from 29% on winter roads, 24% on 2D lines, 8% on 3D conductor lines, and 6% on 3D receiver lines (Figure 4-6).

The frequency of use in adjacent undisturbed areas, corrected to account for different survey extents between the linear features and the undisturbed areas, was 1%. As discussed in the methods, it was difficult to compare the frequency of use along linear features to use in undisturbed areas. The issue is that for the comparison to be relevant, the survey design needs to account for the size of the sample units (i.e., the extent of the undisturbed area needs to be comparable to the width of the linear features), and the two samples should be independent. These conditions were not achieved under the current survey design (i.e., the extent of the survey area in the undisturbed area was much larger than the width of the linear feature, and the location of the undisturbed area was spatially correlated to the linear feature). The estimated relative use rate of 1% in undisturbed areas adjusts the total counts within the 200 m survey area to 5 m (i.e., the average linear feature width); however, the adjustment fails to account for spatial correlation between the two samples. Therefore, the estimate of use in undisturbed areas could be biased. Notwithstanding this limitation in the estimate of travel rates in undisturbed areas, it is supported by qualitative observations of the survey crew that travel rates on even the least used linear features (i.e., 3D lines) are higher than undisturbed areas.

The relative use of linear features by ungulates also appeared to vary with distance from the Dempster Highway, with features within 1 km of the highway receiving lower use than features equal to or greater than 5 km from the highway (Figure 4-7). It is worth noting that the Highway and 1 km transects were completed on the first and second day of surveys, respectively, and the other transects were surveyed one to six days later, providing more time for tracks to accumulate. Snowfall data prior to the crew's arrival on site was not

available; however, road crews at Eagle Plains reported that there had not been a major snowfall in the area for at least a week. Based on this information, the issue of time since last snow has less potential to bias results than if a track-erasing snow event had recently occurred.

[4] percent of lines with ungulate tracks during March 2020.

2D Seismic — 2D lines are, on average, the oldest features in the area and have had the longest time to regenerate. Most features were cleared before 1985, but some were developed in the early 2000s. Historical 2D lines were generally long and straight, with moderate widths of 4–8 m. Lines were typically constructed with bulldozers that cut into the moss layer and often included some patches of soil disturbance. The combination of site disturbance and wider widths generally resulted in a successional reset to pioneering vegetation (including early seral graminoids, forbs, and shrubs). Most sites were following a normal successional pathway (73%). However, 27% of sites exhibited atypical pathways, dominated by magnified succession (21%, mostly in burns), stagnated succession (3%) or no succession (1%). Sixty-one percent of the 2D sites had regenerated to a Tall Shrub or more advanced structural stage. 2D lines had the shortest sightlines and slowest walk test speeds of all feature types (including off-line controls), reflecting the regenerating vegetation's effect on these functional metrics. During winter, ungulates regularly used 2D lines to travel along.

3D Seismic — All 3D lines were created during the last exploration period, during the winter of 2013/14. 3D lines constitute the most extensive combined lengths of the different linear feature types, but their areal extent is limited to a relatively small portion of the RSA along the Dempster Highway. Due to their basic design, as well as specific mitigations, 3D lines minimize environmental effects compared to other linear feature types. They are narrow (averaging 3.2 m and 2.0 m for conductor and receiver, respectively), often

narrower than average tree spacing in the region. They were constructed during winter, over snow, using low-ground pressure equipment, which avoids ground disturbance and maintains vegetation in the moss, herb and low shrub layers. The lines were constructed with a meandering path, and strategically placed sharp angle dogleg bends to reduce the visibility of the lines from roads, reduce sightlines along them, and hamper travel by OHVs. All 3D lines that were surveyed were undergoing a normal successional pathway and were dominated by the same vegetation as in adjacent undisturbed areas. Regenerating vegetation was mostly in a Low Shrub structural stage, consistent with the relatively short six-year period since they were cleared. Sightlines and movement speeds were intermediate compared to other linear feature types, with sightlines primarily controlled by dogleg bends purposely designed to reduce sightline distances. Ungulates occasionally used 3D lines to travel on in winter, but at less than a third of the rate as 2D lines and winter roads.

Winter Roads — A network of winter roads across much of the RSA results from the historical exploration programs that have occurred. Although many of the winter roads were initially developed during the earliest exploration programs, vegetation has not had the same opportunity to regenerate as on 2D lines because the vegetation was re-cleared on several roads during subsequent exploration programs. The average width of winter roads was 7.4 m, but major roads, like the Chance road, were often 10–12 m wide. Historical winter roads were typically cleared with a bulldozer, and then snow was packed and graded to create a road surface. Similar to historical 2D seismic, the combination of site disturbance and wider widths (i.e., that increases solar exposure) generally resulted in a successional reset to pioneering vegetation (including early seral graminoids, forbs, and shrubs). Most sites were following a normal successional pathway (72%), but 26% of sites exhibited atypical pathways, dominated by stagnated succession (19%), magnified succession (6%) and no succession (1%); 2% of the sites were classified as no disturbance (indistinguishable from vegetation community off the road). Thirty-nine percent of the winter road sites had regenerated to a Tall Shrub or older structural stages. Winter roads had the longest sightlines and fastest walk test speeds of all feature types, other than the Dempster Highway, reflecting the variable levels of regenerating vegetation that occurred on winter roads. During winter, ungulates regularly used 2D lines for travel.

Dempster Highway — The Dempster Highway is the only all-season road in the RSA (except for short spurs off the Dempster to well sites and gravel pits). It is fundamentally different from all other linear features in the area in terms of wide width, surface material and maintenance, long sightlines, regular traffic, and base of access for human land use activities such as hunting, camping, and trapping.

5.2 LINEAR FEATURE CHARACTERISTICS

5.2.1 FIRE

The presence or absence of recent forest fires affected several linear feature characteristics, including linear feature width, successional class, structural stage, and vegetation height and cover. Mean measured linear features widths were 0.2–0.6 m wider at burnt sites than at unburnt sites. This may be due to the already shorter vegetation at burnt sites, which would reduce overgrowth occurring from forest edges and decrease the measured width between driplines (branches extending into the linear feature from either side of the line).

Magnified succession was nearly four times more common in burnt plots than unburnt plots, and stagnated succession was half as common. Fire likely facilitates magnified succession by increasing soil temperatures, accelerating decomposition, and releasing stored water and nutrients to promote vegetation growth (Seccombe-Hett and Walker-Larsen 2004, Simpson 2008). Stagnated succession is likely less common at burnt sites because the associated nutrient and water increase allows woody plant species to colonize more easily and advance through successional stages.

Overall structural stage distribution was very similar between burnt on-line and off-line plots, but was markedly different between unburnt on-line and off-line plots. Furthermore, when the structural stages were compared between paired on-line and off-line plots, they matched two to four times more frequently at burnt sites than at unburnt sites and were mismatched two to six more frequently at unburnt sites than at burnt sites. Nearly all burnt plots were in a low shrub, or tall shrub structural stage, which is expected as fires tend to remove overstory trees, and shrubs generally colonize rapidly post-fire (Seccombe-Hett and Walker-Larsen 2004).

Vegetation height was 4.4 m shorter in burnt than unburnt reference plots, and tree cover was approximately 6% less. These modest differences reflect the stunted and open nature of the taiga forest. There was little change in vegetation height between burnt and unburnt linear features, likely because there were very few linear disturbances in a forested structural stage; most of them, even in unburnt conditions, were already in a shrub-dominated stage due to the clearing of trees. For shrub cover, except for 2D seismic lines, the mean was approximately 10% to 20% greater at burnt plots than at unburnt plots. The increase in shrub cover at burnt sites was most prominent in 3D seismic lines due to their comparatively lower pre-fire shrub cover.

Post-burn vegetation was, on average, shorter and shrubbier than unburnt off-line plots, but taller and shrubbier than unburnt on-line plots. Furthermore, burnt paired plots were more similar in vegetation characteristics than unburnt paired plots. This evidence supports the theory that forest fires in taiga ecosystems resets the landscape to some extent and effectively erase signs of anthropogenic disturbance (Seccombe-Hett and Walker-Larsen 2004, Simpson 2008). Forest fire in the taiga returns ecosystems to an early successional stage (i.e., low shrub) and synchronizes baseline biophysical conditions on a landscape scale, allowing previously disturbed and undisturbed areas to recover at equal rates, as has been documented by Seccombe-Hett and Walker-Larsen (2004). Thus, most linear features that have experienced forest fires no longer create different ecological conditions or functional disturbances than the surrounding landscape.

5.2.2 SUCCESSIONAL CLASS

The idea that vegetation regeneration on linear features could follow different successional trajectories came out of work by the Yukon Government in the early 2000s (Simpson 2008). That work described six successional trajectory classes observed in the Eagle Plains area. However, that study did not quantify the relative extents of linear features that followed the different trajectories. This study used the classes that the Yukon Government work developed and quantified the proportion of linear features in each successional class across a random sample of linear features.

Successional classes in the Eagle Plains RSA varied according to linear feature type and burn status. However, one of the key findings was that normal succession was the dominant trajectory observed for all linear features except the Dempster Highway. All 3D seismic lines followed a normal successional trajectory, except for one recently disturbed site. This was likely attributable to the low impact methods used in 3D line creation that minimize ground and vegetation disturbance, creating conditions more likely to result in a normal successional trajectory (Yukon Energy Mines and Resources 2006, Golder Associates 2016). Magnified and stagnated succession were only observed in 2D seismic lines and winter roads. These linear features were generally wider and were created using methods that cause greater disturbance to soils, hydrology, and vegetation, leading to these alternative successional trajectories (Simpson 2008, Jorgenson et al. 2010, Dabros et al. 2018). Magnified succession is unique among the classes in that it results in accelerated vegetation regeneration. Magnified succession was most common on burned 2D seismic lines where the combination of site disturbance associated with the 2D lines and fire is suspected of causing accelerated soil warming, moisture availability, and nutrient flush, which increase on-line vegetation growth (Simpson 2008). Successional stagnation was most common on unburnt winter roads. Stagnation tends to occur on features that have experienced ground disturbance or have been seeded to agronomic species, which may have happened on winter roads in the RSA (Simpson 2008). Repeated disturbance associated with multiple exploration programs over time may also limit successional advancement and contribute to successional stagnation (Lee and Boutin 2006, Jorgenson et al. 2010).

Although some alternative successional pathways were observed in this study, most linear features in the Eagle Plains RSA are following a normal successional trajectory. This implies that most of these disturbances will recover to an ecological condition like that of the surrounding community with adequate time.

5.2.3 STRUCTURAL STAGE

The taiga forest in Eagle Plains presents a unique situation where the Tall Shrub stage is applied to two very different stand conditions. One condition, the more traditional, is of regenerating stands following a natural or anthropogenic disturbance. In this setting, the vegetation consists of deciduous shrubs and 2–8 m tall, 10–30 years old trees. The stage is transitional, with the vegetation expected to advance to the Pole-Sapling stage over time. The second condition where the Tall Shrub stage is applied is to stunted, old, black spruce stands in a disclimax state. In this setting, the vegetation consists of open, stunted, black spruce stands that are typically ≥50 years old and 2–8 m tall. Stands in this condition are expected to remain in the same condition over time(i.e., a disclimax state). Structurally, the stunted black spruce trees function more like shrubs than trees. Both Tall Shrub conditions (referred to as disturbance and disclimax forms hereafter) are widespread across the RSA in off-line sites. Only the disturbance form was observed on linear features.

The structural stage on linear features was predominantly Low Shrub or Tall Shrub, determined mainly by the time since line clearing and burn status. Less than 4% of surveyed features were in forested stages (Pole-Sapling or greater). Off-line plots had a higher proportion of forested structural stages (37%). However, they were still predominantly Low Shrub and Tall Shrub, resulting from extensive burns across the RSA and large extents in the disclimax form for Tall Shrub in un-burned areas.

The structural stage of on-line plots was also influenced by successional class. The small number of forested structural stages observed on features only occurred on sites undergoing normal succession. Stagnated succession was associated with only the Herb structural stage, which was expected as stagnation is defined by its high herbaceous species cover (among other factors) that limits the establishment of other structural groups. Magnified succession was the one atypical successional class with accelerated vegetation growth. Most structural stages on sites with magnified succession were in Tall Shrub and, occasionally, Pole/Sapling. Often the structural stage on magnified succession sites was one stage greater than the off-line plot.

5.2.4 VEGETATION HEIGHT

This study observed a range of vegetation heights across different feature types. Except for the 3D lines, the linear features' age was unknown, so it was impossible to estimate growth rates. Although some regenerating vegetation on 2D seismic lines and winter roads reached 8 m high, most were between 1.5 m and 2 m. Though the ages of specific features were mostly unknown, the minimum age for most was at least 35 years. Having most vegetation heights at only 1.5–2.0 m after this long period suggests regeneration growth rates on linear features may be quite slow. This pattern of slow vegetation growth on linear features may partly reflect the generally poor growing conditions in the taiga region. Still, it is also a pattern that has been observed on linear features in other studies in the southern boreal forest.

Interestingly, the vegetation heights on linear features in Eagle Plains are greater than reported in several other studies. For example, approximately 65% of sites on linear features in northeast Alberta had not advanced beyond a cover low forbs after 35 years (Lee and Boutin 2006). Key factors that have been linked to slow vegetation regeneration on linear features were continued human disturbance (e.g., OHV travel), ecosystem type (bogs and fens regenerated much slower than upland sites), competition from early seral and invasive graminoids and forbs, and soil or site degradation associated with feature construction (Lee and Boutin 2006, van Rensen et al. 2015, Finnegan et al. 2018).

There is limited data on vegetation regeneration in the taiga. A study from NWT found that vegetation regeneration on conventional seismic lines was affected by both a time lag for seedling establishment (as long as 17 years for black spruce) and slow growth rates (83 years to reach 5 m) (Seccombe-Hett and Walker-Larsen 2004). In burned areas, the seedling establishment delay was reduced to five years.

Although the 3D lines in Eagle Plains were only six years old when they were surveyed, a combination of field survey results and information from other studies suggests that vegetation recovery on 3D lines could be much faster than the previous examples for conventional 2D lines. This is because the undisturbed ground conditions and maintenance of the vegetation community in the moss, forb and low shrub layer provide both plants and growing conditions that support faster shrub and tree growth compared to sites beginning primary succession. In northeast British Columbia, Golder Associates (2016) found that in the first year following 3D seismic line creation, there were already black spruce seedlings exceeding 0.5 m in height. These seedlings were plants that were initially present on the site and that had survived line clearing. This is consistent with the results of this study, where nearly all of the 3D plots contained black spruce seedlings. Despite their relatively young age, most 3D seismic lines in Eagle Plains included shrubs and trees between 0.5 m and 1 m

tall. Although growth rates in Eagle Plains are not known, similar species that occur in Eagle Plains were observed to grow 5–10 cm per year on 3D lines in the boreal forest in northeastern British Columbia (Golder Associates 2016). If similar growth rates occur in Eagle Plains, regeneration on the 3D lines can be 2 m over the next 5–20 years.

5.3 HUMAN USE AND ACCESS ALONG LINEAR FEATURES

The NYRLUP and the PWRLUP indicate that one of the primary concerns about linear features is that they can increase human access into remote areas. This has been demonstrated in southern regions, and that access can have secondary effects of inhibiting vegetation regeneration (Lee and Boutin 2006) and, in winter, packing snow that can affect predator-prey dynamics (Latham et al. 2011, McKenzie et al. 2012, Keim et al. 2019a). In the boreal forest in northern Alberta, OHV travel was common on most conventional 2D seismic lines. After 35 years, approximately 20% of the lines were considered to have been converted to tracked access routes (Lee and Boutin 2006). In the same study, about 65% of the lines remained cleared after 35 years, and OHV use along the lines was identified as one factor contributing to the lack of vegetation regeneration. In contrast, there is little evidence of human use along linear features in the Eagle Plains RSA. No sign of human use was detected along linear features during the summer ground surveys (e.g., OHV tracks, ruts, water crossings, vegetation trampling/scarring, tree blazes, trap sets, garbage, campsites, etc.) or the winter track survey (e.g., snowmobile tracks). Although these surveys provided limited snapshots in time, and that some types of human activity leave little sign (e.g., evidence of snowmobile tracks have limited persistence during winter and leave no sign behind after snow melt), the results suggest that human use of the area is very limited outside of the Dempster Highway corridor. This is consistent with general comments from highway workers, staff at the Eagle Plains Hotel, pilots, and some First Nation residents that most areas beyond the Dempster Highway corridor receive very little human use. Specific instances of use of the area outside the Dempster Highway corridor include intermittent activity on the community trapline that occurs in Eagle Plains and occasional forays by hunters (First Nation and non-First Nation), mostly in winter.

People's limited use of the Eagle Plains area is likely due to its far distance from any human settlements and the difficulty of travel off the Dempster Highway. The network of winter roads in the area does provide access via specific types of OHVs in summer and snowmobiles in winter. However, there was no evidence observed that this occurs regularly. Travel along seismic lines, though possible in specific locations, would be hampered over any substantial distance by vegetation regeneration along the historical 2D lines, the narrow widths of and frequent dogleg bends in 3D lines and, during summer, difficult terrain (extensive peatlands and graminoid tussocks).

5.3.1 EFFECTIVENESS OF MITIGATION MEASURES FOR 3D SEISMIC LINES

In addition to the narrow widths of 3D lines, which hampers OHV travel, the 3D lines included regular bends in the lines, which were designed to limit the visibility of the lines at intersections with roads and other seismic lines, and to hamper OHV along the lines further. The driving survey along the Dempster found that this mitigation was very effective in reducing the visibility of the 3D lines from the road (i.e., only 6 of the 74 3D

lines intersecting the Dempster Highway were visible). Incidental observations during ground surveys observed similarly reduced visibility of 3D lines crossing winter roads. Regular bends in the 3D lines away from roads were also designed to limit human access by reducing sightlines and making travel more difficult along the line (i.e., needing to reduce speed to navigate the tight turns of a dogleg bend approximately every 70 m).

5.4 FUNCTIONAL CHARACTERISTICS OF LINEAR FEATURES

In addition to human travel, linear features can also affect how wildlife move within a landscape. Several studies in western Canada have documented the effects of linear features on the movements and population dynamics of large mammals, such as caribou, moose, deer, wolves and bears (Latham et al. 2011, McKenzie et al. 2012, Dickie et al. 2017b, Keim et al. 2019a). EDI focused on two established indicators of human and wildlife access and travel on linear features: sightline distance and ease of travel. These measurements act as a proxy for the functional recovery of disturbed areas. They are mainly dependent on vegetation height, cover, and terrain.

5.4.1 LINE-OF-SIGHT

Line-of-sight or sightline distance is how far one can see under normal conditions and was compared between linear features and paired reference plots. It has been proposed that humans and predators select linear disturbances because it is easier to travel and detect prey using those features (Finnegan et al. 2018). As vegetation grows taller and denser, sightlines diminish, and the use of linear features decreases (e.g., for wolves, Dickie et al. 2017a). This study found that average sightlines were farther on-line versus off-line for most linear feature types, but that sightlines varied substantially across line types. Sightlines were shorter on seismic lines than on roads, especially 2D lines which had more advanced vegetation regeneration than other feature types. On 3D lines, sightlines averaged approximately 30 m farther on lines than off lines. However, this difference probably provides little advantage to predators or human hunters because the increase is still within the olfactory and auditory detection zone for most large prey species. Average sightlines were 60 m farther on winter roads than surrounding forest, which may begin to confer more advantage to predators and hunters.

The range of sightlines observed on most linear features probably do not provide an advantage to detect prey species visually. For 2D lines and winter roads, sightline distances were primarily driven by the height and density of regenerating vegetation. The recovery period for 2D seismic lines appears to be sufficient to support vegetation that reduces visibility to a similar level as the surrounding habitats. The reason for longer sightlines on winter roads is that they are subject to intermittent re-activation, where the vegetation is cleared once again, which resets vegetation recovery and maintains longer sightlines. In contrast to 2D lines and winter roads, where sightlines were largely determined by vegetation regeneration, the sightlines on 3D lines were presently limited by the bends purposely constructed into the lines. Sightlines along all feature types will continue to diminish over time as vegetation regeneration continues.

5.4.2 EASE OF TRAVEL

Ease of travel is a fundamental indicator of functional recovery of linear features. Wolves, bears, and humans have been documented to select linear features with greater ease of travel, which is generally associated with lower and more sparse vegetation and stable, even terrain (Dickie et al. 2017b, Keim et al. 2019a). Access and travel resistance are the main determinants of predator and human use of linear features and the key concern of linear disturbances in the RSA (Vuntut Gwitchin Government and Yukon Government 2009, Peel Watershed Planning Commission 2019).

The walk test used in this study, as an index of ease of travel, found differences among linear feature types and between linear features and controls. However, the magnitude of the differences for both comparisons was modest. Even the Dempster Highway only conveyed a 35% increase in walking speed over off-line plots. Other researchers, in other areas, often observed walk speeds on linear features were often at least twice as fast as off-line transects (Keim et al. 2019a). Two conditions associated with the Eagle Plains area appear to limit the advantage of travelling on linear features. One is that the vegetation in most ecosites and structural stages is relatively open and has a limited effect on impeding movement. The second factor is that ground conditions limiting movement, including soft, thick peat and graminoid tussocks, were similar on both on-line and off-line plots for most linear feature types.

Notwithstanding the modest magnitude of faster walking speeds on-lines, there were clear patterns in walking speed differences across linear feature types. 2D lines were the one feature type where walking speeds were slower on lines than off lines. This reflected the thick, shrub stage vegetation that had regenerated on most 2D lines, which impeded travel (similar to the effect that regenerating vegetation had on sightline distances in the previous section). Walk speeds decreased across the other feature types in relation to line width and the degree to which ground cover was levelled or compacted. 3D seismic lines allowed slightly easier travel than paired off-line plots. They usually had lower vegetation cover and clearer route selection. As linear feature width decreased in 3D lines, walking speed also decreased. This implies that width may be related to functional recovery, with narrower lines having smaller impacts than wider lines, even within an already narrow linear feature type. Although ease of travel was greater in 3D seismic lines than surrounding community, it is expected that this will decrease in future years as vegetation increases in height and density.

5.5 FUNCTIONAL RECOVERY OF LINEAR FEATURES

Functional disturbance is defined in the NYRLUP and PWRLUP as "*physical land use disturbance that results in disruption of soil or hydrology, or that requires the cutting of trees*." One of the main concerns with linear disturbances under these land use plans is that such features can technically allow increased access to previously remote areas, potentially leading to a greater harvest of wildlife and fish, higher predation rates, and a change in how people and wildlife use the land (Vuntut Gwitchin Government and Yukon Government 2009). A disturbance can be considered functionally recovered and subtracted from the overall linear density when it no longer facilitates access or travel by humans or wildlife (Vuntut Gwitchin Government and Yukon Government 2009), or otherwise no longer functions as a surface disturbance (Peel Watershed Planning Commission 2019). Both plans use 1.5 m vegetation height as a threshold for functional recovery in forested communities. The

PWRLUP includes the following additional criterion for recovery "*in non-forested areas (dominated by vegetation under 1.5 m), when the disturbed area is covered by native species roughly the same height and composition as the surrounding dominant vegetation*" (Peel Watershed Planning Commission 2019):

One limitation of using height alone as a functional recovery criterion is that it does not consider vegetation density. Although regeneration may meet the recommended height criteria, if it is very sparse (as is often the case in the Eagle Plains Ecoregion), it may still facilitate access and travel by humans and wildlife. Attachment Photo A-25 provides an example in the Eagle Plains RSA where tall but sparse regeneration meets the 1.5 m criteria but does not inhibit access or travel.

The combined results of this study indicate that using regeneration to the Tall Shrub structural stage may be a more appropriate criterion for functional recovery. Attachment Photo A-3 and Attachment Photo A-10 provide examples of linear features that have regenerated to a tall shrub structural stage. Using the Tall Shrub criterion, 38% of all linear features in the RSA would be considered functionally recovered compared to 53% using the 1.5 m height criterion. For this study, the more conservative criterion of reaching the Tall Shrub structural stage was used to adjust (reduce) linear feature densities.

5.6 LINEAR FEATURE INVENTORY AND DENSITY

This study was successful in mapping all linear features within the RSA. The combined results of the mapping exercise and the field studies found that the extent of open habitats (burns and naturally open habitats like wetlands and shrublands), and the degree of vegetation regeneration, played a significant role in the effective density of linear features across the RSA. Before accounting for open areas and regeneration, the total linear feature density was 1.79 km/km². After accounting for open areas and vegetation regeneration (to the Tall Shrub structural stage), the effective linear feature density was 0.52 km/km². The NYRLUP and PWRLUP suggest cautionary levels for linear density of 0.75 km/km² and critical levels of 1.0 km/km² (Vuntut Gwitchin Government and Yukon Government 2009, Peel Watershed Planning Commission 2019).

The Yukon Land Use Planning Council (YLUPC) was conducting a pilot study of surface disturbance across the broader Eagle Plains Ecoregion (Skinner 2021) at the same time as this study. The methods they used consisted of mapping and attributing human-caused disturbances solely using high-resolution satellite imagery. The YLUPC classified vegetation into eight broad classes based on whether the surrounding area was forested or non-forested, the similarity of vegetation on-line to off-line, and the presence or absence of woody cover (i.e., shrubs or trees). The features were then classified as recovered or not-recovered based on the presence of woody cover (recovered) or, if woody cover was not present, the similarity to surrounding vegetation (i.e., if similar then recovered, if not similar, then not-recovered). Historical field data and photographs from the area (Simpson 2008) were used to verify interpretations.

The spatial data from the YLUPC work was not available to compare in detail to the linear feature inventory compiled in this study. However, the mapping linework is expected to be very similar because satellite imagery was used to verify and supplement the linear feature geospatial data compiled in this study (presumably the same satellite imagery that YLUPC used because the imagery was obtained from Yukon Geomatics). One

difference between the two products is that the YLUPC completed the inventory for the entire Eagle Plains Ecoregion, while this study was restricted to the RSA. Another difference is that the attribute data in this study is expected to be more detailed and more precise than the YLUPC data because (i) the original geospatial data includes some information, like date of creation, that would be impossible to estimate from imagery, and (ii) because this study linked field surveys to the mapping exercise to determine line widths and other characteristics more precisely.

Although it is impossible to directly compare the linear feature density estimates between the two studies, due to the different study extents, the general pattern of results is similar. The YLUPC estimated the linear density (accounting for recovery) to be 0.38 km/km² across the entire Eagle Plains Ecoregion. This is consistent with the estimate from this study for the RSA of 0.52 km/km² because the portion of the Ecoregion outside the RSA has lower linear feature density than the RSA.

6 CONCLUSION

This study successfully mapped all linear features within the RSA and measured a suite of structural, vegetation, and functional characteristics across different feature types. Generally, the effects associated with linear features (i.e., differences between conditions on-line and adjacent off-line areas) correlated to feature width and the degree of ground disturbance. In terms of combined effects across the range of feature types that occur in the Eagle Plains RSA, the ranks were:

Dempster Highway >>> Winter Roads > 2D Seismic > 3D-5m >> 3D Conductor > 3D Receiver[2]

The effects of 3D lines (both conductor and receiver lines) appear to be substantially lower than other feature types. This reduced magnitude of effects is important because 3D lines have the longest combined length of exiting linear features. They are also the predominant feature planned for the next exploration program. Important findings for 3D lines include:

- Relatively narrow line widths of 2–3 m are often smaller than natural tree spacing and minimize the potential for changes to microsite conditions (e.g., solar radiation, air and ground moisture) reported in other studies.
- Minimal ground disturbance and maintenance of the moss, herb, and low shrub layers, which retains the natural vegetation community and accelerates vegetation regeneration.
- Successful application of mitigations, notably dogleg bends that minimize sightlines, ease of human travel, and visibility of lines from roads.
- Ungulate use of 3D lines in winter was less than a third of the rate observed on 2D lines and winter roads.

The adverse effects of linear features in other areas are often caused or exacerbated by human use after the lines are initially constructed, including effects on vegetation regeneration and predator-prey dynamics. Human use does not appear to be a significant factor in Eagle Plains. No sign of human use was observed outside the Dempster Highway corridor.

Substantial vegetation regeneration has occurred on existing features in the Eagle Plains RSA. Previous work by the Yukon Government identified the potential for atypical successional trajectories to occur on linear features in the region. Although atypical succession occurred to a limited extent, this study determined that 81% of the sites exhibited a normal succession (100% on 3D lines). Only 5% exhibited inhibited regeneration trajectories (mostly stagnated succession on winter roads). Regarding functional recovery, 53% of sites met the NYRLUP and PWRLUP criterion of vegetation reaching 1.5 m, and 38% of sites met the criterion of attaining a Tall Shrub structural stage. Using the Tall Shrub structural stage as a criterion of functional recovery may be a more ecologically appropriate criterion to meet LUP objectives.

The extent of open habitats (e.g., burns, wetlands and shrublands) and the degree of regeneration on existing linear features (mostly the older 2D lines and winter roads) play an important role in calculating effective linear

[2] Relative magnitudes of effects: >>> large effect, >> moderate effect, > small effect.

feature density in the RSA. Before accounting for open areas and regeneration, the total linear feature density was 1.79 km/km². After accounting for open areas and vegetation regeneration (to the Tall Shrub structural stage), the effective linear feature density was 0.52 km/km².

Appendix C. Literature Summary

1 SUMMARY OF ZOI STUDIES ON CARIBOU

This document was prepared by K. Bajina, and reviewed by Todd Mahon (January 2023) and Mike Setterington (April 2023). It was prepared as background materisl or the Chance Oil and Gas Project caribou effects assessment.

Key notes on the summary of studies presented in Table 1 are presented below.

- There is a weight of evidence that ZOIs often do occur for caribou, but some studies found no effect or even selection for proximity to disturbances.
- Estimates of ZOI distances vary widely from several hundred metres to tens of kilometres. Estimates of a zone of influence distances vary with disturbance type, location, habitat, season, year, weather, herd, sex/age classes, study design, sample size, and analytical method used.
- Estimates for the same herd vary substantially from year to year.
- In all studies, the observed effect was reduced use within a ZOI, not complete avoidance. The response is graded, with maximum reduction occurring at the disturbance and then use increasing out to the ZOI distance. Most studies report the maximum reduction, so the overall magnitude of the effect across the ZOI is approximately half the magnitude of the effects reported (but a few studies indicate non-linear responses or provide estimates at varying distances).
    - The effects on the CAH and the Bathurst herds, which have been studied intensively, have been mostly linked to habitat use, movement, and local distribution. No effects have been linked to changes in abundance, demographics, or seasonal movement patterns.
    - The magnitude of the effect of ZOI relative to environmental covariates is variable. Often the magnitude of the effect of the ZOI is weaker than environmental variables, contributing to the variability of ZOI distances reported.
- Both the distance and magnitude of effects for ZOIs typically relate to the intensity of human disturbance. A general pattern across studies is that effects are greatest for Settlements and Mines, followed by high-use roads, then oil and gas development, and forestry.
    - The relationship between effects and intensity of disturbance also applies within a sector. For example, effects are greater for high-use roads than low-use roads. For O&G wells, ZOI distances relate to activity level – drilling > production > inactive.
- Several researchers suggest that the primary mechanism behind caribou ZOIs is that caribou perceive anthropogenic features and/or sensory disturbances as a threat, real or not, and avoid those areas (Frid and Dill 2002, Boulanger et al. 2021). Where hunting or facilitated predation occurs, ZOIs are likely to be larger, have a higher magnitude of effects, and persist longer.

- Some studies suggest that habituation to predictable disturbances over time (e.g., CAH) has resulted in reduced effects. Areas with variable disturbances, especially where hunting occurs, have greater effects that do not diminish over time.

Table 1. Summary zones of influence and management buffers for caribou

#	ZOI/Management Buffer	Source	Literature Type	Subspecies/ Ecotype	Location/ Herd	Mechanism	Type of Assessment	Context/Comments
1	No ZOI detected; same data as Boulanger et al. (2012)	(Golder Associates Ltd. 2020)	Report	Barren-ground	Bathurst caribou herd	Change in distribution (sensory disturbance)	Quantitative	RSF analysis of caribou abundance from aerial survey data during July-Nov (1998-2012) ZOI is calculated by controlling for area effect when evaluating caribou habitat and numbers (i.e., as the availability of area around a footprint increases (buffer size considered), so too does the potential for preferred caribou habitat Tested interaction between distance to development and area of preferred habitat; no significant interaction was found, meaning preferred habitat area increased at farther distances (as expected) Animal relative abundance increased with the amount of preferred habitat (and distance to development)
2	1–5 km for linear features 1–15 km for polygonal (largest are active mine site [14 km] and settlement [15 km], all else ≤ 5 km)	(GNWT Environment 2018)	Report	Barren-ground	Bathurst caribou herd	Effective habitat loss	Qualitative	Bathurst range plan (draft, supporting report); prescribed ZOIs around human developments for barren-ground caribou Different ZOIs prescribed to feature type (e.g., linear vs polygonal) and class (e.g., all-season vs winter road) based on a compilation of literature and project examples
3	<u>Aerial surveys:</u> 20.5 km ZOI based on caribou presence/absence (but odds ratio no different from 1, thus no true ZOI) 37.5 km based on caribou counts <u>Camera traps:</u> 5 km from the project	(TMAC Resources 2017)	Report	Barren-ground	Dolphin and Union, and Beverly herds	Change in distribution (sensory disturbance)	Quantitative	ZOI analysis from 1996-2005 (aerial surveys) and 2012+ (camera traps) for the Final Environmental Impact Statement for the Madrid-Boston Project (based on effects of the Doris Project) RSF (presence/counts) using PCA compositive variables describing habitat and NDVI for the post-calving season, and segmented regression as per Boulanger et al. (2012)
4	Graded ZOI at 4km from mine; reduced habitat effectiveness within ZOI (<1 km, 2 km, and 4 km) 2km from road; reduced habitat effectiveness within ZOI	(EDI Environmental Dynamics Inc. 2017)	Report	Barren-ground	Fortymile caribou herd	Effective habitat loss	Qualitative	YESAB project proposal for the Coffee Gold Mine in Yukon RSF habitat model was created, and multipliers were applied to mapped RSF pixels at intervals within ZOIs ZOIs based on literature review Calculated reduction in habitat effectiveness
5	Graded ZOI at 14 km; disturbance coefficients within ZOI based on distance and feature type	(Agnico Eagle Mines Ltd. and Golder Associates Ltd. 2014)	Report	Barren-ground	Qamanirjuaq caribou herd	Effective habitat loss	Qualitative	Final Environmental Impact Statement for Agnico's Meliadine Gold Project in Nunavut Implemented a ZOI framework based on the results of the study completed by Boulanger et al. (2012)

#	ZOI/Management Buffer	Source	Literature Type	Subspecies/ Ecotype	Location/ Herd	Mechanism	Type of Assessment	Context/Comments
	50–70% of (limited) collar data during winter fell within ZOI							Applied disturbance coefficients within ZOI based on feature and distance, and calculated use of the area within the ZOI by the herd
6	Graded ZOI at 4 km; no effect beyond 4 km and intensifying effect at intervals towards the PDA	(Casino Mining Corporation 2014)	Report	Woodland (Northern mountain)	Klaza caribou herd	Effective habitat loss	Qualitative	Applied ZOI/disturbance buffers for the Casino Project in west-central Yukon, Canada ZOI chosen based on a literature review Reduced habitat effectiveness within the ZOI, ranging from 40-80% reduction to calculate the effect (reduced use) on herd
7	14 km from mine; reduced ratings within ZOI (<7 km and 7–14 km) 4km from roads; reduced ratings within ZOI (<1 km and 1–4km)	(Areva Resources Canada 2014)	Report	Barren-ground	Ahiak and Qamanirjuaq caribou herds	Effective habitat loss	Qualitative	Developed a habitat unit index model for habitat availability (winter [Oct 1-May 31] and growing [June 1-September 30] seasons) and decreased ratings based on the distance to mine and road for the Kiggavik project ZOIs based on literature review Habitat ratings (nil, low, moderate, and high) were reduced two classes for the closest distance interval and 1 class for the furthest distance interval within the ZOI
8	15 km from mine 5 km from road But little to no effect on demography	(Russell 2014)	Report	Barren-ground	Qamanirjuaq caribou herd	Change in population demography (pregnancy rate and mortality) and effective habitat loss	Qualitative ZOIs Quantitative energy model	Implemented qualitative ZOIs (based on literature) to develop energy-protein and population modelling of the herd for the Kiggavik project Final Environmental Impact Statement Assumed 6% decreased foraging and 3% increased walking/ running within the ZOI Determined a potential 1% decline in pregnancy rate and a 0.93% increase in overwinter calf mortality Final population model estimates from Project effects were indistinguishable from baseline conditions
9	Graded ZOI at 14km; no effect beyond 14 km and intensifying effect at intervals towards the PDA	(Baffinland Iron Mines Corporation 2012)	Report	Barren-ground	North Baffin caribou	Effective habitat loss	Qualitative	Final Environmental Impact Statement for Baffinland's Mary River Project Implemented a ZOI framework based on the results of the study completed by Boulanger et al. (2012) RSPF habitat model was created, and multipliers were applied to mapped RSPF pixels at intervals within ZOIs; ZOIs were the same, but intervals were different among features
10	40 km ZOI in 3 years (2001, 2005 and 2009) and 15 km in 2006, but the influence of Lac de Gras was greater than the level of mine activity	(Rio Tinto 2012)	Report	Barren-ground	Bathurst caribou herd	Change in distribution and behaviour (sensory disturbance)	Quantitative	Quantified ZOIs based on aerial survey data for several years at the Diavik mine Distribution was assessed, and behavioural scans were conducted at distance intervals from the mine

#	ZOI/Management Buffer	Source	Literature Type	Subspecies/ Ecotype	Location/ Herd	Mechanism	Type of Assessment	Context/Comments
	10% reduction in feeding/rest within 5km							
11	500 m (10 distances from 50 to 4,000 m were examined)	(Environment Canada 2011)	Report	Woodland (Boreal)	A meta-analysis from herds across Canada	Change in population demography (recruitment)	Quantitative	A meta-analysis examining the effect of anthropogenic disturbance and fire on herd growth rates based on the recruitment-disturbance relationship Found that herds with >35% disturbed (500 m) +fire were consistently declining This finding has been carried forward as a criterion for critical habitat in all woodland caribou recovery strategies, including Mountain Caribou
12	Graded ZOI up to 15 km; disturbance coefficients within ZOI based on distance and feature type	(De Beers Canada Inc. 2010)	Report	Barren-ground	Bathurst, Ahiak, and Beverly caribou herds	Effective habitat loss	Qualitative	Environmental Impact Statement for De Beer's Gahcho Kue Project in Northwest Territories Applied disturbance coefficients to mapped RSF outputs (spring, post-calving, and fall migration) from Johnson et al. (2005) within ZOI based on feature and distance Used results to calculate relative changes in the availability of different quality habitats and residency within ZOI
13	Low-level human influence (500 m) up to high-level human influence (1km); used lower, middle, and upper level ZOIs for different feature types, which also differed in their range of ZOIs	(Applied Ecosystem Management Ltd. 2004)	Report	Woodland (Northern mountain)	Carcross caribou herd	Effective habitat loss	Qualitative	Calculated cumulative effects (i.e., loss of effective habitat) of development on the herd using pre-specified ZOI/disturbance buffers ZOIs were chosen from literature and based on professional judgement
14	−12.8–12.76 km (Negative to positive ZOIs; negative implies attraction to mine areas). OR ranged from 1.7-7.4 for avoided years; −0.4 to −1.3 selected years (but ns)	(Boulanger et al. 2021)	Published	Barren-ground	Bathurst caribou herd	Change in distribution (sensory disturbance)	Quantitative	RSF analysis of GPS telemetry data during the growing season (July 15 to Nov 30) 2009–2017 Quantified ZOIs for each year using segmented regression; 4/9 years had negative ZOIs or no different than zero, and 5/9 years had positive ZOIs Differences in ZOIs possibly linked to drought conditions
15	1 km from oil wells during winter (Fig 2)	(MacNearney et al. 2021)	Published	Woodland (Central mountain)	Narraway and Redrock-Prairie Creek subpopulations	Change in distribution (sensory disturbance)	Quantitative	RSF analysis of GPS telemetry data during early/late winter from 2007-2013 Avoidance was greatest during active drilling and less during inactive/production phases
16	1.5–3 km for cutblocks and linear features	(Palm 2021)	MSc Thesis	Woodland and Barren-ground	31 populations in western	Change in population demography and	Quantitative	Assessed resource selection (step-selection functions) of 31 populations of caribou to determine the effects of human/natural disturbance on behaviour, then evaluated whether those behavioural responses influenced demographic

#	ZOI/Management Buffer	Source	Literature Type	Subspecies/ Ecotype	Location/ Herd	Mechanism	Type of Assessment	Context/Comments
	3–4 km for polygonal disturbances (mines and oil/gas wells)				Canada and Alaska	distribution (sensory disturbance)		processes (calf recruitment [22 populations] and adult female survival [25 populations]) Two seasons were considered: summer (May 25-Oct 5) and winter (Oct 6-May 24) Exp1onential decay functions to identify ZOIs Also found that increased avoidance of roads was the best predictor of adult female survival and a significant predictor of recruitment
17	5 km (calving) 2 km (post-calving) 1 km (mosquito period)	(Johnson et al. 2020)	Published	Barren-ground	Central Arctic caribou herd	Change in distribution (sensory disturbance)	Quantitative	RSF analysis of GPS-collared females for several seasons (2015-2017) in the North Slope of Alaska (oil development area) Iterative predicted-vs-observed utilization at 1km intervals around the development to identify ZOI
18	1–2 km (mosquito season) to 10–11 km (post-calving)	(Prichard et al. 2020)	Published	Barren-ground	Central Arctic caribou herd	Change in distribution and relative density (sensory disturbance)	Quantitative	Assessed relative densities and distribution using GPS telemetry data to calculate the overlap of Brownian bridge models and integrated step-selection functions Relative density in proximity to roads varied by season, e.g., greatest avoidance during post-calving but close to roads during peak mosquito season The relative selection was greater closer to roads in 4/9 seasons/periods
19	40 km from roads during spring 100 km from roads during calving 20 km from roads during insect season 40 km from roads during late-summer No association with roads during the fall 38 km from roads during winter	(Baltensperger and Joly 2019)	Published	Barren-ground	Western Arctic caribou herd	Change in distribution (sensory disturbance)	Quantitative	Machine-learning algorithm (TreeNet) to analyze telemetry data of caribou in northwestern Alaska during several seasons from 2009-2017 ZOIs ranged greatly depending on season and type of disturbances The pooled seasonal model found a ZOI of 40km
20	<u>Summer:</u> 19–23 km from Raglan mine 2–4 km from mining exploration 2–4 km from human settlement 0–8 km from road <u>Winter:</u> 3–21 km from mining exploration	(Plante et al. 2018)	Published	Woodland (Boreal)	Riviere-aux-Feuilles and Riviere-George herds in northern Quebec and Labrador	Change in distribution (sensory disturbance)	Quantitative	RSF analysis of GPS telemetry data during summer and winter from 2009-2015 Iterative predicted-vs-observed utilization at 1km intervals around development to identify ZOI (Raglan mine and road) ZOIs were highly variable for disturbance types, years, and seasons

#	ZOI/Management Buffer	Source	Literature Type	Subspecies/ Ecotype	Location/ Herd	Mechanism	Type of Assessment	Context/Comments
	2–18 km from human settlement 5 km from power lines in 1 year <u>All:</u> 0–15km for other roads							
21	<u>Seismic and pipelines:</u> Attracted in 2/5 subpopulations during winter; 0.5-2km in others Attracted in 3/5 subpopulations during summer; 2.5–13.5km for others <u>Roads</u>: 1–1.75 km during winter Attracted in 2/5 subpopulations during summer; 1.5–1.75 km in others <u>Non-linear oil and gas</u> Attracted in 4/5 subpopulations during winter; 2km in other Attracted in 1/5 subpopulation during summer; 4–12.5 km in others	(Johnson et al. 2015)	Published	Woodland (Central and Northern mountain)	5 subpopulations in the South Peace region, British Columbia, Canada	Change in distribution (sensory disturbance)	Quantitative	RSF analysis of collar data for 5 subpopulations during summer and winter from 2000-2011 ZOIs were determined using log-likelihood asymptotes of models with iterative inclusion of collared/random locations Note: 12.5km and 13.5km in estimates (to left) were uncertain due to more than 1 asymptote in the log-likelihood curve
22	30 km down to 18.5 km (roads) 11 km down to 6 km (wells trails, winter roads, and seismic lines)	(Johnson and Russell 2014)	Published	Barren-ground	Porcupine caribou herd	Change in distribution (sensory disturbance)	Quantitative	RSF analysis of collar data for two periods (1985-1998 and 1999-2012) ZOIs were determined using log-likelihood asymptotes of models with iterative inclusion of collared/random locations Reduced 'avoidance' distance between periods, approximately 50% difference in magnitude
23	5 km from roads	(Leblond et al. 2013)	Published	Woodland (Boreal)	Laurentides Wildlife Reserve, Quebec, Canada	Change in distribution (sensory disturbance)	Quantitative	RSF analysis (all seasons) of GPS telemetry data from April 2004 and March 2010 Reduced use within 5km during and after road construction Avoided habitat types within that zone which were otherwise selected at the home range scale
24	11–14 km	(Boulanger et al. 2012)	Published	Barren-ground	Bathurst caribou herd	Change in distribution (sensory disturbance)	Quantitative	RSF analysis of aerial surveys and satellite-collared cows during growing seasons (summer range; mid-July to mid-Oct) 1998-2008 Segmented regression approach to estimate ZOI (log-likelihood curves), which were potentially linked to dustfall extent

#	ZOI/Management Buffer	Source	Literature Type	Subspecies/ Ecotype	Location/ Herd	Mechanism	Type of Assessment	Context/Comments
25	1 km (low-use roads) 2 km (high-use roads) 9 km in summer and 3km in winter (towns) 2 km in summer and 250 m in winter (mines) 1.5 km in summer (camps)	(Polfus et al. 2011)	Published	Woodland (Northern mountain)	Atlin caribou herd	Change in distribution (sensory disturbance)	Quantitative	RSF analysis of GPS telemetry data during winter and summer from 2000-2002 Avoidance differed depending on activity level and season
26	4 km (most seasons) during mine construction 6 km for decrease in group size and number	(Weir et al. 2007)	Published	Woodland (Boreal)	La Poile caribou herd (Hope Brook mine, Newfoundland)	Change in distribution (sensory disturbance)	Quantitative	Assessed caribou distribution and abundance based on aerial surveys from 1985-1991 during different phases of mine activity (pre-disturbance, construction and open-pit mining, and underground mining and mill operation) Caribou distribution, abundance, and group size decreased in proximity to the mine
27	4–6 km in post-road development phase	(Joly et al. 2006)	Published	Barren-ground	Central Arctic caribou herd	Change in abundance (sensory disturbance)	Quantitative	Re-analyzed Noel et al. (2004) data and found a change in the number of caribou between pre- and post-road construction phases >300% change in the number of caribou at distances 4-6km from the road
28	4 km (fall migration) for mineral exploration to ~130 km (post-calving) for major disturbance	(Johnson et al. 2005)	Published	Barren-ground	Bathurst caribou herd	Change in distribution (sensory disturbance)	Quantitative	RSFs from caribou telemetry data during different seasons (spring migration and calving, post-calving, and fall migration) from 1996-2000 Quadratic terms for distance to disturbance types (i.e., major disturbance, mineral exploration, outfitter) identified potential ZOIs that varied greatly
29	4 km	(Cameron et al. 2005)	Published	Barren-ground	Central Arctic caribou herd	Change in distribution (sensory disturbance)	Quantitative	Assessed abundance of calving caribou in Kuparuk Development Area (KPA) west of Prudhoe Bay Less than expected abundance within 4km of roads and declined exponentially with road density
30	<1 km (no ZOI) (Tested 6 1-km intervals from road) Effect size difficult to interpret because annual diff in N not taken into account	(Noel et al. 2004)	Published	Barren-ground	Central Arctic caribou herd	Change in abundance/ Density (sensory disturbance)	Quantitative	Assessed caribou numbers and densities at the Milne Point oilfield in northern Alaska during 3 periods: pre-road construction, early post-road construction, and recent post-road construction Calf density was higher within 1 km of road than >1 km from road during recent post-road construction period
31	1 km (oil wells) 250 m (roads and seismic lines)	(Dyer et al. 2001)	Published	Woodland (Northern mountain)	Northern Alberta, Canada	Change in distribution (sensory disturbance)	Quantitative	Assessed the proportion/selection of GPS collared caribou within concentric distance buffers from developments during 5 periods (late winter, calving, summer, rut, and early winter), 1998-1999

#	ZOI/Management Buffer	Source	Literature Type	Subspecies/ Ecotype	Location/ Herd	Mechanism	Type of Assessment	Context/Comments
								Use within different buffer distances were compared to identify maximum avoidance distances
32	106 m – distribution 316 m – mortality	(James and Stuart-Smith 2000)	Published	Woodland (Northern mountain)	Northeastern Alberta, Canada	Change in distribution (sensory disturbance)/ mortality risk	Quantitative	Assessed distribution and mortality of caribou near linear corridors using telemetry data from 1991-1997 Caribou were farther from lines than random locations and died closer to lines than distances kept while alive
33	<1 km (Tested 10 1-km intervals surrounding infrastructure)	(Cronin et al. 1998)	Published	Barren-ground	Central Arctic caribou herd	Change in abundance (sensory disturbance)	Quantitative	Assessed caribou numbers at distances from infrastructure at the Prudhoe Bay oil field in northern Alaska using utilization-availability and log-linear analyses Caribou tended to be more abundant than expected at intervals close to infrastructure, especially bulls or all sexes/ages combined No avoidance detected
34	4 km from roads and production-related facilities; displacement of maternal females from rugged terrain	(Nellemann and Cameron 1996)	Published	Barren-ground	Central Arctic caribou herd	Change in distribution (sensory disturbance)	Quantitative	Assessed the density of calving caribou in relation to rugged terrain at three zones of distance from structures (<4km, 4-10km, and >10km) based on aerial survey data (1987–1992); Prudhoe Bay, Alaska Caribou selected rugged terrain more than expected from availability, but this declined by 52% in areas <4km from structures
35	4 km from road	(Cameron et al. 1992)	Published	Barren-ground	Central Arctic caribou herd	Change in abundance (sensory disturbance)	Quantitative	Assessed the abundance/distribution of calving caribou relative to petroleum-related development based on aerial survey data (1978–1987); Prudhoe Bay, Alaska Relative abundance decreased by 2/3 <2 km and tripled at distances >4km
36	500 m (10 distances from 50 to 4,000 m were examined)	(Environment Canada 2011)	Report	Woodland (Boreal)	Meta analysis from herds across Canada	Change in population demography (recruitment)	Quantitative	Meta-analysis examining the effect of anthropogenic disturbance and fire on herd growth rates based on the recruitment-disturbance relationship Found that herds with >35% disturbed(500 m)+fire were consistently declining This finding has been carried forward as a criterion for critical habitat in all woodland caribou recovery strategies, including Mountain Caribou
37	1 km loss of functional habitat along logging road in Manitoba	(Schindler et al. 2007)	Published	Woodlnd (boreal)	SE Manitoba	Change is distribution/habitat use	Quantitative	Loss of functional habitat is suggested to occur within 1 kilometre of the road
38	1.5 km	(Eftestøl et al. 2019)	Published	Reindeer	Northern Norway	Change in distribution due to sensory disturbance	Quantitative	We found that reindeer significantly reduced habitat use at closer distances to the mine, indicating an influence zone up to 1.5 km. Reductions in use were strongest closest to the mine in high-activity periods. No avoidance effect of the mine was found beyond approximately 0.9 km for the 3-week holidays,

#	ZOI/Management Buffer	Source	Literature Type	Subspecies/ Ecotype	Location/ Herd	Mechanism	Type of Assessment	Context/Comments
								1.0 km for weekends, and 1.5 km for workdays with or without rock blasting. Compared to holidays and weekends, probability of use was reduced by 30–34% within 1.3 km from the mine for workday blasting periods, and up to 35% within 1.4 km for other workdays. Since averted areas can be partly utilized again within days or weeks following intensive mining activity periods, reduced mining activity in crucial periods for reindeer, such as during calving and migration, can be an effective mitigation measure.
39	300 m of a pipeline and 600 m of pipe+road combo (examined 100 m bands out to 1,000 m)	(Murphy and Curatolo 1987)	Published	Barren-ground	Central Arctic	Behaviours and movement rates	Quantitative	When insects were absent, caribou within 600 m of an elevated pipeline and road with traffic, and within 300 m of a pipeline and road without traffic, had significantly different activity budgets than undisturbed caribou; disturbance effects were significantly greater in the site with traffic. Time spent lying and running and movement rates were the best indicators of oilfield disturbance, whereas time spent feeding was not affected. Cow-calf-dominated groups and groups larger than 10 animals reacted to lower levels of disturbance than other group types, but all group types reacted similarly to high levels of disturbance. Separation of elevated pipelines from heavily traveled roads is recommended as a means of minimizing disruption of caribou behavior and movements. Energetic stress resulting from disturbance-induced changes in behavior should be minimal in a properly designed oilfield.

EXECUTIVE SUMMARY

On behalf of Chance Oil and Gas Ltd., Ecofor Consulting Ltd. has conducted a Heritage Resource Overview Assessment (HROA) for the Eagle Plains Basin Exploration Project. This study builds on a previous phase of heritage resource assessment conducted under permit 13-16ASR (Buchanan 2014). The proposed project includes oil and gas exploration work including, but not limited to, drilling, seismic exploration, and access development (e.g. roads and cutlines). The study area covers approximately 238,604 ha on NTS mapsheets 116H/14, 116H/15, 116I/02, 116I/03, 116I/04, 116I/05, 116I/06, 116I/12, 116J/01, 116J/08, and 116J/09, and is located within the traditional territory of the First Nation of Na-Cho Nyak Dun, Tetlit Gwich'in First Nation, Vuntut Gwitchin First Nation. **Note: All specific geographic references to heritage site locations, photographs, and some site details have been removed from this YESAB ready version of this report so that it can be issued publicly while protecting sensitive site data.**

The objectives of this HROA are to assess the heritage resource potential and sensitivity within the study area. To accomplish these objectives, Ecofor has completed a desktop review of the physical/environmental and cultural/historical setting of the study area, and used the data to generate a GIS based Topographic Position Index Based Landform Classification (TPI) heritage resource potential model. Elevated potential for encountering heritage resources is determined through review of multiple factors, including, but not limited to, landform, viewshed, proximity to natural resources (e.g. water, food gathering areas, lithic quarries), and proximity to previously recorded heritage resource sites. No traditional knowledge/traditional land use information was collected or reviewed as part of this study.

This review identified multiple areas of elevated heritage potential for surface/subsurface heritage resource sites. Most areas of elevated potential for undocumented surface/subsurface heritage resource sites are associated with knolls and terraces in the valley bottoms and higher elevation terraces and ridgelines. Moreover, seven archaeological sites have been previously recorded within the study area, with 26 more within a 50 km site search buffer around the exploration area. One Yukon Historic Sites Inventory site has been recorded within the study area, with 13 more having been recorded within 50 km of the study area. Culturally modified tree (CMT) potential was not specifically assessed in this HROA due to a lack of available vegetation inventory data.

Based on the results of this HROA, **Heritage Resources Impact Assessments (HRIAs) are recommended for multiple areas of elevated potential for surface/subsurface heritage resource sites. Moreover, avoidance is recommended for all previously recorded heritage resource sites within the study area. If avoidance is not feasible, then further assessment work**

(e.g. systematic data recovery excavations) should be conducted before the commencement of any ground disturbing activities within known site boundaries. It is recommended that this report be provided to the First Nation of Na-Cho Nyak Dun, Tetlit Gwich'in First Nation, Vuntut Gwitchin First Nation, and should further fieldwork be conducted (e.g. HRIA), it is recommended, where possible, to include First Nation of Na-Cho Nyak Dun, Tetlit Gwich'in First Nation, Vuntut Gwitchin First Nation representatives in that fieldwork.

1.0 INTRODUCTION

On behalf of Chance Oil and Gas Ltd., Ecofor Consulting Ltd. has conducted a Heritage Resource Overview Assessment (HROA) for the Eagle Plains Basin Exploration Project (Figure 1). This study builds on a previous phase of heritage resource assessment conducted under permit 13-16ASR (Buchanan 2014). The proposed project includes oil and gas exploration work including, but not limited to, drilling, seismic exploration, and access development (e.g. roads and cutlines). The study area covers approximately 238,604 ha on NTS mapsheets 116H/14, 116H/15, 116I/02, 116I/03, 116I/04, 116I/05, 116I/06, 116I/12, 116J/01, 116J/08, and 116J/09, and is located within the traditional territory of the First Nation of Na-Cho Nyak Dun, Tetlit Gwich'in First Nation, Vuntut Gwitchin First Nation. **Note: All specific geographic references to heritage site locations, photographs, and some site details have been removed from this YESAB ready version of this report so that it can be issued publicly while protecting sensitive site data.**

1.1 HROA Objectives

The objectives of this HROA are to assess the heritage resource potential and sensitivity within the study area. To accomplish these objectives, Ecofor has completed a desktop review of the physical/environmental and cultural/historical setting of the study area, and used the data to generate a GIS based Topographic Position Index Based Landform Classification (TPI) heritage resource potential model. Elevated potential for encountering heritage resources is determined through the review of multiple factors, including, but not limited to, landform, viewshed, proximity to natural resources (e.g. water, food gathering areas, lithic quarries), and proximity to previously recorded heritage resource sites. No traditional knowledge/traditional land use information was collected or reviewed as part of this study.

1.2 Report Format

The report begins with a basic outline of the project and the objectives of the work undertaken. The proposed activities and their impacts are then discussed in Section 2.0. Section 3.0 describes the methods employed in assessing the archaeological potential. Section 4.0 provides a description of the physical/environmental and cultural/historical setting of the study area. Section 5.0 presents an evaluation of the heritage resource potential within the various localities being considered within the study area, Section 6.0 provides a summary of this analysis and a series of heritage resource management recommendations for the study area, and Section 7.0 lists the references cited. Three appendices are included at the end of the report[1]. Appendix A

[1] Note: These appendices A and B have been removed from this YESAB ready version of this report so that it can be issued publicly while protecting sensitive site data.

and B present maps illustrating and supporting the recommendations, and Appendix C presents Guidelines Respecting the Discovery of Human Remains and First Nation Burial Sites in the Yukon.

2.0 PROPOSED ACTIVITIES WITHIN STUDY AREA[2]

The Proponent intends to conduct exploration drilling and flow testing of any discoveries over an area of approximately 2,400 km² in the Eagle Plains area, located between the Ogilvie and Richardson mountain ranges along the Dempster Highway. The purpose of this exploration drilling and flow testing program is to confirm the quality, quantity, and areal extent of any accumulations of hydrocarbons. The Proponent will drill up to 30 wells sequentially over a period of up to 10 years. If a well is successful (i.e. if there is a discovery of crude oil or natural gas in sufficient quantities), the Proponent will conduct an extended flow test (EFT) for a period of up to two years on that particular well. There is considerable uncertainty in terms of the outcome from exploration drilling, so it is only possible at this stage to speculate on the number of discoveries that will be made. For the purposes of this assessment, the Proponent estimates that crews may conduct EFTs on up to 20 wells, depending on the drilling success. Due to the exploratory nature of the work, it is impossible to predict the timing of any discovery, and therefore, the timing of any EFTs.

The Proponent will drill one well at a time and up to five wells per year. For a predominantly natural gas well, EFT may require up to a month to complete, and for a predominantly crude oil well, up to 2 years. The Proponent anticipates that up to eight wells may undergoing EFT at the same time (based on the planned drilling schedule), and that EFT will be undertaken on a maximum of 20 wells during the Project.

If several wells reach successful outcomes and are identified for extended flow testing, the wells will have completion equipment installed within their wellbores, the casing will be perforated, and the wells will be flowed. This would require a completion or service rig to install the completion equipment and the tubing used to conduct produced well fluid to ground surface, at which point surface equipment would then be installed, which may include artificial lift equipment to help the fluid continue to flow.

Fluids produced during EFT will need to be measured, processed, and dealt with in an environmentally responsible manner. Depending on the nature of a discovery, the Proponent anticipates that some combination of natural gas, crude oil, and possibly formation water will be extracted during the EFTs. These fluids are separated and measured in facilities on the surface. Natural gas could be flared for short periods of time, but the Proponent prefers to conserve it to provide fuel for process heating, fuel for engines providing mechanical power, and possibly onsite power generation. If natural gas quantities are significant, the Proponent would consider re-

[2] Information presented in this section has been adapted from Hemmera 2021.

injecting surplus natural gas into a compatible reservoir in the Eagle Plains basin using an existing suspended well. The Proponent currently has eight suspended wells that were drilled in the past, which could be used for re-injection. Alternatively, some of the new wells, drilled as part of this 30 well Project, may be used.

Fluid transportation vehicles will be required to travel from site to site and transport the produced fluid back to the Central Process Facility for storage, further treatment, and transfer to trucks for transport to market or disposal. Crude oil produced during the EFTs will be conserved instead of flared to the greatest extent possible. This will require some processing to stabilize the crude oil for truck transport to a suitable, approved crude oil marketing point, such as terminals in the vicinity of Fort Nelson or Fort St. John, British Columbia, or Grand Prairie, Alberta. All these locations are ready to receive and utilize crude oil produced from Yukon sources without such destinations existing within the Yukon. The Proponent may also consider trucking crude oil produced during the EFT to ports in Alaska such as Skagway, Haines, or Valdez for onward shipping to suitable markets elsewhere in North America.

Formation water produced in conjunction with crude oil or natural gas will be separated from the hydrocarbon streams and disposed of underground into a compatible and approved geological formation at Eagle Plain using one of the suspended wells or one of the wells drilled as part of this Project. These procedures to process, transport, and dispose of various fluids produced are common practice using proven technologies and equipment in every oil and gas province in Canada.

The Proponent also intends to conduct a seismic exploration program consisting of up to 1,500 km² of three-dimensional (3D) seismic and up to 2,000 km of two-dimensional (2D) seismic to identify and map oil and gas geological structures in the area.

Additional activities are required to support the drilling and seismic exploration, including:

- Mix Bury Cover (MBC) sump area to dispose of drill cuttings
- Construct winter and all-season access roads
- Construct airstrip
- Advance borrow source developments
- Transport equipment and supplies to the site and within the Project area

- Use existing camp at km 325 of the Dempster Highway and periodic use of the Eagle Plains Hotel.

The Proponent is planning to begin exploration activities in 2023/2024, and continue for a period of 10 years to cover the various stages of drilling and extended flow testing of the proposed wells. The execution of the EFTs will likely be phased, depending on the nature of the discovery (e.g., natural gas versus crude oil), and the capacity of the 75-person base camp and the Eagle Plains Hotel to accommodate the necessary crews. Until there is more information about the resources discovered, it is difficult to accurately predict the full duration the complete flow testing program.

3.0 METHODOLOGY

This report presents the results of a desktop study designed to predict the potential for encountering heritage resources within the unassessed claims within the study area. The methodology used in this desktop HROA to develop these predictions is described below.

The desktop review relies on two primary lines of evidence, the physical/environmental and cultural/historical setting of the study area:

1. The first line of evidence is predicated upon attributes of the physical/ environmental setting. These attributes are derived from an analysis of the biogeoclimatic zones, physiography, hydrology, bedrock and surficial geology, and vegetation and wildlife distributions. Aerial/satellite photographs, LiDAR-based hillshade imagery including client provided imagery and ArcticDEM hillshade imagery [Porter et al. 2018]), and slope model imagery were also reviewed. This approach relies on the assumption that specific geographic features, such as elevated landforms (e.g. ridges, knolls, terraces, etc.), water features (e.g. lakes, rivers, creeks, wetlands, and their associated banks/margins), and resource patches (e.g. hunting and foraging locales, quarry sources), can be linked to specific settlement and resource exploitation patterns. Close proximity to these types of landforms is considered to be an indicator of high potential for heritage resources regardless of whether previous heritage resources studies have identified sites of interest in the vicinity.

2. The second approach is built upon a review of previous heritage resource management research conducted within the study area and adjacent lands aimed at understanding the area's cultural/historical setting. The review includes a general overview of the culture historical context of the study area and a detailed review of previous archaeological studies, and historical records. No traditional knowledge/traditional land use (TK/TLU) information was reviewed as part of this study. In this stage of the analysis, closer proximity to previously recorded heritage resource sites is considered to be evidence for human use of the area, and it is therefore interpreted as an indicator of elevated potential for heritage resources.

The data obtained through these reviews is used to assess the potential for development related impacts to both known heritage resource sites and possible undocumented sites that may be located within the study area. In terms of the physical/environmental setting, the analysis will be based upon the criteria described in Section 3.1 of this report. A list of potential site types

expected for the study area, and the physical/environmental attributes they are expected to be correlated with, are presented below in Section 3.2. The cultural/historical assessment will be based on a general review of the documented Precontact (Section 4.2.1), Protohistoric (Section 4.2.2), and Historic (Section 4.2.3) Periods in the broader region, and modern First Nations whose traditional territory overlaps with the proposed project area (Section 4.2.4), as well as specific reviews of previous heritage resource studies, documented archaeological site inventory, and Historic sites on file with the Yukon Government Heritage Resource Unit (Section 4.2.5).

Although the sample size of previously recorded sites within the study area is too small to allow for strong conclusions to be made (n=7; 0.003 sites per km^2), trends seen in site distributions from the broader surrounding area suggest that most sites within the study area will likely be located on knolls, terraces, and ridgelines that offer good access to water and/or a commanding view of the surrounding landscape. A slight skew towards east- and south-facing landforms is evident, but sites have also been recorded on landforms with other aspects. A secondary correlation was observed between sites and documented transportation corridors such as trails and waterways.

With these general criteria for elevated heritage resource potential identified, a GIS based Topographic Position Index Based Landform Classification (TPI) was created using the QGIS software package SAGA-GIS (SAGA 2021). TPI identifies landforms by using a DEM to analyze the mean elevation of a specified area surrounding a given pixel (Weiss 2000). The landform categories identified by the TPI classification were then compared to aerial/satellite photographs, hillshade imagery, and slope model imagery to determine which landform categories correlate with the types of landforms identified in the general criteria for elevated heritage resource potential. While the majority of the modeled area was modeled using a proponent provided DEM, that data did not cover four areas within the study area. To fill these data gaps, DEM data from the ArcticDEM project (Porter et al. 2018) was incorporated into the model. These areas are shown in Figure 2. While this did allow for complete coverage of the study area, the results produced show some differences in the nature of the areas of potential (AOPs) generated by the model. These differences stem from three main factors:

- The ArcticDEM data is full feature whereas the proponent provided DEM is bare earth
- The ArcticDEM data has 2 m resolution whereas the proponent provided data has 1 m resolution
- There is an inherent discrepancy between the elevation reported in the two data sets

Disclaimer: This product is for informational purposes only and may not have been prepared for or be suitable for legal, engineering, or surveying purposes. The base data layers have been obtained from the National Topographic Database (NTDB), and GeoYukon.Service Layer Credits: Sources: Esri, HERE, Garmin, Intermap, increment P Corp., GEBCO, USGS, FAO, NPS, NRCAN, GeoBase, IGN, Kadaster NL, Ordnance Survey, Esri Japan, METI, Esri China (Hong Kong), swisstopo, © OpenStreetMap contributors, and the GIS User Community

Despite these differences between the data sets, the AOPs predicted by each are generally consistent. The results of this analysis were then scrutinized by experienced archaeologists who reviewed the predictions in relation to the hypothesized results. The predictions produced by the TPI analysis agreed with the hypothesized results. No significant modifications were made to the areas of potential identified by the TPI analysis.

Low potential is assigned to all areas not identified by the final GIS/desktop analyses. Areas considered to have low potential for heritage resources are typically characterized by nondescript landforms with no significant topographic relief, limited access to fresh water, poorly-drained sediments (as indicated by vegetation cover), and/or significant levels of previous disturbance. This is not to say that there is no chance for encountering heritage resources in these areas, only that the probability of such a find is low enough that it should be considered a chance find that does not fit with the established settlement and land use pattern within the study area.

The results of the TPI analysis and the resulting archaeological potential model are discussed in Section 5.0.

3.1 Landforms and Geographic Features with High Heritage Resource Potential

In addition to the areas around known sites, a number of landforms and landscape features can be used to help identify areas of heightened heritage resource potential. They include:

1. Elevated landforms such as valley edges, terraces, ridges, mid-slope benches, and knolls. These landforms are considered areas of potential for heritage resources because they often offer better drained soils, relative proximity to water and game, and larger viewsheds. Elevated landforms with south-facing margins are considered especially high potential because of their warmer temperatures and better airflow, which helps reduce insects. These types of landforms are associated with a wide variety of site types including campsites, lookout sites, cache sites, etc.

2. Areas within close proximity to water are also considered to be areas of potential for heritage resources. The potential of these areas is bolstered both by human water needs, but also those of large game animals, fish, and bird species. The easy access to water makes these areas ideal for habitation and hunting sites.

3. Areas near lithic raw material sources are considered to have potential for heritage resources due to their value as quarry sites.

4. Caves, rockshelters, and tors, are listed as possessing increased potential for heritage resources due to possible use as temporary shelters from poor weather, as possible quarries for lithic raw materials, and as special places on the landscape that may be associated with spiritualism, ritual practices, and rock art in traditional cultures.

5. Sedimentary rock beds with the potential to contain palaeontological remains.

6. A final component of assessing the physical environment is determining the level of previous disturbance in the area. If areas have been severely disturbed in the past it reduces the potential of finding intact archaeological remains. Disturbance can include previous activities such as mining, oil and gas exploration, winter road or airport construction, etc. Disturbance is determined through analysis of the maps and historical information, which indicate locations of previous known industrial activities. Professional judgment is used to determine the level of impact resulting from a given disturbance.

3.2 Potential Site Types Expected in Study Area

Eleven broad site types are considered in this heritage resource assessment for their likelihood to be present within the study areas. Definitions of these site types, and the physical/ environmental attributes they are expected to be correlated with, are presented below. These general assumptions are extrapolated from previous archaeological studies and known sites in the larger area. Please note these broad site types overlap and are not mutually exclusive (e.g. a habitation site may also have been used as a hunting or fishing site).

3.2.1 Permanent/Long-Term Habitation Sites

Permanent/long-term habitation sites would indicate prolonged or repeated occupation of a locality. In this area, permanent/long-term habitation sites could be considered those sites which are returned to seasonally year after year, such as a summer campsite. Based on previous archaeological and ethnographic research, these sites are considered most likely to be associated with high, well-drained, south-facing landforms with grassy margins and/or open, pine dominated forests, and good access to water. Essentially, permanent/long-term habitation sites are only expected in optimal locations.

3.2.2 Temporary Habitation/Subsistence Sites

Temporary habitation sites tend to be associated with resource gathering activities such as hunting and foraging, but can sometimes be related to ceremonial activities. Subsistence-related sites are typically represented by lithic tools, evidence of tool production/maintenance, hearths, hunting blinds, and possibly faunal remains. Ceremonial sites related to puberty and shamanistic

rituals are often represented by cairns, isolated hearths, and lithics. The locations of hunting related temporary habitation sites are heavily influenced by landforms that also attract animals (e.g. water features) or that offer a commanding view of areas where animals are likely to congregate (e.g. elevated lookouts). Foraging related temporary habitation sites will be focused on areas that support commonly foraged resources such as berries. The exact criteria for these sites will vary depending on the resource being foraged. Ceremonial sites will not necessarily be connected to any specific type of resource, but are often found in difficult to reach places such as high elevation ridges and plateaus. One final area of potential for temporary habitation sites is along travel corridors such as trails. Typically, if found along a travel corridor, these sites will also be associated with some other noteworthy geographic feature such as a lookout or clearing (anything to make the area stand out relative to its surroundings).

3.2.3 Quarry Sites

These sites are found in areas where natural stone was quarried for the fabrication of stone tools. Desirable qualities in raw material types for stone tool manufacture include conchoidal fracture properties and low occurrences of internal flaws and inclusions. Such materials are typically found in a number of contexts including natural veins in bedrock, volcanic formations, or in secondary deposits (e.g. riverbeds).

3.2.4 Rock Art Sites

Rock art is man-made markings or etchings/peckings on natural stone surfaces. Rock art tends to be located along major watercourses, trails, or at boundaries of traditional territories.

3.2.5 Fishing Sites

Fishing sites typically include fish weirs or natural narrowing of major rivers and streams where fish could be caught more easily. Potential also exists in lakes.

3.2.6 Human Remains

Unexpected human remains are rarely encountered during heritage resource studies, however the potential for their presence always exists, especially in areas where higher densities of people are known to have congregated in the past. Prior to the influence of Christian missionaries, First Nations people would often place graves and spirit houses on prominent points or terraces near village/camp sites, or on low, level ground near trails. Once Christian practices became commonplace, graveyard burials became the norm for most people.

3.2.7 Culturally Modified Trees

Culturally modified trees (CMTs) are trees that have been altered by humans for a variety of purposes including cambium, sap, kindling, and/or bark collection, marking trails (blazes), and communicating messages. Most documented CMTs in the Yukon are pine trees.

3.2.8 Trails

Trails are pedestrian travel routes that may be marked by a well-worn trail bed, blazed trees and/or other CMT types, and/or cairns. Trails are often associated with natural corridors such as rivers and elevated ridges.

3.2.9 Historic Sites

It is likely that Europeans stuck closer to their trading routes (rivers and trails), relying on First Nations to procure items from further away. As such, Historic Period sites are expected to be most frequently encountered along documented travel corridors and settlement sites. However, this does not preclude the possibility of encountering isolated Historic Period materials associated with early European exploration, trapping, and prospecting activities. Moreover, artifacts of European origin could have been traded to First Nations persons then transported to locations generally considered to be more indicative of Precontact sites.

3.2.10 Isolated Finds

Isolated finds are small scale archaeological sites, typically of a single artifact. Due to the scale of these sites, they offer little behavioural insight into the people who created them, but they do document human use of the land in the past.

3.2.11 Palaeontological Sites

Palaeontological sites are defined by the fossilized remains of ancient animals. These may include loose fossils in sedimentary contexts, or fossils consolidated within hardrock formations.

4.0 ANALYSIS OF STUDY AREA

The study area is located west of Eagle Plans, YT. It includes portions of the North Yukon and Peel Watershed Planning Regions, and is located within the traditional territories of the Vuntut Gwitchin and the First Nation of Na-Cho Nyak Dun, as well as the Tetlit Gwich'in Primary and Secondary Use Areas of the Gwich'in Settlement Region. The Dempster Highway transects the project area and provides all-season access to the Blackie winter road, the Chance winter road, and the suspended wells at McParlon A-25 and Ehnjuu Choo B-73. Named watercourses include Chance Creek, Dalglish Creek, Enterprise Creek, Greaves Creek, and McParlon Creek.

Further information regarding the broader physical/environmental and cultural/historical setting of the study area are presented below.

4.1 Physical/Environmental Setting

The study area is located within the Eagle Plains Ecoregion of the Taiga Cordillera Ecozone. The following Section provides a summary of this ecoregion to provide environmental context to the results of this HROA (see Smith et al. 2004 for full ecozone and ecoregion discussion).

4.1.1 Eagle Plains Ecoregion

The Eagle Plains Ecoregion is characterized as is an intermontane basin of modest relief between the Richardson Mountains to the east and the North Ogilvie Mountains to the west (Smith et al. 2004). It includes the Eagle Lowland as defined by Matthews (1986), or part of the Porcupine Plateau and Porcupine Plain as defined by Bostock (1948) and Hughes (1987). The majority of the rolling low-relief terrain falls between 300 m a.s.l. and 600 m a.s.l. (Oswald and Senyk 1977), although some mountainous areas reach as high as 1,000 m a.s.l. and some river valleys as low as 250 m a.s.l. (Smith et al. 2004). The majority of the ecoregion drains to the north through the Whitestone, Porcupine, and Eagle River systems to eventually end up in the Yukon River watershed with the exception of the southeast corner that drains east via the Ogilvie, Peel, and Wind rivers to the Mackenzie River (Smith et al. 2004). Lakes are relatively rare in the Eagle Plains Ecoregion, but some oxbow and thermokarstic lakes are located within the floodplains of the Whitestone, Porcupine, and Eagle Rivers Smith et al. 2004).

Due to its latitude, the Eagle Plains Ecoregion does experience periods of continuous daylight and darkness, however these periods are brief. Mean annual temperatures are near -7.5°C, but the area exhibits strong seasonal temperature variation (Smith et al. 2004). In January, average temperatures typically range from -31°C in lower valleys to -25°C at higher elevations (Smith et al. 2004). Summer temperatures are less affected by elevation, and average 13°C (Smith et al.

2004). Recorded extreme temperatures range from -60°C during winter to 30°C in summer (Smith et al. 2004). Precipitation is relatively moderate, with an annual average of 400 mm annually (Smith et al. 2004). The majority of this precipitation falls as rain during the summer months, primarily in showers, with the period between September and April being the driest part of the year (Smith et al. 2004).

The ecoregion's bedrock geology is characterized by Devonian through Cretaceous sedimentary rocks, including sandstones, siltstones, limestones, and shales, representing an intermontane basin sandwiched between the uplifted Richardson, North Ogilvie, and Dave Lord Mountain ranges (Smith et al. 2004). Lands within this ecoregion are not known for metallic minerals or significant coal deposits, but it does contain proven hydrocarbon reserves. Three of 11 test wells drilled before an exploration moratorium in 1968 intersected porous Carboniferous and Permian sandstone in the Chance and Dagleish anticlines in the southern and southeastern part of the ecoregion are estimated to contain 2.8 x 10^9 m^3 of gas and 3.1 x 10^6 m^3 of oil (T. Bird, in Hamblin 1990).

Surficial geology is characterized by colluvial deposits throughout most of the ecoregion, with the remainder consisting of alluvial sediments along river systems and a few glaciofluvial and glaciolacustrine deposits associated with meltwater generated by glacial activity outside the ecoregion (Smith et al. 2004). Modern processes affecting surficial geology include thermokarst subsidence and soil creep, cryoturbation, solifluction, and active layer detachment slides on shale (Smith et al. 2004). Permafrost is discontinuous, but can be up to 200 m thick in places, with taliks focused on major river valleys (Thomas and Rampton 1982).

The majority of the Eagle Plains Ecoregion is composed of unglaciated terrain with some exceptions to this trend in parts of the Nahoni Range where there is scattered evidence of a past local glaciation of undetermined age (Smith et al. 2004). However, glacial processes in neighbouring ecoregions have influenced the major rivers in Eagle Plains, with up to three levels of glacially controlled terraces present along some drainages (Thomas and Rampton 1982). Major meltwater outlets exited the eastern slopes of the North Ogilvie Mountains and the northern slopes of the South Ogilvie Mountains via Ogilvie, Miner, Whitestone, Blackstone, and Hart Rivers channels (Smith et al. 2004). Moreover, during the Late Wisconsinan glacial maximum (ca. 30 ka; Hughes et al. 1981; Schweger and Matthews 1991) the Laurentide Ice Sheet blocked drainage of the Peel River and its southern tributaries forming Glacial Lake Hughes, which diverted the drainage northward through the Eagle River discharge channel (Duk-Rodkin and Hughes 1995). Glacial Lake Hughes received all the water exiting the Mackenzie and Wernecke mountains and the Ogilvie, Blackstone, and Hart River basins. Consequently, the Eagle and

Porcupine rivers were the two major contributors to the inundation of the Old Crow, Bluefish, and Bell basins (Smith et al. 2004).

In terms of vegetation, black spruce-tussock/shrub tundra with understories including shrub birch, Cottongrass tussocks, bog cranberry, cloudberry, Labrador tea, crowberry, lingonberry, spirea, lichen, and moss is typical on the lower slopes (Zoltai and Pettapiece 1973). Upland areas are dominated by black and white spruce woodlands with understories of Labrador tea, shrub birch, willows, alder, blueberry, rose, lowbush cranberry, spirea, moss, and lichen (Smith et al. 2004). Here white spruce is most common in better drained areas (Russell et al. 1992; Murray 1997). Forest fires are a significant factor in these wooded areas. Pioneer species important in recolonizing burn areas include paper birch, aspen, and balsam poplar (Zoltai and Pettapiece 1973). The highest elevation in the Eagle Plains Ecoregion, above approximately 800 m a.s.l., are typified by shrub tundra dominated by scrub birch, willow, and prostrate shrubs with some Cottongrass tussocks (Smith et al. 2004).

Mammalian biodiversity is relatively low in the Eagle Plains Ecoregion compared to other Taiga Cordillera ecoregions due to a lack of suitable habitats for many of the rodent and ungulate species found elsewhere (Smith et al. 2004). However, representative species present do include several predators including wolf, wolverine, grizzly and black bear, marten, ermine, and red fox (Smith et al. 2004). Barren-ground caribou of the Porcupine herd also utilize this area primarily in the fall and winter, and several species of vole can be found (Smith et al. 2004).

Bird populations are more diverse, with riverine areas providing habitats for Common Merganser, Spotted Sandpiper, Herring and Mew Gulls, Bald Eagle, Belted Kingfisher, and Bank and Cliff Swallow colonies, as well as key nesting habitat for Peregrine Falcon along the Porcupine and Eagle rivers (Hayes and Mossop 1978; Frisch 1987; Peepre and Associates 1993). Wetland areas are inhabited by small numbers of Pacific and Red-throated Loons, Tundra Swan, Greater White-fronted Goose, Canada Goose, American Widgeon, Green-winged Teal, Bufflehead, Lesser Yellowlegs, Solitary Sandpiper, and Common Snipe (McKelvey 1977; Frisch 1987). Swift mountain streams support breeding populations of Harlequin Duck and American Dipper, while riparian thickets provide breeding habitat for Willow Ptarmigan, Alder Flycatcher, Yellow Warbler, Wilson's Warbler, American Tree Sparrow, and Lincoln's Sparrow (Frisch 1987). Upland forests provide year-round homes for Northern Goshawk, Spruce Grouse, Northern Hawk Owl, Three-toed Woodpecker, Gray Jay, Common Raven, Boreal Chickadee, Pine Grosbeak, Whitewinged Crossbill, and Common Redpoll (Frisch 1987). Other species, such as Gyrfalcon and Willow Ptarmigan, migrate to these forests to winter, while other, including Swainson's, Gray-cheeked, and Varied Thrushes, Bohemian Waxwing, Yellow-rumped and Blackpoll Warblers, and Dark-eyed

Junco migrate north each spring to breed in these forests (Frisch 1987). High elevation alpine tundra areas support low numbers of Golden Eagle and Rock Ptarmigan, and may be used in summer by small numbers of Horned Lark, American Pipit, and Gray-crowned Rosy Finch (Frisch 1987). Upland Sandpiper and Townsend's Solitaire breed in the subalpine zone (Frisch 1987).

4.2 Cultural/Historical Setting

The following is an overview of the culture history for the broader region surrounding the study area including south-central and southwestern Yukon, and northern British Columbia. Many researchers have reviewed the cultural history of this broader area and have presented the information using a variety of terms and temporal ranges (Clark 1981; West 1996; Workman 1978; J. V. Wright 1995, 1999).

4.2.1 Precontact Period (ca. 15,000 BP to ca. AD 1700s)

Portions of the Yukon, NWT, and Alaska were unglaciated during the Last Glacial Maximum (18,000 Before Present or BP). The area is commonly referred to as Eastern Beringia. Several of the earliest well-documented Precontact archaeological sites in Eastern Beringia are found in the northwestern Yukon and have been dated to the Late Pleistocene from approximately 15,000 BP to 13,000 BP (de Guzman et al. 2014; Easton 2015; Easton et al. 2007, 2011; Easton and MacKay 2008), as well as one outlier site dated to 24,000 BP (Bourgeon et al. 2017)[3]. Artifacts recovered from these sites include technological suites shared by other Eastern Beringian sites such as the Nenana/Chindadn (non-microblade) and Denali (microblade) Complexes, and date between 15,000 and 8,000 BP (Dixon 2011; Heffner 2002: Holmes 2001, 2011; Potter 2011). The material culture recovered from these sites, primarily defined through lithic technology that includes both non-microblade and microblade technology, is known as the Eastern Beringian Tradition (Holmes 2001). The Northern Cordilleran Tradition (11,000 BP to 7,000 BP) is defined from sites in the interior Yukon that notably lack microblade technology. The Northern Cordilleran Tradition is characterized by large straight and round-based lanceolate point forms, large blades and flakes, and transverse notched burins (Clark 1983; Hare 1995).

The Northern Cordilleran Tradition was followed by the Little Arm Phase, which dates from 7,000

[3] Of note regarding early archaeological sites in the Eastern Beringia area is the very early site at Bluefish Caves, which has been recently dated to approximately 24,000 BP (Bourgeon et al. 2017). However, due to the nature of the archaeological assemblage recovered and paucity of known archaeological sites bridging the temporal gap between Bluefish Caves and other early sites, such as the Little John site (Easton 2015; Easton et al. 2007, 2011; Easton and MacKay 2008) and the Britannia Yukon Hill site (de Guzman et al. 2014) which date to approximately 15,000 BP, questions remain for many archaeologist regarding the relationship of the occupation documented at Bluefish Caves to the more recent archaeological record and modern First Nations peoples.

BP to 4,500 BP (Clark and Gotthardt 1999; Workman 1978) and can be defined by the use of microlithic technologies. After about 4,500 BP, there is less evidence of microblade use in the Yukon, and an increase in the use of notched projectile points and a variety of scraping and carving tools. This new tool industry is known as the Taye Lake Phase in southwest Yukon, or more broadly in Yukon and Alaska as the Northern Archaic Tradition (Hare 1995; Workman 1978).

The most recent precontact archaeological component found in the Yukon is that of the late Northern Archaic Tradition, or the Late Precontact period. This period is most clearly represented by the Aishihik Phase found in the Southern Yukon (Hare 1995; Workman 1978). This phase is thought to be a cultural development from the earlier Taye Lake culture, although there are some significant differences in technology. The most notable is the introduction of the bow and arrow, replacing a type of throwing spear known as an atlatl (Hare et al. 2004). The Aishihik Phase sites are found above the White River Volcanic Ash layer (also known as White River Tephra) that is dated to approximately 1,250 BP (Clague et al. 1995).

The Aishihik Phase has been evaluated as ranging from approximately 1,200 BP to 200 BP, and also includes the use of native copper tools, stemmed projectile points, and gorges. Also indicative of the Aishihik Phase are small stemmed Kavik points, end and side scrapers, and ground adzes (Hare 1995). The poor preservation of organic materials makes the task of diet reconstruction more difficult than at the coastal sites, but there is evidence of continued use of a variety of large and small mammals, fish, and birds. In the high elevations of the southern Yukon ice patches, examples of the transition from the older atlatl technology to the bow and arrow use has been clearly documented by recent finds (Hare at al. 2004). The shift to the new technology was a rather abrupt one at roughly 1,200 BP based on a good sample of preserved and dated atlatl dart shafts and bow and arrow remains.

4.2.2 Protohistoric Period (ca. AD 1700s to ca AD 1840s)

The Protohistoric Period, as presented here, also overlaps with late Precontact/Athabaskan Period. It is defined by the appearance of non-indigenous goods, other early trade items, and foreign (western or eastern) influences, but not the documented accounts of contact between indigenous North American peoples and European/Russian/Asian peoples themselves. Other indicators of the Protohistoric Period are the arrival of the first non-indigenous diseases and information concerning non-natives. This period spans the time between the first introduction of non-indigenous influences or artifacts, and the recording of firsthand or primary written accounts. Unlike other cultural periods with more specific temporal ranges it is difficult and

perhaps impossible to determine when the first 'outside' influences of European, Russian, Asian, or other cultures began to impact First Nations people in the Yukon interior.

Some of these far-reaching effects may have been passed along from Russian exploration in the early and mid-1700s (Veniaminov 1984) and other Asian and European (Andreev 1944, Quimby 1985) exploration and contact with coastal communities. The Chilkat Tlingit from the Northwest Coast travelled and traded with many interior First Nation peoples throughout this Protohistoric Period including the Kaska and the Northern Tutchone from the Dawson and Mayo areas, and occasionally the Mountain Dene people from as far away as Fort Norman on the Mackenzie River. The Tlingit protected and controlled the trading routes into the interior and fiercely defended those routes when they were threatened. News of early non-indigenous explorers and traders would have travelled inland along with foreign items such as metals, cloths, glass beads, and later tobacco and other goods.

In some of the earliest cases, the impacts of these foreign cultures could have had significant impacts even without the presence of the foreigners themselves. Such is the case for what is called 'drift-iron' whereby metals and other materials from Asian or European shipwreck wash ashore. Historical accounts of shipwrecks have been reported in the mid-1700s, but much earlier wrecks were possible. Metals and other foreign trade items have been derived from shipwrecks off what is now British Columbia, Southeast Alaska, and perhaps the Northwest Alaska as well.

4.2.3 Historic Period (post ca. AD 1840s)

During the early years of this period the Russians were expanding their exploration and trade network along the Pacific coast and up the major rivers of the Alaskan interior, while the British were exploring eastward into what would become Canada's Northwest and Yukon Territories, as well as Alaska. The North American based explorers and traders entered the Yukon through two main routes: from the north via Fort McPherson and from the south via Fort Liard. In the 1840s, representatives of the Hudson Bay Company established trading posts near portions of the study area, including those at Lapierre House (1846) and Fort Yukon (1847). The next year Robert Campbell established Fort Selkirk southeast of the project area on the upper Yukon River and then relocated to an improved location in 1851. This upset the Chilkat indigenous trading population from the coastal area, who had controlled trade to the interior for many generations, and by 1852 increasing supply-line pressures, trade competition from the Chilkat traders, and flooding forced the Anglo traders to flee.

In 1867, US Secretary of State William Seward was able to focus increasing American interests, and he convinced the United States Senate to purchase Alaska from Russia. Soon after the

purchase, the US Army sent Captain Raymond up the Yukon River on the first stern-wheel steamer to reach Fort Yukon (Grauman 1977). Raymond surveyed the location of Fort Yukon and proved that it was within U.S. territory. The British sold the Fort to the U.S. Government and relocated east across the 141st Meridian.

The inland fur industry continued to drive exploration and settlement into the late 1800s, but mining would shift the focus to the placer gold found in streams and alluvial deposits. Mining in the second half of the nineteenth century was a risky, but often very lucrative enterprise. The impacts of mining spread quickly and drastically changed the project area.

Mineral prospecting and mining efforts in the second half of the nineteenth century were, in some ways, dependent on the existing infrastructure of the fur trading and missionary efforts. As the competition for the inland fur trade grew, so would the number of stern-wheelers on the Yukon River. These steamers could better supply the small number of trading posts along the Yukon and its tributaries and reduce the risk of prospectors running short of supplies. Therefore, more of the fur traders and other explorers turned their attention to search for gold and other minerals. Three key prospectors to the north were L. S. (Jack) McQuesten, Al Mayo, and Arthur Harper. They wrote to miners in the United States to encourage them to come north. They also established outposts along the Yukon River, including Fort Reliance, established in 1874 near the confluence of the Klondike River (what would become Dawson City; A. A. Wright 1976).

Harper and another man may have been the first to travel up the Fortymile River in search of gold in 1881 (Buzzell 2003). They collected a very rich sample, but were unable to relocate the exact location. In 1886, McQuesten, Harper, and Mayo built a post on the confluence of the Stewart and Yukon Rivers which provided supplies for additional prospectors. Also in 1886, Howard Franklin made a richer find on the Fortymile River. Others rushed in and these claims along the Fortymile River attracted miners from across Central, Eastern Alaska, and Southeast Alaska. Fortymile was the first town to grow to over a thousand people by the mid-1890s (Buzzell 2003), and in 1887 the Stewart River post was deserted. Some prospectors that did not find easy success in Fortymile returned to the Stewart and continued work in the area. In 1890, Harper re-established a trading post at the site of the old HBC post at Selkirk as interest in the area grew. This was followed by Jack Dalton who developed a series of existing First Nation trails from tide water at Haines, Alaska, into Fort Selkirk. Then, on August 16, 1896, George Carmack, Skookum Jim, and Tagish Charlie discovered a very rich claim on Bonanza Creek, a tributary to the Klondike River near Dawson. This discovery sparked one of the largest gold rushes in history.

It would take almost a year for the news of the Klondike gold fields to spread south, even to

places relatively close by in southeast Alaska. Most of the prospectors and traders in the Alaskan and Yukon interior had already converged on the Dawson area during the winter and spring, and supplies ran dangerously low. That would quickly change in the summer of 1897 and spring of 1898 as new towns and supply posts sprang up along the Gold Rush routes to cash in on the increased demand.

The population of Dawson City grew very fast and in 1898 reached a peak of over 30,000. However, the boom period did not last long, and the vast majority of population moved on very quickly with the news of other discoveries and hopes of other bonanzas. The Gold Rush period saw greatly increased steamer traffic on the entire Yukon River drainage basin and across the interior. Just prior to the Gold Rush there were only a few steamers, while at its peak there would be hundreds of vessels working the rivers. These shallow draft steamers were supported by a network of wood camps, shipyards, and a large workforce which kept the river traffic moving. This network provided the infrastructure backbone for trading posts, fish camps, missionaries, and mail routes, while meeting the needs of the growing number of prospectors and traders.

Since Dawson City is located on a flood plain at the confluence of the Klondike and Yukon Rivers it has had a long history of fighting with rising water levels. Flooding here is the result of either open water flooding at peak river flows, or the more dangerous spring ice jam events. Dawson City has been the victim of over twenty floods since 1898 (McCreath et al. 1988, Whitehorse Star 1979). The most significant of these were in 1925, 1944, 1966, 1969 and 1979. After flooding in the 1940s and 1950s Front Street was raised in an attempt to keep the waters out, but this did little to stop the flooding. A protective dyke was built around Dawson City in 1959 and was later increased in 1968. The last major flood of Dawson City occurred in 1979 when ice jams on the Indian, Klondike, and the Yukon Rivers caused the spring waters to back up across Dawson City. This prompted the construction of the improved dyke (to the 200 year flood level) in 1987 (McCreath et al. 1988). Dawson City served as the capital of the Yukon government from 1898 until 1952, when the seat was moved to Whitehorse.

The Yukon has also been hosting to oil and gas exploration efforts since the 1950s. The first well was drilled in the Eagle Plains Basin in 1957, but was declared dry in 1958 (Yukon Government Oil and Gas Resources Branch, n.d.). Exploration activity picked up again in the 1960s and 1970s, which played an important role in motivating the construction of the Dempster Highway (see Section 3.4). Interest in exploration has continued intermittently ever since, with 76 wells having been drilled to date in five of eight Yukon sedimentary basins (Eagle Plain, Beaufort Mackenzie, Peel Plateau and Plain, Kandik, and Liard Basins) between 1957 and 2013 (Yukon Government Oil and Gas Resources Branch, n.d.). Over 10,000 line-km of 2D and 3D seismic surveys have been

conducted as part of these exploration efforts (Yukon Government Oil and Gas Resources Branch, n.d.). Six oil and gas pipelines have also been constructed in the Yukon, including four built during World War II as part of the Canol project, one built in the 1950s to supply American Air Force bases in Alaska during the Korean War, and the 2012 Spectra Energy pipeline built in 1972 to move natural gas from the Kotaneelee gas field in southeast Yukon to southern markets (Yukon Government Oil and Gas Resources Branch, n.d.).

4.2.4 Modern First Nations

The study area lies within the traditional territory of the First Nation of Na-Cho Nyak Dun, Tetlit Gwich'in First Nation, Vuntut Gwitchin First Nation. Further information about each First Nation is presented in the following sections.

4.2.4.1 First Nation of Na-Cho Nyak Dun

The study area is located within the traditional territory of the First Nation of Na-Cho Nyak Dun (NND). NND is part of the Northern Tutchone language and culture group. In the past, the Tutchone peoples were highly mobile, travelling in small groups in order to exploit the greatest number of resources. They would modify their movements depending on the patterns of large game animals and fish, or in later years to trade their furs with Westerners. In the summer, small domestic units gathered together to catch fish so that they could dry and store it for the winter months. By mid-summer, several family groups moved upland together to kill large game mammals that they would dry and store in caches scattered in various areas. From there some units moved away independently during the coldest months to trap and live off of the cached foods. The leanest months were March and April. In spring, several units often came together at this point to catch spawning whitefish or trap muskrat and beaver. May was the most plentiful month, with migrating waterfowl, fat ground squirrels, larger and more abundant fish, as well as the arrival of the Coastal Tlingit traders (McClellan 1981).

The principal ethnographic descriptions of the Tutchone are available in Cruikshank (1974, 1975), Johnson and Raup (1964), McClellan (1950, 1964, 1970a, 1970b, 1975), and Tanner (1966). Additional information on camp and village locations can be found in Schwatka (1885). Although villages were not inhabited year-round, people would return to good fishing and/or hunting spots year after year. This would eventually change with the influence of Westerners. Watercraft were constructed for use, however during the summer months Tutchone people preferred to walk overland, rather than brave the sudden winds on the large lakes or the treacherous river rapids. Boats were not the preferred method of transport.

The NND First Nation remained somewhat isolated until the discovery of gold in the area in 1883 (Mayo Historical Society 1999). The NND are known to have used many traditional camps, lookout sites, hunting areas, berry patches, and trails in the larger project area with extensive use of rivers. McClellan (1981) summarized the common seasonal activities beginning in the spring with grayling fishing following spring break up. The NND people remained almost completely isolated from non-First Nation people, except for a few explorers passing through, until miners set up a supply post along the McQuesten River in 1886. The supply post soon turned into a village and from then on permanent camps and villages have existed in the larger area surrounding Mayo Lake. During the Duncan Creek gold rush, a trading post called Gordon Landing was established near the confluence of Janet Creek and the Stewart River. From there a trail allowed people to travel north partially along Davidson Creek to the confluence of Duncan Creek on the Mayo River. The Town of Mayo was established in 1903 and the people of McQuesten and a few other small encampments moved there or to the "Old Village" just outside of town (Mayo Historical Society 1999). This village made it possible for people to receive a western education, live close to Mayo, and continue their preferred way of life and cultural celebrations. Eventually the "Old Village" was abandoned when in 1958 the local health officials determined the drinking water was polluted and the NND were requested to move to the Town of Mayo. The First Nations people in the Mayo area officially chose the name "Na-Cho Nyak Dun" in 1987, which means "Big River People" in reference to the now named Stewart River.

4.2.4.2 Gwich'in Nation

The Gwich'in Nation is an Athapaskan speaking group that includes First Nations/Native American peoples in the Yukon, Northwest Territory, and Alaska (VGFN 2009). Members of the greater Gwich'in Nation include the Vuntut Gwitchin and Tetlit Gwich'in in the Yukon, the Teetl'it Zheh Gwich'in, Gwichya Gwich'in, Ehdiitat Gwich'in, and Nihtat Gwich'in in the NWT, and the Dendu Gwich'in, Draan'jik Gwich'in, Danzhit Hanlaih Gwich'in, Gwich'yaa Gwich'in, and Neets'ąjį Gwich'in in Alaska (McFadyen Clark 2019). Of particular significance to this project are the Teetl'it Zheh Gwich'in (TGC) and Vuntut Gwitchin (VGFN), whose traditional territories/modern community centers are crossed by the proposed project. Oral traditions and ethnographies of Gwich'in people have been documented by Krech (1976), Osgood (1933, 1934, 1936), Petitot (1876, 1889), Savishinsky and Hara (1981), VGFN and Smith (2009), Heine et al. (2007), and McCartney and GTC (2020), among others.

Collectively, the traditional lifeways of the Gwich'in people depended on hunting and fishing. Moose and caribou were of vital economic importance providing both food and hides for clothing and shelter, but salmon, white fish, hare, and plant foods such as berries and rhubarb were also

significant sources of subsistence (McFadyen Clark 2019). Their traditional toolkit was similar to other subarctic Athapaskan groups, and included the bow and arrow, traps, snares, deadfalls, and nets for fishing. People also utilized caribou drift fences and pounds to improve hunting yields. Snowshoes, sleds, and canoes were all employed for greater mobility. Hide covered tents provided the primary source of shelter.

Many Gwich'in communities continue to rely on subsistence harvesting from the land. The Vuntut Gwitchin (which translates to "people of the lakes") are based in Old Crow; the only community in the Yukon without road access (VGFN 2009). The Teetl'it Zheh Gwich'in (which translates to "people of the head waters") are based in Fort McPherson, NWT, which was established in 1852 when Old Fort, a Gwich'in village, was moved from six kilometers upriver to the present town site (Gwich'in Council International 2009). Fort McPherson represents the largest Gwich'in settlement in the NWT with over 80% of its population being of Gwich'in descent (Gwich'in Council International 2009). Gwichya Gwich'in (which translates to "people of the flats") are centered in Tsiigehtchic, NWT, and the Nihtat Gwich'in, meaning "mixed nations", is a group comprised of Gwich'in from various Gwich'in communities that reside in Inuvik (Gwich'in Council International 2009).

4.2.5 Previous Heritage Investigations

The study area has not been extensively explored from a heritage resource perspective, but Consultation with the Yukon Government Heritage Resource Unit did identify a few studies that have assessed portions of the current footprint. These studies include three permitted HRIAs related to previous oil and gas exploration (01-07ASR [Hammer 2001], 07-04ASR [Heffner and Ross 2008], and Commisso and Heffner [2008]), and one HRIA related to a fibre optic cable project along the Dempster Highway ROW (16-16ASR [Bennett 2016a]). Two non-permitted studies, including a historic resource overview assessment (HROA; Bennett 2016b), a traditional knowledge/traditional land use study (Bennett 2017), and an update to the original HROA (Bennett 2019), have also been completed in association with the fibre optic project along the Dempster Highway.

In total, these studies have identified seven archaeological sites and one Yukon Historic Sites Inventory (YHSI) site within the current study area. Further detail about these sites is presented in Sections 5.2 and 5.3 of this report.

5.0 RESULTS

This section presents the results of the HROA analysis. These results are divided into four categories: areas of elevated potential for previously undocumented heritage resource sites (Section 5.1), previously recorded archaeological sites (Section 5.2), previously recorded Yukon Historic Sites Inventory (YHSI) sites (Section 5.3), areas with potential for culturally modified trees (CMTs; Section 5.4).

It should be noted that although all efforts were made during the production of this report to make its assessment of heritage resource potential as comprehensive and accurate as possible, the methods employed provide relatively coarse resolution. As such, small undocumented areas of heritage resource potential may be present within the study area that were not captured by this overview. Moreover, there is always a possibility that chance finds of heritage resources will be made in areas of low perceived potential. If such areas or finds are encountered at any point during development, all work in the find area should cease and staff at the Yukon Government Heritage Resources Unit should be contacted immediately.

5.1 Areas of Elevated Potential for Previously Undocumented Heritage Resource Sites

Areas of elevated heritage potential for surface/subsurface heritage resource sites were identified through the development of a TPI-based heritage resource potential model. The TPI classification identified 10 landform categories, three of which were found to correlate with landforms that are commonly associated with heritage resource sites. Upon review of the results, one of the landform categories did well at identifying areas of high potential along watercourses, but it also identified many areas on the slopes leading down to the drainages that do not fit with the general criteria for elevated heritage resource potential. To eliminate these low potential areas from the heritage potential model, this layer was clipped to only include identified areas within 100 m of a watercourse.

In total, the heritage resource potential model predicted high potential for 13.71% of the modeled area. Of the seven sites known within the study area, the model successfully predicted the locations of all of them. It should also be noted that the locations of some of the sites are not accurate. However, after consultation with Christian Thomas at the Yukon Government Heritage Resource Unit, the likely true locations of the sites have been determined, and it is these revised locations that are used in this analysis. Based on these results, the model efficiency was evaluated using Kvamme's gain statistic (Kvamme 1988), which returned a value of 0.8629. This value shows the model to function with moderate efficiency based on the criteria published in the British Columbia Archaeological Overview Assessment Standards and Guidelines (BC 2009).

With further refinement of the model parameters, the model could likely be brought into the high efficiency range (Kvamme's gain statistic of ≥0.9; BC 2009). However, given the very low known site density within the study area (n=7; 0.003 sites per km^2), it is maintained that the model should be designed to err on the side of caution and capture a larger percentage of the landscape at this point in time. Once more data is available from future field studies becomes available, the model parameters can be adjusted to bring the model up to the high efficiency level.

Maps showing all identified areas of elevated heritage resource potential are presented in Appendix A – Figure 3 and Appendix B – Figure 4. An assessment of the potential for encountering each of the eleven site types outlined in Section 3.2 of this report is presented in Table 1.

5.2 Previously Recorded Archaeological Sites

Seven archaeological sites have been documented within the study area, with 26 more documented within 50 km of the study area (Table 2). Precontact sites dominate the list of known sites (n=25), with lithic scatters being the most common site type (n=21). However, Indigenous Historic, Historic, and palaeontological sites are also represented. This low number of archaeological sites (0.003 sites per km^2) is likely a reflection of the limited amount of archaeological survey that has been done within the study area. The locations of these sites are illustrated in Appendix A.

5.3 Previously Recorded Yukon Historic Sites Inventory Sites

One YHSI site, 116I/03/001 – Tth'an Dhidlii Njik Dalgish Creek Resource Area, has been recorded within the study area. Thirteen additional YHSI sites have been recorded within 50 km of the study area. These sites are summarized in Table 3. Due to the low level of heritage resource survey work within the study area, it is considered likely that additional historic sites remain to be recorded within the exploration area boundary.

5.4 Areas of Culturally Modified Tree Potential

Potential for CMTs was not specifically assessed in this HROA due to a lack of available vegetation inventory data. CMT potential is primarily identified through the presence or absence of old growth pine-leading stands, with the presence of such stands being interpreted as a potential elevating factor. Should old growth pine-leading stands of forest be encountered during any future field assessments, crews should be vigilant for CMTs. If pine-leading stands are not encountered, minor potential for certain types of CMT, such as blazes, trap trees, and Historic claim markers, may still exist in stands of spruce and/or aspen.

Site Type	Potential	Comments
Permanent/ Long-Term Habitation	Low	Permanent/long-term habitation tend to be located near significant landscape features that provide optimal places for campsites such as major rivers and lakes. Such landforms are not present within the study area.
Temporary Habitation/ Subsistence	High	The most likely temporary habitation sites to be encountered are those related to subsistence activities. They are most likely to be located on well-drained terraces above watercourses and prominent knolls/ridgelines.
Quarry Sites	Low	Review of geological bedrock mapping shows that sedimentary rocks characterize the areas lithology. The descriptions of the bedrock formations mention few rock types that are commonly exploited used in stone tool production, although there is some potential for mudstone and siltstone. However, minor potential for knappable rocks, such as chert, may exist in the creekbeds.
Rock Art Sites	Low	The potential for rock art is considered to be low.
Fishing Sites	Low	Although many creeks flow across the study area, no major rivers or lakes are present.
Human Remains	Low	Organic preservation conditions in the study area is not considered to be favorable for the preservation of undocumented human remains.
Culturally Modified Trees	Unknown	Potential for CMTs was not specifically assessed in this HROA due to a lack of available vegetation inventory data.
Trails	Moderate	No historic trails have been documented within the study area. However, the Dempster highway follows a natural travel corridor, and the sheer size of the study area bolsters the chance of encountering previously undocumented trails.
Historic	Moderate	No YHSI sites have been recorded within the study area. However, it should be noted that this absence of recorded sites may be a consequence of the lack of historic site survey within the study area rather than a true indication of the absence of historic sites given the fact that 14 YHSI sites have been recorded within 50 km of the study area.
Isolated Finds	High	The potential for isolated finds exists throughout the study area. If other site types are present, the probability of identifying additional associated isolated finds in their vicinity will be elevated.
Palaeonto-logical Sites	Moderate-High	The study area is located within an area of predominately sedimentary bedrock. As such, there is potential for pre-Pleistocene palaeontological remains. Potential also exists for Pleistocene/early Holocene fossils within placer deposits in the lower valleys.

Table 1: Assessment of the probability of encountering predicted site types.

Borden #	Site Class	Site Type	Permits	Notes
Sites Located Within the Study Area				
LlVc-1	Precontact	Isolated find	00-21ASR	Located on a west-facing knoll 15 m above the valley bottom on Dalglish Creek. Six shovel tests were excavated with one chert flake recovered.
LlVd-1	Precontact	Subsurface lithic scatter	00-21ASR	Located on a southeast facing bedrock knoll with exposures to the southeast and northeast overlooking Enterprise Creek. Four tests were excavated and several chert flakes resulting from the production of stone tools were recovered from two of the tests. The site is considered to be a small lithic scatter likely representing temporary camp of game lookout.
MaVc-3	Precontact	Subsurface lithic scatter	01-07ASR 13-16ASR	Located on a north-south running terrace with an east view overlooking a pond and a sedge tussock meadow. Nine test pits excavated, with one being positive. Collection consists of two chert flakes.
MaVc-4	Precontact	Surface lithic scatter	08-06ASR 13-16ASR	Located on the west branch of a small tributary of the Upper Eagle River on the southeast edge of a terrace. Two flakes were found in surface exposures on the front edge of terrace.
MaVc-5	Precontact	Subsurface lithic scatter	13-16ASR	Located on outer SE nose of a large, squared terrace bench point along small tributary of upper Eagle River. Finds include a small assemblage of chert and siltstone lithics.
MaVc-6	Precontact	Subsurface lithic scatter	13-16ASR	Located on the outer edge of a large terrace bench formation along a small tributary of upper Eagle River. Finds include a small assemblage of chert and rhyolite/tuff lithics recovered from a tree throw.
MaVe-1	Precontact	Subsurface lithic scatter	13-16ASR	Located on a small terrace knoll overlooking a large expanse of tussock meadows framed between two small tributaries feeding in from the north. Finds include a small assemblage of chert lithics.
Sites Located Within 50 km of the Study Area				
MaVc-2	Precontact	Subsurface lithic scatter	01-07ASR	Located on a bedrock knob overlooking an old creek bed, south of the Dempster Highway, southeast of Eagle Plains. Eight test pits excavated, with two being positive. Collections include chert core fragment and chert flakes.

Table 2: Known archaeological sites within/near the study area.

Borden #	Site Class	Site Type	Permits	Notes
Sites Located Within 50 km of the Study Area				
MbTx-1	Precontact	Lithic scatter	94-15ASR	Located on a medium elevation bedrock rubble ridge, in the upper Canyon Creek Valley. A small collection of flakes and one scraper was made over an area of about 50 m in diameter near the highest point in the valley.
MbTx-2	Precontact	Isolated find	94-15ASR	Located on the right bank of a small tributary that drains west into the upper part of Canyon Creek. A single flake was found and collected.
MbTx-3	Precontact	Lithic scatter	94-15ASR	Located on a series of terrace beaches on the north side of an east-west running tributary of the upper Canyon Creek. A single flake was found on the upper bench. A large scraper made of welded tuff (?) was found on the lower bench.
MbVa-1	Precontact	Isolated find	94-15ASR	Located on a ridge complex in the foothills of the Richardson Mountains, near the headwaters of a tributary of the Eagle River. A single, broken biface was collected.
MbVa-2	Precontact	Lithic scatter	94-15ASR	Located on a knoll complex, three clusters of artifacts were found within an area of about 30 m. in diameter. Artifacts include substantial quantities of debitage and 2 bifaces, one of which is made on a large (15 cm long) macroblade. Site also known as the Ziehe Site.
MbVa-3	Precontact	Lithic scatter	94-15ASR	Located on a medium elevation complex of bedrock rubble ridges. Site consists of two clusters of large argillite (?) flakes/core fragments.
MbVa-4	Indigenous historic	Pole structure	94-15ASR	Located on a heavily wooded terrace, on the right bank of a mountain stream at the foot of a bedrock rubble ridge in the foothills of the Richardson Mountains. Consists of two collapsed pole/log structures. The poles are steel axe cut. Noted one wire nail and a piece of string.
MbVa-5	Precontact	Surface lithic scatter	94-15ASR	Two flakes were collected from the surface.
McVa-1	Precontact	Isolated find	00-14ASR	Located on the south end of a ridge complex, on the east side of Canyon Creek, near the headwaters of the creek. Collection consists of one chert flake.
McVh-1	Historic	Historic scatter	69-00ASR	Located on the west bank of Whitestone River at on a long prominent bend. Metal, shell, glass bottles, and beads collected.

Table 3: Known archaeological sites within/near the study area (continued).

Borden #	Site Class	Site Type	Permits	Notes
Sites Located Within 50 km of the Study Area				
McVh-2	Precontact	Lithic scatter	69-00ASR	Located on northwest bank of Miner River, just downstream from island below confluence of Miner River and Fishing Branch. Lithic debitage collected.
McVh-3	Historic	Precontact/ historic scatter	69-00ASR	Located on north bank of fishing branch, where channel narrows to a line on the Porcupine River. Some flakes, bone, wood, glass objects collected.
McVh-4	Palaeontological	Isolated find	67-01ASR	Located on left bank of Whitestone River on the outside of a bend below the mouth of Chance Creek. A mammoth or mastodon tusk was collected from the surface of a river bar deposit in 1976.
MdVa-1	Precontact	Lithic scatter	74-01ASR	Located along the Dempster Highway ROW where the road crosses the headwaters of a major tributary of the Eagle River. Lithic artifacts and debitage collected.
MdVa-2	Precontact	Lithic scatter	78-11ASR	Located on low bench on the south side of a tributary of the Eagle River. Isolated tool and flake finds.
MdVh-1	Undetermined	Faunal materials	69-00ASR	Located on right bank of Whitestone River, just above its confluence with the Porcupine River. Faunal samples (bone) collected.
MeVb-1	Precontact	Lithic scatter	74-01ASR	Lithic artifacts and debitage collected.
MeVb-2	Precontact	Lithic scatter	74-01ASR 96-07ASR	Located on the Dempster Highway right of way where the road crosses the headwaters of Rock River. Flakes collected.
MeVb-3	Precontact	Lithic scatter	74-01ASR	Located just east of the Dempster Highway right of way where the road crosses the headwaters of the Rock River. Lithic artifacts and debitage collected.
MeVb-4	Precontact	Lithic scatter	74-01ASR	Located just west of Dempster Highway near the headwaters of Rock River. Lithics collected.
MeVb-5	Precontact	Lithic scatter	81-02ASR 96-07ASR	Located on an old terrace of the middle Rock River. Twenty artifacts were collected.
MeVd-1	Precontact	Isolated find	n/a	One possible flake collected.
MeVf-1	Undetermined	Isolated find	69-00ASR	Located on west bank of Porcupine River, on second major bend above Johnson Creek. Two specimens of modified bone collected.

Table 3: Known archaeological sites within/near the study area (continued).

Table 3: YHSI sites within 50 km of the study area.

6.0 SUMMARY AND RECOMMENDATIONS

The goal of this study was to identify areas of archaeological potential within the Eagle Plains Basin Exploration Project permitted area. This was accomplished through a detailed review of the physical/environmental setting, cultural/historical setting, previous heritage studies/ identified sites within the study area, topographic maps, geological maps, aerial/satellite photographs, LiDAR-based hillshade imagery, and the creation of a GIS-based archaeological potential model.

This review identified multiple areas of elevated heritage potential for surface/subsurface heritage resource sites. Most areas of elevated potential for undocumented surface/subsurface heritage resource sites are associated with knolls and terraces in the valley bottoms and higher elevation terraces and ridgelines. Moreover, seven archaeological sites have been previously recorded within the study area, with 26 more within a 50 km site search buffer around the exploration area. One Yukon Historic Sites Inventory site has been recorded within the study area, with 13 more having been recorded within 50 km of the study area. Lastly, culturally modified tree (CMT) potential was not specifically assessed in this HROA due to a lack of available vegetation inventory data.

Heritage resource management recommendations for the Eagle Plains Basin Exploration Project directly follow the assessment of heritage resource potential discussed in Section 5.0. These recommendations include:

1. Heritage Resource Impact Assessments (HRIAs) are recommended for all lands with elevated heritage resource potential, as illustrated in Appendix A, before any ground disturbing activities are allowed to proceed within them. Should additional areas of potential be identified within a proposed development area during HRIA work, they should be assessed following the same standards recommended for the areas of potential identified in this report. HRIA work should be conducted under a Class 2 archaeological research permit issued by the Heritage Resources Unit of Yukon Tourism and Culture. HRIAs should, at minimum, include provisions for surficial survey and subsurface testing within the boundaries of the HRIA area identified in this document and any associated areas of potential that are identified in the field which are at risk of being impacted by proposed ground disturbing activities. Additional recommendations may be made following an HRIA depending on the results obtained.

2. Avoidance of areas within 30 m of any known heritage resource sites is recommended. If avoidance is not feasible, then further assessment work (e.g. systematic data recovery

excavations) should be conducted before the commencement of any ground disturbing activities within known site boundaries. This further assessment work should be conducted under a Class 2 archaeological research permit issued by the Heritage Resources Unit of Yukon Tourism and Culture.

3. No specific recommendations are made in regard to CMTs due to a lack of available vegetation inventory data. However, field crews should be vigilant for CMTs in all forested areas.

4. No Further Work (NFW) is recommended in areas identified as having low heritage resource potential prior to allowing ground disturbing activities. However, development should only be allowed to proceed on the condition that all chance finds of heritage resource materials be reported immediately to the Heritage Resources Unit of Yukon Tourism and Culture, and that all work at the location of a chance find cease until the Heritage Resources Unit is able to assess the finds and issue a response (clearance to proceed or requirements for avoidance/further mitigative work). If human remains are encountered, the guidelines provided in Appendix C should be followed.

5. It is recommended that this HROA report be submitted to the First Nation of Na-Cho Nyak Dun, Tetlit Gwich'in First Nation, Vuntut Gwitchin First Nation for review.

6. Where possible, it is recommended that representatives from the First Nation of Na-Cho Nyak Dun, Tetlit Gwich'in First Nation, Vuntut Gwitchin First Nation be given the opportunity to participate in any field investigations (e.g. HRIA).

Should future HRIA work be conducted, all heritage resource sites identified, whether new or revisited, should be recorded as per the requirements outlined in the Yukon Archaeological Sites Regulation (O.I.C. 2003/73). Once recorded/revisited, specific heritage resource management recommendations should be made for each site that reflect the potential impacts associated with the proposed development that spurred the HRIA.

Lastly, although all efforts were made during the production of this report to make its assessment of heritage resource potential as comprehensive and accurate as possible, the methods employed provide relatively coarse resolution. As such, small undocumented areas of heritage resource potential may be present within the study area. Moreover, there is always a possibility that chance finds of heritage resources will be made in areas of low perceived potential. The recommendations contained herein are intended to be used for planning purposes. Should intensive development be proposed for areas within the Eagle Plains Basin Exploration Project

permitted area in the future, further assessment, focused on the specific footprint of the proposed development is recommended.

Introduction and Background

The treatment of every burial site requires respect. Legislation of various types protects burial sites and cemeteries from being disturbed. Government agencies and First Nations keep and consult records of known sites so that land use plans or proposals can avoid such sites.

There are many historic and First Nation graves in the Yukon however which are no longer marked and which may be disturbed accidentally through land use or development. Other sites may be disturbed by natural forces, such as erosion, leading to the exposure of human remains.

As more people travel in backcountry areas, for work or pleasure, it is expected that the number of such discoveries may increase. It is important therefore to have guidelines for reporting, investigating and managing such sites in a coordinated and effective manner, to give them proper respect.

Yukon First Nation (YFN) Final Agreements (Section 13.9.0) and the transboundary agreement with the Gwich'in Tribal Council (Tetlit Gwich'in) (Section 9.5) require the development of procedures to protect and manage YFN or TG burial sites, and specify certain actions when such sites are discovered.

Consistent with these obligations, these guidelines were developed at two workshops held jointly in March and October l998, involving First Nation Elders, heritage and implementation staff, the RCMP, Coroner and other Yukon and federal government officials.

Purpose

To provide direction on the reporting, identification, treatment and disposition of human remains found outside of recognized cemeteries in the Yukon, to ensure these remains are respected and protected consistent with legislation and Yukon land claims agreements.

Scope and Application

These guidelines apply to anyone who discovers human remains or grave goods outside of recognized cemeteries in the Yukon, and to the Yukon, Federal and First Nation government officials involved in protecting and caring for such sites.

The guidelines reflect existing practices in many ways. They do not replace legislation or regulations protecting burial sites, but are intended to integrate obligations contained in Yukon land claim agreements with land use permitting regimes and the Development Assessment Process . These guidelines may apply on Settlement Lands at the discretion of each First Nation. Government approval is required for management plans for sites on non-Settlement Land.

Existing known burial sites that are marked or otherwise recorded are protected by existing legislation. Management plans for these sites may be developed on a case by case basis.

Burial sites discovered within the boundaries of a designated heritage site may be subject to the management plan for that site.

The guidelines do not apply within National Historic Sites or National Parks. Parks Canada has its own guidelines respecting burial sites and human remains.

Evaluation and Revision of Guidelines

The implementation of these guidelines will be evaluated as necessary to ensure that they are fulfilling their purpose.

GUIDING PRINCIPLES

All human remains, and items found at graves (grave offerings, markers etc.) shall be treated with respect and dignity regardless of their cultural affiliation.

Actions taken following the discovery of sites will be consistent with Yukon and transboundary land claim agreement provisions respecting Yukon First Nation and Tetlit Gwich'in Burial Sites.

Each discovery will be handled on a case by case basis in consultation with the affected parties, in a coordinated and timely manner.

Definitions - see Appendix 1
References - see Appendix 2
Land claims provisions - see Appendix 3

Guidelines Respecting the Discovery of Human Remains and First Nation Burial Sites

See also Figure 1.

These guidelines cover five steps: discovery and notification; site protection and investigation; investigation and reporting; and site disposition or management agreements. A final step, arbitration, is provided for where no disposition agreement is reached.

1. Discovery and Notification

If human burial remains are accidentally discovered the following guidelines apply:

a) The finder will immediately cease any further activity at the site and report the site to the RCMP.

b) *If the finder is operating under a land use licence or permit*, the site must also be reported immediately to the land manager/permitting authority, as set out on the permit. The land manager/permitting authority shall confirm that the site is reported to the RCMP.

c) Based on the information it receives, the RCMP will notify: 1) the Coroner's office if the site is of a forensic or criminal nature; or 2) both the First Nation(s) in whose Traditional Territory the Site is located and the Heritage Branch, if the site is a suspected historic or First Nation burial site.

2. Site Protection and Identification

a) the land manager/permitting authority shall take reasonable measures to protect the site from environmental factors and any form of unauthorized interference or disturbance.

b) based on the evidence reported at the scene, the RCMP/Coroner will investigate the site and make a preliminary determination as to the nature of the remains.

c) *if the site is of a criminal or forensic nature* (potential crime scene or missing person), then the Coroner's office and police will assume authority over the site/remains.

d) Heritage Branch may recommend that an archaeologist assist police or coroner in the preliminary assessment of the site.

e) *If the site is **not** of police/coroner interest* then the Director, Heritage Branch, the affected First Nation(s) and the land manager will assume interim responsibility for protection and investigation of the site. If it's a suspected First Nation site, the Heritage Branch and First Nation would assume this responsibility.

f) the Director, Heritage Branch, the affected First Nation(s) and land manager shall take reasonable measures to restrict access and ensure that the human remains and any grave offerings are not further disturbed pending the investigation and identification of the remains. The RCMP may be consulted about protecting the site.

Figure 1

Guidelines respecting the Discovery of Human Remains and First Nation* Burial Sites

2. Site Protection and Investigation
-protection/no disturbance or access

If not a criminal matter, Heritage Branch takes lead with affected FN or transboundary group. RCMP may assist if requested.

- *First Nation, Minister*
- *permitting authority - person may continue activity*

with FN consent. If consent is not provided, proceed according to terms and conditions of arbitrator(UFA 26.7.0 TG Ch.18)

or

- *rebury, relocate or remove remains*
- *restrict/specify access if necessary and possible*
- *may designate existing or new site as burial site/cemetery or heritage site*
- *management plan (jointly prepared/approved by FN and Government on Non-Settlement Lands)*

Maps, inventories, reports, plans, agreements.

**the Tetlit Gwich'in will be involved in steps to protect and manage Tetlit Gwich'in burial sites discovered within their Primary Use Area (Fort McPherson Group Trapping area within the Peel River Basin).*

g) Where human remains are at risk of being destroyed or damaged, the Minister of Tourism for Heritage may issue a stop work order prohibiting any further activities and may make an agreement with the First Nation or the Tetlit Gwich'in or land owner or user for any investigation, excavation, examination and preservation and removal of the remains, consistent with land claim provisions. (s.*72, Historic Resources Act- This would address concerns about unknown remains.)*

Existing site inventories, land use records, affected First Nations and community elders, and military authorities, should be consulted as soon as possible about possible identification of the remains.

Some examination of the site/remains may be required to determine its cultural affiliation and age, and whether or not the site is modern or historic.

3. Investigation and Reporting

a) The Heritage Branch/land manager will direct an archaeologist or qualified examiner to carry out an investigation under any required permits, in consultation with the affected First Nation and other affected parties, to make an initial report citing, if possible*, the cultural affiliation of the human remains.

b) Within a reasonable time to be specified by the Minister, and the affected First Nation(s), the archaeologist or qualified examiner shall deliver a written report and any notification not yet made, to:

- the Minister, and the affected First Nation(s) if appropriate;
- the Director of the Heritage Branch;
- the land manager/permitting authority;
- any other representative of the interred, if known.

c) The written report shall attempt *to identify:

- the representative group of the interred;
- the geographic boundaries of the site;
- the grave offerings or other heritage resources that may be associated with the remains or the site.

d) The archaeologist or examiner may, with the agreement of the proper authority and the representative of the interred, if known, remove all or part of the human remains for further analysis or for temporary custody where the remains may otherwise be at risk.

e) Any exhumation, examination and reburial of human remains from a YFN/TG burial site shall be at the discretion of the affected YFN/TG; and if ordered by an arbitrator pursuant to land claim provisions, will be done or supervised by the YFN or Tetlit Gwich'in.

*it is often difficult to determine the cultural ancestry or affiliation of fragmentary human remains

3.1 Reporting

a) If the site is determined to be a Yukon First Nation Burial Site, or Tetlit Gwich'in burial site, the appropriate representative will be contacted in writing to provide further direction on the disposition of the remains. *

b) A person carrying out Government or First Nation authorized activity where a First Nation site is discovered can continue that activity with the consent of the First Nation in whose Traditional Territory the Yukon site is located. The consent of the Tetlit Gwich'in is required if the site is in the Tetlit Gwich'in primary use area. If consent is denied, the person can seek terms and conditions from an arbitrator about continuing the activity (see Section 5).

c) If after the final report, the human remains are found to be those of a different aboriginal people than those mentioned previously, the proper authority of that group shall be notified in order that they may assume the role of the representative.

d) Where a site is **not** found to be a Yukon First Nation or Tetlit Gwich'in burial site, or a military or mariner's burial site, the Director, Heritage Branch may publish notice of the discovery in a newspaper or other public notice seeking information on the remains.

4. Site Disposition Agreement (Management Plan)

4.1 When the site or remains are identified

a) The site shall not be disturbed and the Director, Heritage Branch or First Nation if on Settlement Land, shall initiate discussions towards entering into a site disposition agreement with the representative of the interred.

b) If the site is a Yukon First Nation Burial Site or a Tetlit Gwich'in burial site on non-settlement land, there must be joint approval of the site management plan by the Yukon First Nation in whose Traditional Territory the site is located and the Government. If the site is a Tetlit Gwich'in burial site located off Tetlit Gwich'in land but in the primary use area, the management plan must be jointly approved by the Tetlit Gwich'in and the Government.

c) Decisions regarding reburial, relocation or other disposition should be determined on a case by case basis in consultation with those concerned and in a timely manner.

Site disposition agreements shall determine such things as:
1. the interim care of the human remains*;*

2. the scope and extent of analysis to be performed on the human remains, if any;
3. the exact location of the place where the human remains are to remain or to be interred;
4. the style and manner of disinterment, if applicable;
5. the style and manner of reinterment, if applicable;
6. the time period in which disinterment and reinterment is to take place;
7. the procedures relating to, and the final disposition of any grave offerings discovered with the human remains and any additional analysis of them;
8. the provision for future maintenance of the cemetery or site where the human remains are to be located;
9. access to the site and ways to prevent disturbance;
10. any other issue agreed upon.

*it is often difficult to determine the cultural ancestry or affiliation of fragmentary human remains

4.2 When no representative is identified or no disposition is specified:

If disposition is not specified by a representative, or the remains are not claimed or no affiliation is established within a reasonable time, the Minister, or First Nation if on Settlement Land, shall with the necessary permits and approvals provide for the following disposition:

a) cover and leave the remains where they were found and have the site recorded as a burial site/ heritage site, if on land suitable for a burial site; or
b) have the remains disinterred and reinterred in the nearest appropriate cemetery; or
c) remove the remains from the site for analysis and may have them reinterred in a recognized cemetery or;
d) may act as the temporary repository of the remains.

(Where the remains were found on Settlement Land but are not considered First Nations remains, the Government may remove the remains in consultation with the First Nation.)

5. Arbitration

a) If no disposition agreement or management plan is reached within a reasonable time the matter may be referred to arbitration for settlement. If this matter concerns a Yukon First Nation Burial Site, this shall be done pursuant to 26.7.0 of the UFA; or Chapter 18, if the matter concerns a Tetlit Gwich'in site in the primary use area.

6. Records

a) A record of the site and a report of the discovery and disposition plan shall by kept by the Government and the affected First Nation(s)/representative for future reference to protect the site.

b) Access to information about discovered sites will be addressed in any site management plan developed under these guidelines, and will be protected under the *Access to Information and Protection of Privacy Act*, and the *Historic Resources Act* or *any similar First Nations legislation.*

Appendix 1

Definitions

burial site

the location of any human grave or remains that have been interred, cremated or otherwise placed, and include ossuaries, single burials, multiple burials; rock cairns; cave or cache burials etc. not situated within a cemetery

First Nation Burial Site

This refers to a Yukon First Nation Burial Site or a Tetlit Gwich'in burial site, which is defined as: a place outside a recognized cemetery where the remains of a cultural ancestor of a Yukon Indian Person (or the Tetlit Gwich'in) have been interred, cremated or otherwise placed."

[from the Definitions section of the *Umbrella Final Agreement for the Council for Yukon Indians (now Council of Yukon First Nations) and the Transboundary Agreement between Canada and the Gwich'in Tribal Council*]

human remains

mean the remains of a dead human body and include partial skeletons, bones, cremated remains and complete human bodies that are found outside a recognized cemetery" *(adapted from Historic Resources Act)*

grave offering

any object or objects associated with the human remains which may reflect the religious practices, customs or belief system of the interred.

historic

under the Historic Resources Act this generally means something older than 45 years.

land manager

Agency responsible for the administration of the land on which the site is located. For example, currently territorial parks are managed by Yukon Parks and Outdoor Recreation; gravel pits and rural airports are administered by Community and Transportation Services. Settlement Land is administered by the First Nation. Private land is administered by the land owner. (Burial sites may not be disturbed on any land without proper authorization.)

Recognized cemetery

a defined area of land that is set aside for the burial of human bodies.

representative

means a descendant of the interred or of the person whose remains are found, or where no descendant survives or is identified, an official representative of the appropriate First Nation in whose Traditional Territory the burial site is located or the closest culturally affiliated group, religious denomination, military or marine authority as evidenced by the location or mode of burial.

Where no representative can be determined the Minister shall act as the representative on Non-Settlement Lands and on Settlement Lands at the discretion and with the consent of the First Nation

representative group

means the appropriate Yukon First Nation or the closest culturally affiliated group, religious denomination, military or marine authority as evidenced by mode and style of burial which is willing to act as a representative.

Site disposition agreement

means a written agreement to be reached between the Director of the Heritage Branch and the representative of the interred regarding the disposition of the remains, including any disinterment and reinterment, and management plan

Management plan

means a plan to identify the roles of the representative, Government and land owner or manager respecting the care and protection of the site, including a consideration of site records, site access, and ways to protect a site from disturbance.

Appendix 3

Land Claims Provisions Relating to Burial Sites

13.9.0 Yukon First Nation Burial Sites*

13.9.1 Government and Yukon First Nations shall each establish procedures to manage and protect Yukon First Nation Burial Sites which shall:

13.9.1.1 restrict access to Yukon First Nation Burial Sites to preserve the dignity of the Yukon First Nation Burial Sites;

13.9.1.2 where the Yukon First Nation Burial Site is on Non-Settlement Land, require the joint approval of Government and the Yukon First Nation in whose Traditional Territory the Yukon First Nation Burial Site is located for any management plans for the Yukon First Nation Burial Site; and

13.9.1.3 provide that, subject to 13.9.2, where a Yukon First Nation Burial Site is discovered, the Yukon First Nation in whose Traditional Territory the Yukon First Nation Burial Site is located shall be informed, and the Yukon First Nation Burial Site shall not be further disturbed.

13.9.2 Where a Person discovers a Yukon First Nation Burial Site in the course of carrying on an activity authorized by Government or a Yukon First Nation, as the case may be, that Person may carry on the activity with the agreement of the Yukon First Nation in whose Traditional Territory the Yukon First Nation Burial Site is located.

13.9.3 In the absence of agreement under 13.9.2, the Person may refer the dispute to arbitration under 26.7.0 for a determination of the terms and conditions upon which the Yukon First Nation Burial Site may be further disturbed.

13.9.4 Any exhumation, examination, and reburial of human remains from a Yukon First Nation Burial Site ordered by an arbitrator under 13.9.3 shall be done by, or under the supervision of, that Yukon First Nation.

13.9.5 Except as provided in 13.9.2 to 13.9.4, any exhumation, scientific examination and reburial of remains from Yukon First Nation Burial Sites shall be at the discretion of the affected Yukon First Nation.

13.9.6 The management of burial sites of a transboundary claimant group in the Yukon shall be addressed in that Transboundary Agreement.

*This is an excerpt from the Umbrella Final Agreement between Canada, the Council for Yukon Indians and the Government of the Yukon (l993),Ch. 13, pp. 128-129, and subsequent Yukon First Nation Final Agreements.

9.5. Tetlit Gwich'in Burial Sites*

9.5.1 Government and Tetlit Gwich'in shall each establish procedures to manage and protect Tetlit Gwich'in burial sites which shall:

(a) restrict access to Tetlit Gwich'in burial sites to preserve the dignity of Tetlit Gwich'in burial sites;

(b) where the Tetlit Gwich'in burial site is outside the primary use area *(Fort McPherson Group Trapping Area)*, require the joint approval of government and the Yukon First Nation in whose traditional territory the Tetlit Gwich'in burial site is located for any management plans for the Tetlit Gwich'in burial site;

(c) where the Tetlit Gwich'in burial site is on land in the primary use area which is not Tetlit Gwich'in Yukon land, require the joint approval of government and the Tetlit Gwich'in for any management plans for the Tetlit Gwich'in burial site; and

(d) provide that, subject to 9.5.2, where a Tetlit Gwich'in burial site is discovered, the Yukon First Nation in whose traditional territory the Tetlit Gwich'in burial site is located or the Tetlit Gwich'in, if the Tetlit Gwich'in burial site is in the primary use area, shall be informed and the Tetlit Gwich'in burial site shall not be further disturbed.

9.5.2 Where a person discovers a Tetlit Gwich'in burial site in the course of carrying on an activity authorized by government, a Yukon First Nation or the Tetlit Gwich'in, as the case may be, that person may carry on the activity with the agreement of the Yukon First Nation in whose traditional territory the Tetlit Gwich'in burial site is located or the Tetlit Gwich'in if the Tetlit Gwich'in burial site is in the primary use area.

9.5.3 In the absence of agreement under 9.5.2, the person may refer the dispute to arbitration under chapter 18 of this appendix for a determination of the terms and conditions upon which the Tetlit Gwich'in burial site may be further disturbed.

9.5.4 Any exhumation, examination and reburial of human remains from a Tetlit Gwich'in burial site ordered by an arbitrator under 9.5.3 shall be done by, or under the supervision of, the Tetlit Gwich'in.

9.5.5. Except as provided in 9.5.2 to 9.5.4, any exhumation, scientific examination and reburial of remains from Tetlit Gwich'in burial sites shall be at the discretion of the Tetlit Gwich'in**.**

LOCATION

The proposed project includes oil and gas exploration work including, but not limited to, drilling, seismic exploration, and access development (e.g. roads and cutlines). The full study area covers approximately 238,604 ha on NTS mapsheets 116H/14, 116H/15, 116I/02, 116I/03, 116I/04, 116I/05, 116I/06, 116I/12, 116J/01, 116J/08, and 116J/09, and is located within the traditional territory of the First Nation of Na-Cho Nyak Dun, Tetlit Gwich'in First Nation, Vuntut Gwitchin First Nation (Figure 1).

MANAGEMENT SUMMARY

On behalf of Chance Oil and Gas Ltd., Ecofor Consulting Ltd. has conducted a Heritage Resource Impact Assessment (HRIA) for Eagle Plains Exploration Project 2023 study area (Figure 1). This study focused primarily on areas of predicted heritage resource potential (AOPs) in the northeastern part of the exploration area that were identified in a preceding Heritage Resource Overview Assessment (HROA; see Bennett 2022). One other area in the southern portion of the exploration area, related to an existing winter road leading to an existing well site, was also assessed from a helicopter to look for any potential areas of heritage resource concern. **Note: All specific geographic references to heritage site locations, photographs, and some site details have been removed from this YESAB ready version of this report so that it can be issued publicly while protecting sensitive site data.**

HRIA work included helicopter survey throughout the study area, with pedestrian survey and shovel testing within five AOPs/shovel test locations (STLs). In total, 232 shovel tests were excavated, with 20 in STL 20091-1 being positive for heritage resources, and leading to the recording of archaeological site McVd-1. All other STLs were negative for heritage resources. Moreover, no heritage resource concerns were observed during the aerial survey of the southern winter road area.

Further information about the newly recorded archaeological site and tested areas is presented below in the Evaluation section of this report.

POTENTIAL IMPACTS

Potential impacts include activities related to oil and gas exploration, including seismic programs, winter road creation, well pad building, and drilling.

ARCHAEOLOGICAL ASSESSMENT METHODOLOGY

This study builds on previous phases of heritage resource assessment, including Heritage Resource Impact Assessments (HRIAs) conducted under permits 01-07ASR (Hammer 2001), 07-04ASR (Heffner and Ross 2008), 08-06ASR (Commisso and Heffner 2008), and 13-16ASR (Buchanan 2014) and a 2022 Heritage Resource Overview Assessment (HROA; Bennett 2022). AOPs were first identified using a GIS model in the 2021 HROA, then manually reviewed by the applicant to eliminate false AOPs picked up by the GIS model. Given the size of the study area, it was not feasible to fully assess all AOPs within the study area footprint. As such, the assessment began with aerial reconnaissance from a helicopter to further refine the AOPs and identify those

with the best potential within the study area. HRIA field efforts focused on assessing a representative sample consisting of five of these AOPs.

Fieldwork in the assessed AOPs was conducted by a crew of three Ecofor archaeologists, including Tim Bennett (permit holder), Jacob Risk, and Mia Kelly, with assistance from Bruce Charlie (Vuntut Gwitchin First Nation). Assessment work began with pedestrian survey throughout the selected AOPs to search for any surficial heritage resources and areas with substantiated subsurface heritage resource potential. Areas with substantiated elevated subsurface potential were further investigated through shovel testing. In STLs, shovel tests were excavated every 5-15 m. Shovel tests measured at least 35 cm by 35 cm and were excavated with shovel and trowel as needed into sterile subsoils. All excavated sediments were screened through ¼ inch mesh. Artifacts identified were collected and bagged according to the shovel test unit and stratum, or arbitrary 5-10 cm vertical interval. The profile of representative shovel tests in each tested area was recorded by depth below surface and natural and cultural soil strata. All shovel tests were backfilled and returned to as close to natural conditions as possible. Where cultural materials were identified, additional shovel testing was conducted to assess the vertical and horizontal limits of the site, and to recover a sample of the material culture to assist in the assessment of the site use and cultural affiliation. All survey tracks and shovel tests were documented via hand-held GPS.

The newly recorded heritage resource site was recorded, mapped, photographed, and its location was recorded using a hand-held GPS unit. Moreover, it was flagged with a 30 m avoidance buffer (marked with “no work zone” flagging tape) in the field. It was given a temporary site number and comprehensive site data, including site setting, access, vegetation, hydrology, elevation, sedimentary and cultural stratigraphy, artifacts recovered, features present, etc. was collected. This information has been submitted to the Yukon Government Heritage Resource Unit for site inventory and return of Borden number.

All artifacts recovered will be cleaned, analyzed, and cataloged as per the requirements of the Yukon Archaeological Sites Regulations (YG 2020) at Ecofor’s Whitehorse lab, and detailed results will be included with the project final report. Lithic artifacts will be recorded by provenience and macroscopically analyzed. Flakes will be assigned to a reduction stage, tool categorized by type, raw material will be identified, and metric data will be recorded.

Final reporting, site forms, and artifact curation preparations will meet the Yukon Archaeological Sites Regulations Guidelines for Permit Holders (YG 2020).

EVALUATION

HRIA work included helicopter survey throughout the study area, with pedestrian survey and shovel testing within five AOPs/ STLs. In total, 232 shovel tests were excavated, with 20 in STL 20091-1 being positive for heritage resources, and leading to the recording of archaeological site McVd-1. All other STLs were negative for heritage resources. One other area in the southern portion of the exploration area, related to an existing winter road leading to an existing well site, was also assessed from a helicopter to look for any potential areas of heritage resource concern.

Further information about the tested areas is presented below.

Newly Recorded Archaeological Site

McVd-1 (AOP 20091/STL 20091-1)

Newly recorded archaeological site McVd-1 is located on a knoll overlooking an unnamed creek to the southwest (Figure 2 and Figure 3 – Map 3 of 6; Photo 1). Vegetation in the site area is characterized by open spruce with dwarf birch, young aspen, crowberry, lichen, and various small plants. In total, 74 shovel tests were excavated, 20 of which were positive for heritage resources, leading to the recording of new archaeological site McVd-1. Artifacts recovered are summarized in Table 1. Sediments encountered in these shovel tests consisted of organics from 0-1 cm, followed by fine grey brown sand from 1-6 cm, fine tan grey sand from 6-12 cm, light brown sand with pebbles from 12-18 cm, then grey sand with tabular pebbles from 18-23 cm below surface (Photo 2). A thick, charcoal rich lens was observed in two shovel tests located approximately 1 m from each other (Photo 3). As such, it is interpreted as being over 1 m in width. No artifacts were associated with the charcoal lens. Given the large size of the lens, and the fact that no artifacts were associated with it, it is considered likely that it is likely a product of a natural burn rather than a hearth. Based on these results, McVd-1 is interpreted as a subsurface lithic scatter. A 30 m site avoidance buffer around the positive test is recommended and was flagged in the field.

Negative Shovel Test Locations

STL 9071-1 (AOP 9071)

STL 9071-1 is located on a high, undulating, north facing terrace with sandstone bedrock exposures overlooking a small unnamed creek (Figure 2 and Figure 3 – Map 2 of 6; Photo 4). The terrace top is largely burned by past forest fires. Vegetation is characterized by open spruce forest

Artifact Type	Material	Colour	Quantity
Core Fragment	Chert	Grey	1
Flake Fragment	Chert	Black	11
		Brown	1
		Dark Grey	2
		Grey	7
		Light grey	2
	Dacite	Black	8
		Dark Grey	3
	Siltstone	Brown	1
		Grey	2
		Grey and brown	1
Scraper	Chert	Black	1
		Grey	1

Table 1: Artifact Summary from McVd-1.

with cranberry, crowberry, and lichen. In total, 40 shovel tests were excavated at STL 9071-1. Sediment profiles encountered in these shovel tests consisted of organics from 0-4 cm, followed by orange brown silty sand from 4-25 cm, then grey sand with sandstone cobbles and pebbles from 25-36 cm below surface (Photo 5). All shovel tests were negative for heritage resources.

STL 26381-1 (AOP 26381)

STL 26381-1 is located on a high northeast and east facing terrace overlooking an unnamed creek (Figure 2 and Figure 3 – Map 3 of 6; Photo 6). Vegetation is characterized by mixed aspen and spruce forest with an understory of Labrador tea, crowberry, lichen, and various small plants. In total, 42 shovel tests were excavated at STL 26381-1. Sediment profiles encountered in these shovel tests consisted of organics from 0-3 cm, followed by coarse light brown silt from 3-22 cm, fine grey brown sand from 22-40 cm, then grey sand with cobbles and pebbles from 40-50 cm below surface (Photo 7). All shovel tests were negative for heritage resources.

STL 28669-1 (AOP 28669)

STL 28669-1 is located on a high east and southeast facing terrace overlooking an unnamed creek (Figure 2 and Figure 3 – Map 3 of 6; Photo 8). Vegetation is characterized by spruce forest with occasional birch and an understory of cranberry, crowberry, blueberry, rose, and various small plants. In total, 42 shovel tests were excavated at STL 28669-1. Sediment profiles encountered in these shovel tests consisted of organics from 0-2 cm, followed by brown silt from 2-40 cm, then grey sand with cobbles and pebbles from 40-45 cm below surface (Photo 9). All shovel tests were negative for heritage resources.

STL 38131-1 (AOP 38131)

STL 38131-1 is located on a high southeast facing terrace overlooking an unnamed creek (Figure 2 and Figure 3 – Map 4 of 6; Photo 10). Vegetation is characterized by spruce forest with an understory of dwarf birch, Labrador tea, cranberry, blueberry, moss, and lichen. In total, 35 shovel tests were excavated at STL 38131-1. Sediment profiles encountered in these shovel tests consisted of moss from 0-12 cm, followed by organics from 12-17 cm, moist grey brown silty clay with pebbles from 17-35 cm, then moist grey brown silty clay with over 50% cobbles and pebbles from 35-40 cm below surface (Photo 11). All shovel tests were negative for heritage resources.

Winter Road Helicopter Survey

One other area in the southern portion of the exploration area, related to an existing winter road leading to an existing well site, was also assessed from a helicopter to look for any potential areas of heritage resource concern (Figure 2 and Figure 3 – Map 6 of 6). The area was found to be characterized by rolling hills with no well defined landforms that would indicate elevated heritage resource potential (Photo 12). No heritage resource concerns were identified along the winter road corridor.

Future Assessment Directions

In general, terrain within the study area was found to be gently rolling with very few well defined landforms. As such, the majority of AOPs identified in the preceding HROA (see Bennett 2022) were found to possess overall low potential for heritage resources based on their nature as broad, poorly defined, undulating ridges and hills. Review of the nine archaeological sites that are known

within the study area suggests that the highest potential landforms for finding sites are relatively low well defined terraces and large well defined knolls that clearly stand out against the surrounding terrain.

Based on these observations, the AOPs as predicted in the preceding HROA should be reviewed and revised on a footprint specific basis as new developments are planned for the Eagle Plains Exploration project or any other projects that are proposed in this area. These revisions should be aimed at refining the potential model to eliminate specific types of landforms that should now be considered to be low potential for heritage resources after the in field observations made during this study.

RECOMMENDATIONS

HRIA work included helicopter survey throughout the study area, with pedestrian survey and shovel testing within five AOPs/shovel test locations (STLs). In total, 232 shovel tests were excavated, with 20 in STL 20091-1 being positive for heritage resources, and leading to the recording of archaeological site McVd-1. All other STLs were negative for heritage resources. Moreover, no heritage resource concerns were observed during the aerial survey of the southern winter road area.

Based on these results, **avoidance is recommended for newly recorded archaeological site McVd-1 and previously recorded archaeological sites LlVc-1, LiVd-1, MaVc-3, MaVc-4, MaVc-5, MaVc-6, MaVe-1, and MbVf-1. If avoidance is deemed to be infeasible, then further assessment (e.g. additional shovel testing and systematic data recovery excavations) should be conducted before the commencement of ground disturbing activities. The specific mitigative plan should be developed through consultation with the Yukon Government Heritage Resource Unit and First Nations. No further work is recommended for any of the negative STLs. Untested AOPs should be reviewed and revised on a footprint specific basis as new developments are planned for the Eagle Plains Exploration project or any other projects that are proposed in this area.**

If crews encounter any undocumented heritage resources during any exploration activities, all work in the area should cease and the finds should be reported to the Yukon Government Heritage Resource Unit and First Nations immediately for guidance in managing impacts to unrecorded heritage resource sites.

Moreover, if any additional development areas are added to the project, then those new areas should also be reviewed for possible impacts to heritage resources. This follow-up heritage review may be conducted through desktop overview and/or field study. Final project reporting, to meet Yukon Heritage Permit requirements is pending, and will be completed prior to March 31, 2024.

EXECUTIVE SUMMARY

On behalf of Chance Oil and Gas Ltd., Ecofor Consulting Ltd. has conducted a Heritage Resource Impact Assessment (HRIA) for Eagle Plains Exploration Project 2022 study area. HRIA efforts focused on areas of predicted elevated heritage resource potential (AOPs) identified in a preceding Heritage Resource Overview Assessment (HROA; see Bennett 2022). The proposed project includes oil and gas exploration work including, but not limited to, drilling, seismic exploration, and access development (e.g. roads and cutlines). The full permitted exploration area covers approximately 238,604 ha on NTS mapsheets 116H/14, 116H/15, 116I/02, 116I/03, 116I/04, 116I/05, 116I/06, 116I/12, 116J/01, 116J/08, and 116J/09, and is located within the traditional territories of the First Nation of Na-Cho Nyak Dun, Tetlit Gwich'in First Nation, and Vuntut Gwitchin First Nation. **Note: All specific geographic references to heritage site locations, photographs, and some site details have been removed from this YESAB ready version of this report so that it can be issued publicly while protecting sensitive site data.**

This study focuses on a subsection of the full exploration area where an oil and gas exploration program is proposed. The exploration area is located in the northern part of the greater exploration area, and covers 62,521.7 ha. The exploration work will be conducted under winter conditions, with frozen ground and limited vegetation clearing, and will have very little associated ground disturbance.

HRIA work included helicopter survey throughout the study area, with pedestrian survey and shovel testing within 12 AOPs/shovel test locations (STLs). In total, 228 shovel tests were excavated, with four in STL E10 being positive for heritage resources, and leading to the recording of archaeological site MbVf-1. All other STLs were negative for heritage resources.

Based on these results, **avoidance is recommended for newly recorded archaeological site MbVf-1. If avoidance is deemed to be infeasible, then further assessment (e.g. additional shovel testing and systematic data recovery excavations) should be conducted before the commencement of ground disturbing activities. The specific mitigative plan should be developed through consultation with the Yukon Government Heritage Resource Unit and First Nations. No further work is recommended for any of the negative STLs. Untested AOPs should be reviewed and revised on a footprint specific basis as new developments are planned for the Eagle Plains Exploration project or any other projects that are proposed in this area. No further heritage resource assessment is recommended prior to the proposed exploration program due to the low impact nature of the work as long as new archaeological site MbVf-1 is avoided.** However, if crews encounter any undocumented heritage resources during any exploration

activities, all work in the area should cease and the finds should be reported to the Yukon Government Heritage Resource Unit and First Nations immediately for guidance in managing impacts to unrecorded heritage resource sites.

1.0 INTRODUCTION

On behalf of Chance Oil and Gas Ltd., Ecofor Consulting Ltd. has conducted a Heritage Resource Impact Assessment (HRIA) for Eagle Plains Exploration Project 2022 study area (Figure 1). HRIA efforts focused on areas of predicted elevated heritage resource potential (AOPs) identified in a preceding Heritage Resource Overview Assessment (HROA; see Bennett 2022). The proposed project includes oil and gas exploration work including, but not limited to, drilling, seismic exploration, and access development (e.g. roads and cutlines). The full study area covers approximately 238,604 ha on NTS mapsheets 116H/14, 116H/15, 116I/02, 116I/03, 116I/04, 116I/05, 116I/06, 116I/12, 116J/01, 116J/08, and 116J/09, but this study focuses on a 62,521.7 ha subsection of the full exploration area where an exploration program is proposed. The study area is located within the traditional territory of the First Nation of Na-Cho Nyak Dun, Tetlit Gwich'in First Nation, Vuntut Gwitchin First Nation. **Note: All specific geographic references to heritage site locations, photographs, and some site details have been removed from this YESAB ready version of this report so that it can be issued publicly while protecting sensitive site data.**

1.1 Project Overview

This study focuses on a subsection of the full exploration area where an oil and gas exploration program is proposed. The exploration area is located in the northern part of the greater exploration area, and covers 62,521.7 ha (Figure 1). The exploration work will be conducted under winter conditions, with frozen ground and limited vegetation clearing, and will have very little associated ground disturbance. Additional exploration work (e.g. well pad construction, drilling, winter road construction, etc.) may occur within this area in the future, and similar programs may be completed in other parts of the greater exploration area as the overall project develops.

This work sought to identify and record any heritage resource sites within that study area that may be affected by development and make management recommendations to minimize development related impacts to heritage resources within the development area. This work builds on a previous phases of desktop overview study that assessed the baseline heritage resource potential within the exploration area (see Bennett 2022).

1.2 Personnel

Fieldwork was completed between July 26-Aug 2, 2022 by a crew of three Ecofor archaeologists, including Tim Bennett (permit holder), Alexa Lauer, and Jacob Risk, with assistance from Vuntut Gwitchin First Nation.

1.3 Report Format

Following this introduction in Section 1.0, Section 2.0 provides a discussion of the environmental setting that the proposed project is located within, Section 3.0 discusses the culture history of the area in which the proposed project is located, Section 4.0 details the methodologies employed in completing this work, Section 5.0 presents the results of this HRIA, Section 6.0 provides a summary and recommendations for the ongoing management of heritage resources within the assessed project area, and Section 7.0 closes the report with a listing of references cited. Four appendices are included at the end of this report[1]. Appendix A shows project results mapping, Appendix B provides project photographs, Appendix C presents details about newly recorded archaeological site MbVf-1, and Appendix D provides the project field notes.

[1] Note: These appendices have been removed from this YESAB ready version of this report so that it can be issued publicly while protecting sensitive site data.

2.0 ENVIRONMENTAL SETTING

The Eagle Plains Exploration Project is located west and south of Eagle Plains, YT on public land. It includes portions of the North Yukon and Peel Watershed Planning Regions, and is located within the traditional territories of the Vuntut Gwitchin and the First Nation of Na-Cho Nyak Dun, as well as the Tetlit Gwich'in Primary and Secondary Use Areas of the Gwich'in Settlement Region. The Dempster Highway transects the project area and provides all-season access to the Blackie winter road, the Chance winter road, and the suspended wells at McParlon A-25 and Ehnjuu Choo B-73. Named watercourses include Chance Creek, Dalglish Creek, Enterprise Creek, Greaves Creek, and McParlon Creek. Further information regarding the broader physical/environmental setting of the study area is presented below.

2.1 Physical/Environmental Setting

The study area is located within the Eagle Plains Ecoregion. This ecoregion is characterized as is an intermontane sedimentary basin of modest relief between the Richardson Mountains to the east and the North Ogilvie Mountains to the west (Smith et al. 2004). It includes the Eagle Lowland as defined by Mathews (1986), or part of the Porcupine Plateau and Porcupine Plain as defined by Bostock (1948) and Hughes (1987). The majority of the rolling low-relief terrain falls between 300 m a.s.l. and 600 m a.s.l. (Oswald and Senyk 1977), although some mountainous areas reach as high as 1,000 m a.s.l. and some river valleys as low as 250 m a.s.l. (Smith et al. 2004). The majority of the ecoregion drains to the north through the Whitestone, Porcupine, and Eagle River systems to eventually end up in the Yukon River watershed with the exception of the southeast corner which drains east via the Ogilvie and Peel Rivers to the Mackenzie River (Smith et al. 2004). Lakes are relatively rare in the Eagle Plains Ecoregion, but some oxbow and thermokarstic lakes are located within the floodplains of the Whitestone, Porcupine, and Eagle Rivers (Smith et al. 2004).

Due to its latitude, the Eagle Plains Ecoregion does experience periods of continuous daylight and darkness, however these periods are brief. Mean annual temperatures are near -7.5°C, but the area exhibits strong seasonal temperature variation (Smith et al. 2004). In January, average temperatures typically range from -31°C in lower valleys to -25°C at higher elevations (Smith et al. 2004). Summer temperatures are less affected by elevation, and average 13°C (Smith et al. 2004). Recorded extreme temperatures range from -60°C during winter to 30°C in summer (Smith et al. 2004). Precipitation is relatively moderate, with an annual average of 400 mm annually (Smith et al. 2004). The majority of this precipitation falls as rain during the summer months, primarily in showers, with the period between September and April being the driest part of the year (Smith et al. 2004).

The bedrock geology of the ecoregion is characterized by Devonian through Cretaceous sedimentary rocks, including sandstones, siltstones, limestones, and shales, representing an intermontane basin sandwiched between the uplifted Richardson, North Ogilvie, and Dave Lord Mountain ranges (Smith et al. 2004). Lands within this ecoregion are not known for metallic minerals or significant coal deposits, but it does contain hydrocarbon resources. Three of 11 test wells drilled before an exploration moratorium in 1968 intersected porous Carboniferous, Permian, and Cretaceous sandstones in the Chance and Dagleish anticlines in the southern and southeastern part of the ecoregion are estimated to contain 2.8×10^9 m^3 of gas and 3.1×10^6 m^3 of oil (T. Bird, in Hamblin 1990).

Surficial geology is characterized by colluvial deposits throughout most of the ecoregion, with the remainder consisting of alluvial sediments along river systems and a few glaciofluvial and glaciolacustrine deposits associated with meltwater generated by glacial activity outside the ecoregion (Smith et al. 2004). Modern processes affecting the surficial geology include thermokarst subsidence and soil creep, cryoturbation, solifluction, and active layer detachment slides (Smith et al. 2004). Permafrost is discontinuous in the ecoregion, but is continuous within the exploration area, and can be up to 200 m thick in places with taliks focused in major river valleys (Thomas and Rampton 1982).

The majority of the Eagle Plains Ecoregion in composed of unglaciated terrain with some exceptions to this trend in parts of the Nahoni Range where there is scattered evidence of a past local glaciation of undetermined age (Smith et al. 2004). However, glacial processes in neighbouring ecoregions have influenced the major rivers in Eagle Plains, with up to three levels of glacially controlled terraces present along some drainages (Thomas and Rampton 1982). Major meltwater outlets exited the eastern slopes of the North Ogilvie Mountains and the northern slopes of the South Ogilvie Mountains via Ogilvie, Miner, Whitestone, Blackstone, and Hart Rivers channels (Smith et al. 2004). Moreover, during the Late Wisconsinan glacial maximum (ca. 30 ka; Hughes et al. 1981; Schweger and Matthews 1991) the Laurentide Ice Sheet blocked drainage of the Peel River and its southern tributaries forming Glacial Lake Hughes, which diverted the drainage northward through the Eagle River discharge channel (Duk-Rodkin and Hughes 1995). Glacial Lake Hughes received all the water exiting the Mackenzie and Wernecke mountains and the Ogilvie, Blackstone, and Hart river basins. Consequently, the Eagle and Porcupine rivers were the two major contributors to the inundation of the Old Crow, Bluefish, and Bell basins (Smith et al. 2004).

In terms of vegetation, black spruce-tussock/shrub tundra with understories including shrub birch, Cottongrass tussocks, bog cranberry, cloudberry, Labrador tea, crowberry, lingonberry,

spirea, lichen, and moss is typical on the lower slopes (Zoltai and Pettapiece 1973). Upland areas are dominated by black and white spruce woodlands with understories of Labrador tea, shrub birch, willows, alder, blueberry, rose, lowbush cranberry, spirea, moss, and lichen (Smith et al. 2004). Here white spruce is most common in better drained areas (Russell et al. 1992; Murray 1997). Forest fires are a significant factor in these wooded areas. Pioneer species important in recolonizing burn areas include paper birch, aspen, and balsam poplar (Zoltai and Pettapiece 1973). The highest elevation in the Eagle Plains Ecoregion, above approximately 800 m a.s.l., are typified by shrub tundra dominated by scrub birch, willow, and prostrate shrubs with some Cottongrass tussocks (Smith et al. 2004).

Mammalian biodiversity is relatively low in the Eagle Plains Ecoregion compared to other Taiga Cordillera ecoregions due to a lack of suitable habitats for many of the rodent and ungulate species found elsewhere (Smith et al. 2004). However, representative species present do include several predators including wolf, wolverine, grizzly and black bear, marten, ermine, and red fox (Smith et al. 2004). Barren-ground caribou of the Porcupine herd also utilize this area primarily in the fall and winter, and several species of vole can be found (Smith et al. 2004). The Eagle Plains Ecoregion also supports a large and greatly diverse avian population, including both permanent and migratory birds (Smith et al. 2004).

3.0 CULTURAL HISTORY

The following is an overview of the culture history for the broader region surrounding the study area including south-central and southwestern Yukon, and northern British Columbia. Many researchers have reviewed the cultural history of this broader area and have presented the information using a variety of terms and temporal ranges (Clark 1981; West 1996; Workman 1978; Wright 1995, 1999).

3.1 Precontact Period (ca. 15,000 BP to ca. AD 1700s)

Portions of the Yukon, NWT, and Alaska were unglaciated during the Last Glacial Maximum (18,000 BP). The area is commonly referred to as Eastern Beringia. Several of the earliest well-documented Precontact archaeological sites in Eastern Beringia are found in the northwestern Yukon and have been dated to the Late Pleistocene from approximately 15,000 BP to 13,000 BP (de Guzman et al. 2014; Easton 2015; Easton et al. 2007, 2011; Easton and MacKay 2008), as well as one outlier site dated to 24,000 BP (Bourgeon et al. 2017)[2]. Artifacts recovered from these sites include technological suites shared by other Eastern Beringian sites such as the Nenana/Chindadn (non-microblade) and Denali (microblade) Complexes, and date between 15,000 and 8,000 BP (Dixon 2011; Heffner 2002; Holmes 2001, 2011; Potter 2011). The material culture recovered from these sites, primarily defined through lithic technology that includes both non-microblade and microblade technology, is known as the Eastern Beringian Tradition (Holmes 2001). The Northern Cordilleran Tradition (11,000 BP to 7,000 BP) is defined from sites in the interior Yukon that notably lack microblade technology. The Northern Cordilleran Tradition is characterized by large straight and round-based lanceolate point forms, large blades and flakes, and transverse notched burins (Clark 1983; Hare 1995).

The Northern Cordilleran Tradition was followed by the Little Arm Phase, which dates from 7,000 BP to 4,500 BP (Clark and Gotthardt 1999; Workman 1978) and can be defined by the use of microlithic technologies. After about 4,500 BP, there is less evidence of microblade use in the Yukon, and an increase in the use of notched projectile points and a variety of scraping and carving tools. This new tool industry is known as the Taye Lake Phase in southwest Yukon, or

[2] Of note regarding early archaeological sites in the Eastern Beringia area is the very early site at Bluefish Caves, which has been recently dated to approximately 24,000 BP (Bourgeon et al. 2017). However, due to the nature of the archaeological assemblage recovered and paucity of known archaeological sites bridging the temporal gap between Bluefish Caves and other early sites, such as the Little John site (Easton 2015; Easton et al. 2007, 2011; Easton and MacKay 2008) and the Britannia Yukon Hill site (de Guzman et al. 2014) which date to approximately 15,000 BP, questions remain for many archaeologist regarding the relationship of the occupation documented at Bluefish Caves to the more recent archaeological record and modern First Nations peoples.

more broadly in the Yukon and Alaska as the Northern Archaic Tradition (Hare 1995; Workman 1978).

The most recent precontact archaeological component found in the Yukon is that of the late Northern Archaic Tradition, or the Late Precontact period. This period is most clearly represented by the Aishihik Phase found in the Southern Yukon (Hare 1995; Workman 1978). This phase is thought to be a cultural development from the earlier Taye Lake culture, although there are some significant differences in technology. The most notable is the introduction of the bow and arrow, replacing a type of throwing spear known as an atlatl (Hare et al. 2004). The Aishihik Phase sites are found above the White River Volcanic Ash layer (also known as White River Tephra) that is dated to approximately 1,250 BP (Clague et al. 1995).

The Aishihik Phase has been evaluated as ranging from approximately 1,200 BP to 200 BP, and also includes the use of native copper tools, stemmed projectile points, and gorges. Also indicative of the Aishihik Phase are small stemmed Kavik points, end and side scrapers, and ground adzes (Hare 1995). The poor preservation of organic materials makes the task of diet reconstruction more difficult than at the coastal sites, but there is evidence of continued use of a variety of large and small mammals, fish, and birds. In the high elevations of the southern Yukon ice patches, examples of the transition from the older atlatl technology to the bow and arrow use has been clearly documented by recent finds (Hare et al. 2004). The shift to the new technology was a rather abrupt one at roughly 1,200 BP based on a good sample of preserved and dated atlatl dart shafts and bow and arrow remains.

3.2 Protohistoric Period (A.D. 1700s to ca. AD 1840s)

The Protohistoric Period, as presented here, also overlaps with late Prehistoric/Athabaskan Period. It is defined by the appearance of non-indigenous goods, other early trade items, and foreign (western or eastern) influences, but not the documented accounts of contact between indigenous North American peoples and European/Russian/Asian peoples themselves. Other indicators of the Protohistoric Period are the arrival of the first non-indigenous diseases and information concerning non-indigenous peoples. Unlike other cultural periods with more specific temporal ranges it is difficult and perhaps impossible to determine when the first 'outside' influences of European, Russian, Asian, or other cultures began to impact First Nations people in the Yukon interior.

Some of these far-reaching effects may have been passed along from Russian exploration in the early and mid-1700s (Veniaminov 1984) and other Asian and European (Andreev 1944; Quimby 1985) exploration and contact with coastal communities. The Chilkat Tlingit from the Northwest

Coast travelled and traded with many interior First Nation peoples throughout this Protohistoric Period including the Kaska and the Northern Tutchone from the Dawson and Mayo areas, and occasionally the Mountain Dene people from as far away as Fort Norman on the Mackenzie River. The Tlingit protected and controlled the trading routes into the interior and fiercely defended those routes when they were threatened. News of early non-indigenous explorers and traders would have travelled inland along with foreign items such as metals, cloths, glass beads, and later tobacco and other goods.

In some of the earliest cases, the impacts of these foreign cultures could have had significant impacts even without the presence of the foreigners themselves. Such is the case for what is called 'drift-iron' whereby metals and other materials from Asian or European shipwreck wash ashore. Historical accounts of shipwrecks have been reported in the mid-1700s, but much earlier wrecks were possible. Metals and other foreign trade items have been derived from shipwrecks off what is now British Columbia, Southeast Alaska, and perhaps the Northwest Alaska as well.

3.3 Historic Period (post-A.D. 1840s)

During the early years of this period the Russians were exploring along the Pacific coast and up the major rivers of the Alaskan interior, while the British were exploring eastward into what would become Canada's Northwest and Yukon Territories, and Alaska. In the 1840s, representatives of the Hudson Bay Company (HBC) established trading posts throughout much of the northern territories. The closest trading post to the study area would have been the HBC Fort Francis post, located on the north side of Frances Lake, at the junction of the East and West Arms. In 1840 Robert Campbell of the HBC built "Glenlyon House" and began trading there in 1842. When trading began Campbell changed the name from Glenlyon House to Fort Francis, after Lady Francis Simpson the wife of the governor of the HBC. It was the first trading post in the Yukon Territory and was successful for the first few years, however when Fort Selkirk and Fort Pelly Banks were established it deteriorated and eventually shut down in 1852 (Coutts 1980). The location of Fort Selkirk was known to upset the Chilkat Tlingit who controlled the trade routes from the coast to the central Yukon. In 1852, a Chilkat Tlingit raiding party travelled inland and forced Robert Campbell and his crew to leave the trading post, which was consequently burned by the Northern Tutchone (Castillo 2012).

In 1867, US Secretary of State William Seward was able to focus increasing American interests, and he convinced the United States Senate to purchase Alaska from Russia. Soon after the purchase, the US Army sent Captain Raymond up the Yukon River on the first stern-wheel steamer to reach Fort Yukon (Grauman 1977). Raymond surveyed the location of Fort Yukon and

proved that it was within U.S. territory. The British sold the Fort to the U.S. Government and relocated east across the 141st Meridian.

The inland fur industry continued to drive exploration and settlement into the late 1800s, but mining would shift the focus to the placer gold found in streams and alluvial deposits. Mining in the second half of the nineteenth century was a risky, but often very lucrative enterprise. The impacts of mining spread quickly and drastically changed the project area.

Mineral prospecting and mining efforts in the second half of the nineteenth century were, in some ways, dependent on the existing infrastructure of the fur trading and missionary efforts. As the competition for the inland fur trade grew, so would the number of stern-wheelers on the Yukon River. These steamers could better supply the small number of trading posts along the Yukon and its tributaries and reduce the risk of prospectors running short of supplies. Therefore, more of the fur traders and other explorers turned their attention to search for gold and other minerals. Three key prospectors to the north were L. S. (Jack) McQuesten, Al Mayo, and Arthur Harper. They wrote to miners in the United States to encourage them to come north. They also established outposts along the Yukon River, including Fort Reliance, established in 1874 near the confluence of the Klondike River (what would become Dawson City; Wright 1976).

Harper and another man may have been the first to travel up the Fortymile River in search of gold in 1881 (Buzzell 2003). They collected a very rich sample, but were unable to relocate the exact location. In 1886, McQuesten, Harper, and Mayo built a post on the confluence of the Stewart and Yukon Rivers which provided supplies for additional prospectors. Also in 1886, Howard Franklin made a richer find on the Fortymile River. Others rushed in and these claims along the Fortymile River attracted miners from across Central, Eastern Alaska, and Southeast Alaska. Fortymile was the first town to grow to over a thousand people by the mid-1890s (Buzzell 2003), and in 1887 the Stewart River post was deserted. Some prospectors that did not find easy success in Fortymile returned to the Stewart and continued work in the area. In 1890, Harper re-established a trading post at the site of the old HBC post at Selkirk as interest in the area grew. This was followed by Jack Dalton who developed a series of existing First Nation trails from tide water at Haines Alaska, into Fort Selkirk. Then, on August 16, 1896, George Carmack, Skookum Jim, and Tagish Charlie discovered a very rich claim on Bonanza Creek, a tributary to the Klondike River near Dawson. This discovery sparked one of the largest gold rushes in history.

It would take almost a year for the news of the Klondike gold fields to spread south, even to places relatively close by in southeast Alaska. Most of the prospectors and traders in the Alaskan and Yukon interior had already converged on the Dawson area during the winter and spring, and

supplies ran dangerously low. That would quickly change in the summer of 1897 and spring of 1898 as new towns and supply posts sprang up along the Gold Rush routes to cash in on the increased demand.

The population of Dawson City grew very fast and in 1898 reached a peak of over 30,000. However, the boom period did not last long, and the vast majority of population moved on very quickly with the news of other discoveries and hopes of other bonanzas. The Gold Rush period saw greatly increased steamer traffic on the entire Yukon River drainage basin and across the interior. Just prior to the Gold Rush there were only a few steamers, while at its peak there would be hundreds of vessels working the rivers. These shallow draft steamers were supported by a network of wood camps, shipyards, and a large workforce which kept the river traffic moving. This network provided the infrastructure backbone for trading posts, fish camps, missionaries, and mail routes, while meeting the needs of the growing number of prospectors and traders.

Since Dawson City is located on a flood plain at the confluence of the Klondike and Yukon Rivers it has had a long history of fighting with rising water levels. Flooding here is the result of either open water flooding at peak river flows, or the more dangerous spring ice jam events. Dawson City has been the victim of over twenty floods since 1898 (McCreath et al. 1988; Whitehorse Star 1979). The most significant of these were in 1925, 1944, 1966, 1969 and 1979. After flooding in the 1940s and 1950s Front Street was raised in an attempt to keep the waters out, but this did little to stop the flooding. A protective dyke was built around the City in 1959 and was later increased in 1968. The last major flood of Dawson City occurred in 1979 when ice jams on the Indian, Klondike, and the Yukon Rivers caused the spring waters to back up across the City. This prompted the construction of the improved dyke (to the 200 year flood level) in 1987 (McCreath et al. 1988). Dawson City served as the capital of the Yukon government from 1898 until 1952, when the seat was moved to Whitehorse.

The Yukon has also hosted oil and gas exploration efforts since the 1950s. The first well was drilled in the Eagle Plains Basin in 1957, but was declared dry in 1958 (Yukon Government Oil and Gas Resources Branch, n.d.). Exploration activity picked up again in the 1960s and 1970s, which played an important role in motivating the construction of the Dempster Highway. Interest in exploration has continued intermittently ever since, with 76 wells having been drilled to date in five of eight Yukon sedimentary basins (Eagle Plain, Beaufort Mackenzie, Peel Plateau and Plain, Kandik, and Liard Basins) between 1957 and 2013 (Yukon Government Oil and Gas Resources Branch, n.d.). Over 10,000 line-km of 2D and 3D seismic surveys have been conducted as part of these exploration efforts (Yukon Government Oil and Gas Resources Branch, n.d.). Six oil and gas pipelines have also been constructed in the Yukon, including four built during World War II as

part of the Canol project, one built in the 1950s to supply American Air Force bases in Alaska during the Korean War, and the 2012 Spectra Energy pipeline built in 1972 to move natural gas from the Kotaneelee gas field in southeast Yukon to southern markets (Yukon Government Oil and Gas Resources Branch, n.d.).

3.4 Modern First Nations

3.4.1 Gwich'in Nation

The Gwich'in Nation is an Athapaskan speaking group that includes First Nations/Native American peoples in the Yukon, Northwest Territory, and Alaska (VGFN 2009). Members of the greater Gwich'in Nation include the Vuntut Gwitchin and Tetlit Gwich'in in the Yukon, the Teetl'it Zheh Gwich'in, Gwichya Gwich'in, Ehdiitat Gwich'in, and Nihtat Gwich'in in the NWT, and the Dendu Gwich'in, Draan'jik Gwich'in, Danzhit Hanlaih Gwich'in, Gwich'yaa Gwich'in, and Neets'ąjį Gwich'in in Alaska (McFadyen Clark 2020). Of particular significance to this project are the Teetl'it Zheh Gwich'in (TGC) and Vuntut Gwitchin (VGFN), whose traditional territories/modern community centers are crossed by the proposed project. Oral traditions and ethnographies of Gwich'in people have been documented by Krech (1976), Osgood (1933, 1934, 1936), Petitot (1876, 1889), Savishinsky and Hara (1981), VGFN and Smith (2009), Heine et al. (2007), and McCartney and Gwich'in Tribal Council (2020), among others.

Collectively, the traditional lifeways of the Gwich'in people depended on hunting and fishing. Moose and caribou were of vital economic importance providing both food and hides for clothing and shelter, but salmon, white fish, hare, and plant foods such as berries and rhubarb were also significant sources of subsistence (McFadyen Clark 2020). Their traditional toolkit was similar to other subarctic Athapaskan groups, and included the bow and arrow, traps, snares, deadfalls, and nets for fishing. People also utilized caribou drift fences and pounds to improve hunting yields. Snowshoes, sleds, and canoes were all employed for greater mobility. Hide covered tents provided the primary source of shelter.

Many Gwich'in communities continue to rely on subsistence harvesting from the land. The Vuntut Gwitchin (which translates to "people of the lakes") are based in Old Crow; the only community in the Yukon without road access (VGFN 2009). The Teetl'it Zheh Gwich'in (which translates to "people of the head waters") are based in Fort McPherson, NWT, which was established in 1852 when Old Fort, a Gwich'in village, was moved from six kilometers upriver to the present town site (Gwich'in Council International 2009). Fort McPherson represents the largest Gwich'in settlement in the NWT with over 80% of its population being of Gwich'in descent (Gwich'in Council International 2009). Gwichya Gwich'in (which translates to "people of the flats") are centered in Tsiigehtchic, NWT, and the Nihtat Gwich'in, meaning "mixed nations", is a

group comprised of Gwich'in from various Gwich'in communities that reside in Inuvik (Gwich'in Council International 2009).

3.4.2 First Nation of Na-Cho Nyak Dun

The First Nation of Na-Cho Nyak Dun (NND) is part of the Northern Tutchone language and culture group. In the past, the Tutchone peoples were highly mobile, travelling in small groups in order to exploit the greatest number of resources. They would modify their movements depending on the patterns of large game animals and fish, or in later years to trade their furs with non-indigenous peoples. In the summer, small domestic units gathered together to catch fish so that they could dry and store it for the winter months. By mid-summer, several family groups moved upland together in order to kill large game mammals that they would dry and store in caches scattered in a variety of areas. From there some units moved away independently during the coldest months to trap and live off of the cached foods. The leanest months were March and April. In spring, several units often came together at this point to catch spawning whitefish or trap muskrat and beaver. May was the most plentiful month, with migrating waterfowl, fat ground squirrels, larger and more abundant fish, as well as the arrival of the Coastal Tlingit traders (McClellan 1981).

The principal ethnographic descriptions of the Tutchone are available in Cruikshank (1974, 1975), Johnson and Raup (1964), McClellan (1950, 1964, 1970a, 1970b, 1975), and Tanner (1966). Additional information on camp and village locations can be found in Schwatka (1885). Although villages were not inhabited year-round, people would return to good fishing and/or hunting spots year after year. This would eventually change with the influence of Westerners. Watercraft were constructed for use, however during the summer months Tutchone people preferred to walk overland, rather than brave the sudden winds on the large lakes or the treacherous river rapids. Boats were not the preferred method of transport.

NND remained somewhat isolated until the discovery of gold in the area in 1883 (Mayo Historical Society 1999). The NND are known to have used many traditional camps, lookout sites, hunting areas, berry patches, and trails in the larger project area with extensive use of rivers. McClellan (1981) summarized the common seasonal activities beginning in the spring with grayling fishing following spring break up. The NND people remained almost completely isolated from non-First Nation people, except for a few explorers passing through, until miners set up a supply post along the McQuesten River in 1886. The supply post soon turned into a village and from then on permanent camps and villages have existed in the larger area surrounding Mayo Lake. During the Duncan Creek gold rush, a trading post called Gordon Landing was established near the confluence of Janet Creek and the Stewart River. From there a trail allowed people to travel

north partially along Davidson Creek to the confluence of Duncan Creek on the Mayo River. The Town of Mayo was established in 1903 and the people of McQuesten and a few other small encampments moved there or to the "Old Village" just outside of town (Mayo Historical Society 1999). This village made it possible for people to receive a western education, live close to Mayo, and continue their preferred way of life and cultural celebrations. Eventually the "Old Village" was abandoned when in 1958 the local health officials determined the drinking water was polluted and the NND were requested to move to the Town of Mayo. The First Nations people in the Mayo area officially chose the name "Na-Cho Nyak Dun" in 1987 which means "Big River People" in reference to the now named Stewart River.

3.5 Previous Heritage Investigations

The study area has not been extensively explored from a heritage resource perspective, but consultation with the Yukon Government Heritage Resource Unit did identify a few studies that have assessed portions of the current footprint. These studies include three permitted HRIAs related to previous oil and gas exploration (01-07ASR [Hammer 2001], 07-04ASR [Heffner and Ross 2008], and Commisso and Heffner [2008]), and one HRIA related to a fibre optic cable project along the Dempster Highway ROW (16-16ASR [Bennett 2016a]). Three non-permitted studies, including a historic resource overview assessment (HROA; Bennett 2016b), a traditional knowledge/traditional land use study (Bennett 2017), and an update to the original HROA (Bennett 2019), have also been completed in association with the fibre optic project along the Dempster Highway, and an HROA was completed in 2022 for the Eagle Plains Exploration Project (Bennett 2022). Known sites within the 50 km of the study area are summarized below in Table 1 and Table 2.

Borden #	Site Class	Site Type	Permits	Notes
LlVc-1	Precontact	Isolated find	00-21ASR	Located on a west-facing knoll 15 m above the valley bottom on Dalglish Creek. Six shovel tests were excavated with one chert flake recovered.
LlVd-1	Precontact	Subsurface lithic scatter	00-21ASR	Located on a southeast facing bedrock knoll with exposures to the southeast and northeast overlooking Enterprise Creek. Four tests were excavated and several chert flakes resulting from the production of stone tools were recovered from two of the tests. The site is considered to be a small lithic scatter likely representing temporary camp of game lookout.
MaVc-3	Precontact	Subsurface lithic scatter	01-07ASR 13-16ASR	Located on a north-south running terrace with an east view overlooking a pond and a sedge tussock meadow. Nine test pits excavated, with one being positive. Collection consists of two chert flakes.
MaVc-4	Precontact	Surface lithic scatter	08-06ASR 13-16ASR	Located on the west branch of a small tributary of the Upper Eagle River on the southeast edge of a terrace. Two flakes were found in surface exposures on the front edge of terrace.
MaVc-5	Precontact	Subsurface lithic scatter	13-16ASR	Located on outer SE nose of a large, squared terrace bench point along small tributary of upper Eagle River. Finds include a small assemblage of chert and siltstone lithics.
MaVc-6	Precontact	Subsurface lithic scatter	13-16ASR	Located on the outer edge of a large terrace bench formation along a small tributary of upper Eagle River. Finds include a small assemblage of chert and rhyolite/tuff lithics recovered from a tree throw.
MaVe-1	Precontact	Subsurface lithic scatter	13-16ASR	Located on a small terrace knoll overlooking a large expanse of tussock meadows framed between two small tributaries feeding in from the north. Finds include a small assemblage of chert lithics.
MaVc-2	Precontact	Subsurface lithic scatter	01-07ASR	Located on a bedrock knob overlooking an old creek bed, south of the Dempster Highway, southeast of Eagle Plains. Eight test pits excavated, with two being positive. Collections include chert core fragment and chert flakes.

Table 1: Known archaeological sites within/near the study area.

Borden #	Site Class	Site Type	Permits	Notes
MbTx-1	Precontact	Lithic scatter	94-15ASR	Located on a medium elevation bedrock rubble ridge, in the upper Canyon Creek Valley. A small collection of flakes and one scraper was made over an area of about 50 m in diameter near the highest point in the valley.
MbTx-2	Precontact	Isolated find	94-15ASR	Located on the right bank of a small tributary that drains west into the upper part of Canyon Creek. A single flake was found and collected.
MbTx-3	Precontact	Lithic scatter	94-15ASR	Located on a series of terrace beaches on the north side of an east-west running tributary of the upper Canyon Creek. A single flake was found on the upper bench. A large scraper made of welded tuff (?) was found on the lower bench.
MbVa-1	Precontact	Isolated find	94-15ASR	Located on a ridge complex in the foothills of the Richardson Mountains, near the headwaters of a tributary of the Eagle River. A single, broken biface was collected.
MbVa-2	Precontact	Lithic scatter	94-15ASR	Located on a knoll complex, three clusters of artifacts were found within an area of about 30 m. in diameter. Artifacts include substantial quantities of debitage and 2 bifaces, one of which is made on a large (15 cm long) macroblade. Site also known as the Ziehe Site.
MbVa-3	Precontact	Lithic scatter	94-15ASR	Located on a medium elevation complex of bedrock rubble ridges. Site consists of two clusters of large argillite (?) flakes/core fragments.
MbVa-4	Indigenous historic	Pole structure	94-15ASR	Located on a heavily wooded terrace, on the right bank of a mountain stream at the foot of a bedrock rubble ridge in the foothills of the Richardson Mountains. Consists of two collapsed pole/log structures. The poles are steel axe cut. Noted one wire nail and a piece of string.
MbVa-5	Precontact	Surface lithic scatter	94-15ASR	Two flakes were collected from the surface.
McVa-1	Precontact	Isolated find	00-14ASR	Located on the south end of a ridge complex, on the east side of Canyon Creek, near the headwaters of the creek. Collection consists of one chert flake.

Table 1: Known archaeological sites within/near the study area (continued).

Borden #	Site Class	Site Type	Permits	Notes
McVh-1	Historic	Historic scatter	69-00ASR	Located on the west bank of Whitestone River at on a long prominent bend. Metal, shell, glass bottles, and beads collected.
McVh-2	Precontact	Lithic scatter	69-00ASR	Located on northwest bank of Miner River, just downstream from island below confluence of Miner River and Fishing Branch. Lithic debitage collected.
McVh-3	Historic	Precontact/ historic scatter	69-00ASR	Located on north bank of fishing branch, where channel narrows to a line on the Porcupine River. Some flakes, bone, wood, glass objects collected.
McVh-4	Palaeontological	Isolated find	67-01ASR	Located on left bank of Whitestone River on the outside of a bend below the mouth of Chance Creek. A mammoth or mastodon tusk was collected from the surface of a river bar deposit in 1976.
MdVa-1	Precontact	Lithic scatter	74-01ASR	Located along the Dempster Highway ROW where the road crosses the headwaters of a major tributary of the Eagle River. Lithic artifacts and debitage collected.
MdVa-2	Precontact	Lithic scatter	78-11ASR	Located on low bench on the south side of a tributary of the Eagle River. Isolated tool and flake finds.
MdVh-1	Undetermined	Faunal materials	69-00ASR	Located on right bank of Whitestone River, just above its confluence with the Porcupine River. Faunal samples (bone) collected.
MeVb-1	Precontact	Lithic scatter	74-01ASR	Lithic artifacts and debitage collected.
MeVb-2	Precontact	Lithic scatter	74-01ASR 96-07ASR	Located on the Dempster Highway right of way where the road crosses the headwaters of Rock River. Flakes collected.
MeVb-3	Precontact	Lithic scatter	74-01ASR	Located just east of the Dempster Highway right of way where the road crosses the headwaters of the Rock River. Lithic artifacts and debitage collected.
MeVb-4	Precontact	Lithic scatter	74-01ASR	Located west of Dempster Highway near the headwaters of Rock River. Lithics collected.
MeVb-5	Precontact	Lithic scatter	81-02ASR 96-07ASR	Located on an old terrace of the middle Rock River. Twenty artifacts were collected.
MeVd-1	Precontact	Isolated find	n/a	One possible flake collected.
MeVf-1	Undetermined	Isolated find	69-00ASR	Located on west bank of Porcupine River, on second major bend above Johnson Creek. Two specimens of modified bone collected.
MeVf-2	Undetermined	Isolated find	69-00ASR	Located on bank of Porcupine River, north of small stream flowing from west into large meander, below mouth of Ellen Creek. One wood specimen collected.

Table 1: Known archaeological sites within/near the study area (continued).

Table 2: YHSI sites within 50 km of the study area.

4.0 METHODOLOGY

This study builds on previous phases of heritage resource assessment, including Heritage Resource Impact Assessments (HRIAs) conducted under permits 01-07ASR (Hammer 2001), 07-04ASR (Heffner and Ross 2008), 08-06ASR (Commisso and Heffner 2008), and 13-16ASR (Buchanan 2014) and a 2022 Heritage Resource Overview Assessment (HROA; Bennett 2022). Areas of potential (AOPs) were first identified using a GIS model in the 2021 HROA, then manually reviewed by the applicant to eliminate false AOPs picked up by the GIS model. Given the size of the study area, it was not feasible to fully assess all AOPs within the exploration area footprint. As such, the assessment began with aerial reconnaissance from a helicopter to further refine the AOPs and identify those with the best potential within the study area. HRIA field efforts focused on assessing a representative sample consisting of twelve of these AOPs.

Assessment work began with pedestrian survey throughout the selected AOPs to search for any surficial heritage resources and areas with substantiated subsurface heritage resource potential. Areas with substantiated elevated subsurface potential were further investigated through shovel testing. In shovel test locations (STLs), shovel tests were excavated every 5-15 m. Shovel tests measured at least 35 cm by 35 cm and were excavated with shovel and trowel as needed into sterile subsoils. All excavated sediments were screened through ¼ inch mesh. Artifacts identified were collected and bagged according to the shovel test unit and stratum, or arbitrary 5-10 cm vertical interval. The profile of representative shovel tests in each tested area was recorded by depth below surface and natural and cultural soil strata. All shovel tests were backfilled and returned to as close to natural conditions as possible. Where cultural materials were identified, additional shovel testing was conducted to assess the vertical and horizontal limits of the site, and to recover a sample of the material culture to assist in the assessment of the site use and cultural affiliation. All survey tracks and shovel tests were documented via hand-held GPS.

The newly recorded heritage resource site was recorded, mapped, photographed, and its location was recorded using a hand-held GPS unit. Moreover, it was flagged with a 30 m avoidance buffer (marked with “no work zone” flagging tape) in the field. It was given a temporary site number and comprehensive site data, including site setting, access, vegetation, hydrology, elevation, sedimentary and cultural stratigraphy, artifacts recovered, features present, etc. was collected. This information has been submitted to the Yukon Government Heritage Resource Unit for site inventory and return of Borden number.

All artifacts recovered have been cleaned, analyzed, and cataloged as per the requirements of the Yukon Archaeological Sites Regulations (YG 2020) at Ecofor’s Whitehorse lab. Lithic artifacts were recorded by provenience and macroscopically analyzed. Flakes will be assigned to a

reduction stage, tool categorized by type, raw material will be identified, and metric data will be recorded.

5.0 RESULTS

HRIA work included helicopter survey throughout the study area, with pedestrian survey and shovel testing within 12 AOPs/shovel test locations (STLs). In total, 228 shovel tests were excavated, with four in STL E10 being positive for heritage resources, and leading to the recording of archaeological site MbVf-1. All other STLs were negative for heritage resources. Further information about the tested areas is presented below.

5.1 Newly Recorded Archaeological Site

5.1.1 MbVf-1 – STL E10 (AOP 56587)

Newly recorded archaeological site MbVf-1 is located in STL E10 (AOP 56587) on a V-shaped point terrace overlooking the confluence of three drainage channels to the west (Figure 2 – Mapsheet 12 of 13; Photo 1). The site is located approximately 56 km west southwest of Eagle Plains. Vegetation in the site area is characterized by recently burnt spruce forest. Regenerating vegetation currently present at the site includes dwarf birch, rose, fireweed, Labrador tea, and various small plants with standing and fallen burnt spruce. In total, 47 shovel tests were excavated. Four were positive for heritage resources, leading to the recording of new archaeological site MbVf-1. Finds include eight chert flakes/flake fragments and one siltstone flake fragment. Sediments encountered in the positive test consisted of organics from 0-9 cm, followed by brown sandy silt from 9-25 cm, then greyish brown sandy silt from 25-32 cm below surface (Photo 2). Based on these results, MbVf-1 is interpreted as a subsurface lithic scatter that likely represents an ephemeral occupation of the area. A 30 m site avoidance buffer around the positive test is recommended and was flagged in the field.

5.2 Negative Shovel Test Locations

5.2.1 STL E1 (AOP 22214)

STL E1 (AOP 22214) is located on a high terrace overlooking a small unnamed drainage to the south (Figure 2 – Mapsheet 2 of 13; Photo 3). The terrace top is largely burned by past forest fires. Vegetation is characterized by standing and fallen burnt spruce, live birch, fireweed, rose, and various small plants. The surrounding unburnt areas is characterized by mature spruce forest. In total, eight shovel tests were excavated at STL E1. Sediment profiles encountered in these shovel tests consisted of organics from 0-7 cm, followed by brown clayey silt from 7-29 cm, dark brown sand from 29-57 cm, then dark brown sand with tabular cobbles from 57-60 cm below surface (Photo 4). All shovel tests were negative for heritage resources.

5.2.2 STL E2 (AOP 22214)

STL E2 (AOP 22214) is located on the same terrace as STL E1 with the same vegetation cover

(Figure 2 – Mapsheet 2 of 13; Photo 5). In total, seven shovel tests were excavated at STL E2. Sediment profiles encountered in these shovel tests consisted of organics from 0-7 cm, followed by tan silt from 7-25 cm, then light brown clayey silt (clay content increasing with depth) from 25-54 cm below surface (Photo 6). All shovel tests were negative for heritage resources.

5.2.3 STL E3 and STL E4 (AOP 22214)

STL E3 and STL E4 (AOP 22214) are located on the same terrace as STL E1 and STL E2 (Figure 2 – Mapsheet 2 of 13; Photo 7 and Photo 8). By the time they were completed, they had grown together to effectively become a single STL. Vegetation is characterized by partially burnt open spruce and aspen forest. In total, 10 shovel tests were excavated at STL E3 with an additional 16 tests in the STL E4 section. Sediment profiles encountered in STL E3 shovel tests consisted of organics from 0-4 cm, followed by brown clayey silt from 4-28 cm, olive brown silty clay from 28-49 cm, then brown sand with pebbles from 49-61 cm below surface (Photo 9). STL E4 sediment profiles were characterized by organics from 0-2 cm, followed by reddish brown silt from 2-24 cm, brown silty sand from 24-34 cm, then light brown sand from 34-42 cm below surface (Photo 10). All shovel tests were negative for heritage resources.

5.2.4 STL E5 (AOP 148087)

STL E5 (AOP 148087) is located on a high U-shaped terrace offering views to the south and west (Figure 2 – Mapsheet 2 of 13; Photo 11). The terrace becomes poorly defined in the more northerly part of AOP 148087, and no testing was conducted in that area as it was interpreted as possessing low potential for heritage resources. Forest fires have burnt this area, and vegetation is characterized by fire killed spruce and birch with living alder, rose, fireweed, Labrador tea, kinnikinnick, blueberry, cloud berry, and grass tussocks. In total, 30 shovel tests were excavated. Sediment profiles encountered in these shovel tests range from organics from 0-5 cm, followed by light brown clayey silt from 5-16 cm, brown clayey sand that grades to grey with depth from 16-40 cm, then grey moist sand from 40-45 cm below surface in shovel test E5-7 (Photo 12) to organics/root mat from 0-5 cm then grey/brown compact clay from 5-29 cm below surface in shovel test E5-19 (Photo 13). All shovel tests were negative for heritage resources.

5.2.5 STL E6 (AOP 17886)

STL E6 (AOP 17886) is located on a moderately defined terrace overlooking Chance Creek and a pond to the east (Figure 2 – Mapsheet 3 of 13; Photo 14). The area had moderate potential at best, but was identified by Vuntut Gwitchin participant Bruce Charlie as a typical winter use area, so the decision was made to excavate some shovel tests. Vegetation is characterized by young spruce (fire regeneration) with an understory of moss, lichen, dwarf birch, willow, and various

small plants. In total, 15 shovel tests were excavated. Sediment profiles encountered in these shovel tests consisted of organics from 0-9 cm, followed by brown clayey silt from 9-19 cm, then grey/brown sticky compact clay from 19-35 cm below surface (Photo 15). All shovel tests were negative for heritage resources.

5.2.6 STL E7 (AOP 18907)

STL E7 (AOP 18907) is located on a variably well-defined terrace overlooking Chance Creek to the east (Figure 2 – Mapsheet 3 of 13; Photo 16). Vegetation is characterized by spruce forest with an understory of moss, lichen, rose, Labrador tea, kinnikinnick, and various small plants. In total, 11 shovel tests were excavated. Sediment profiles encountered in these shovel tests consisted of organics from 0-6 cm, followed by brown clayey silt with small pebbles from 6-28 cm, then dark brown sand with pebbles from 28-43 cm below surface (Photo 17). All shovel tests were negative for heritage resources.

5.2.7 STL E8 (AOP 38363)

STL E8 (AOP 38363) is located on a long terrace with views to the south and southwest (Figure 2 – Mapsheet 8 of 13; Photo 18). Vegetation is characterized by medium sized spruce with birch at the terrace edge and an understory of moss, lichen, rose, kinnikinnick, and grass tussocks. In total, 27 shovel tests were excavated. Sediment profiles encountered in these tests were variable. In the eastern portion of the STL profiles consisted of moss from 0-8 cm, organics from 8-15 cm, then compact grey clay from 15-30 cm below surface (Photo 19). In the central part of the STL profiles were characterized by moss from 0-9 cm, followed by organics from 9-14 cm, brown silty clay from 14-16 cm, grey clay with veins of ice from 16-29 cm, then permafrost below 29 cm below surface (Photo 20). It the western part of the STL permafrost was much more pronounced appearing immediately below 19 cm of moss (Photo 21). All shovel tests were negative for heritage resources.

5.2.8 STL E9 (AOP 38753)

STL E9 (AOP 38753) is located on a south facing midslope terrace downslope from STL E8 (Figure 2 – Mapsheet 8 of 13; Photo 22). The primary view is to the south to a small unnamed drainage, but Chance Creek would also be visible to the west if not for the trees. Vegetation is open spruce forest with kinnikinnick, Labrador tea, rose, moss, lichen, and various small plants. In total, 10 shovel tests. Sediment profiles encountered in these shovel tests consisted of organics from 0-6 cm, followed by tan silt from 6-10 cm, brown clayey silt from 10-32 cm, then grey sand with 50% cobbles and pebbles from 32-50 cm below surface (Photo 23). All shovel tests were negative for heritage resources.

5.2.9 STL E11 (AOP 56058)

STL E11 (AOP 56058) is located on a U-shaped terrace with views over drainages to the south, southeast, and southwest (Figure 2 – Mapsheet 12 of 13; Photo 24). The area has been burnt by forest fires, with current vegetation represented by dwarf birch, rose, fireweed, Labrador tea, and various small plants with standing and fallen burnt spruce. In total, 22 shovel tests were excavated. Sediment profiles encountered in these shovel tests consisted of organics from 0-2 cm, followed by pinkish tan silt from 2-7 cm, orangish brown silt from 7-16 cm, then coarse brown sand with 50% pebbles from 16-30 cm below surface (Photo 25). All shovel tests were negative for heritage resources.

5.2.10 STL E12 (AOP 148076)

STL E12 (AOP 148076) is located on a high point terrace overlooking a valley to the south (Figure 2 – Mapsheet 12 of 13; Photo 26). The terrace edge has been burnt by forest fires, and current vegetation is characterized by dead spruce and birch with living fireweed, rose, grasses, and various small plants. In total, 25 shovel tests were excavated. Sediment profiles encountered in these shovel tests consisted of organics from 0-9 cm, followed by brown clayey silt from 9-29 cm, then greyish brown silty clay with cobbles and pebbles from 29-37 cm below surface (Photo 27). All shovel tests were negative for heritage resources.

5.3 Helicopter Survey Observations and Future Assessment Directions

Helicopter based survey was conducted throughout the study area while searching for AOPs with substantiated potential for shovel testing. The locations of previously recorded archaeological sites (LlVc-1, LiVd-1, MaVc-3, MaVc-4, MaVc-5, MaVc-6, and MaVe-1) were also flown over to observe the landforms on which they were identified. In general, terrain within the study area was found to be gently rolling with very few well defined landforms. As such, the majority of AOPs identified in the preceding HROA (see Bennett 2022) were found to possess overall low potential for heritage resources based on their nature as broad, poorly defined, undulating ridges and hills. Review of the eight archaeological sites that are known within the study area suggests that the highest potential landforms for finding sites are relatively low well defined terraces and large well defined knolls that clearly stand out against the surrounding terrain.

Based on these observations, the AOPs as predicted in the preceding HROA should be reviewed and revised on a footprint specific basis as new developments are planned for the Eagle Plains Exploration project or any other projects that are proposed in this area. These revisions should be aimed at refining the potential model to eliminate specific types of landforms that should now

be considered to be low potential for heritage resources after the in field observations made during this study.

6.0 SUMMARY AND RECOMMENDATIONS

HRIA work included helicopter survey throughout the study area, with pedestrian survey and shovel testing within 12 AOPs/shovel test locations (STLs). In total, 228 shovel tests were excavated, with four in STL E10 being positive for heritage resources, and leading to the recording of archaeological site MbVf-1. All other STLs were negative for heritage resources.

Based on these results, **avoidance is recommended for newly recorded archaeological site MbVf-1. If avoidance is deemed to be infeasible, then further assessment (e.g. additional shovel testing and systematic data recovery excavations) should be conducted before the commencement of ground disturbing activities. The specific mitigative plan should be developed through consultation with the Yukon Government Heritage Resource Unit and First Nations. No further work is recommended for any of the negative STLs. Untested AOPs should be reviewed and revised on a footprint specific basis as new developments are planned for the Eagle Plains Exploration project or any other projects that are proposed in this area. No further heritage resource assessment is recommended prior to the proposed exploration program due to the low impact nature of the work as long as new archaeological site MbVf-1 is avoided.** However, if crews encounter any undocumented heritage resources during any exploration activities, all work in the area should cease and the finds should be reported to the Yukon Government Heritage Resource Unit and First Nations immediately for guidance in managing impacts to unrecorded heritage resource sites.

If any additional development areas are added to the project, then those new areas should also be reviewed for possible impacts to heritage resources. This follow-up heritage review may be conducted through desktop overview and/or field study.

APPENDIX A. Eagle Plains Exploration Project Socio-Economic Baseline Technical Data Report (TDR)

Non-Confidential Summary

Chance is submitting **Appendix 11-A Eagle Plains Exploration Project Socio-Economic Baseline Technical Data Report (TDR)** as CONFIDENTIAL in **Section 11** of the Project Proposal. Documents requested to be designated confidential are being shared with the Yukon Environmental and Socio-economic Assessment Board (YESAB) Executive Committee to support their assessment of the Project.

The Socio-economic Technical Data Report has been requested to be designated confidential to meet the criteria below per this *Yukon Environmental Socio-economic Assessment Act,* S.C. 2003, c. 7 *(YESAA*) requirement:

- "traditional knowledge that is determined to be confidential under the applicable rules and that is provided in confidence to them for the purposes of this Act" (Yukon Environmental and Socio-economic Assessment Board 2024).

Appendix 11-A describes the existing socio-economic conditions for the human environment in the Yukon that may be potentially affected by the Project-related activities described in **Section 1 Details of the Proposed Project**. The existing conditions characterization includes:

- Regional Context
  - description of the regional context of the Yukon and NWT and potentially affected First Nations and communities.
- Community Profiles
  - description of geographic, historical, and governance information for potentially affected First Nations and communities in the Yukon and NWT.
- Demographic Information
  - description of population and demographic information for potentially affected First Nations and communities in the Yukon and NWT.
- Employment and Economic Conditions
  - description of information on the labour force, income, businesses, and infrastructure developments for potentially affected First Nations and communities in the Yukon and NWT, including a description of traditional economies.
- Community Infrastructure and Services
  - description of existing community infrastructure and services, including housing; healthcare; educational and cultural facilities; police, fire, and emergency services; waste management systems; water supply and sewage; transportation; and other public utilities.
- Land and Resource Use
  - description of First Nations cultural land and resource use, commercial and recreational land and resource use, and relevant land and resource plans or strategies and designated lands that are applicable to the Project and surrounding lands.

- Community Health and Wellbeing
    - description of existing conditions for community health and wellbeing according to environmental quality and the social determinants of health.

This information is summarized in the relevant sections of **Section 11** and will be used to inform the baseline socio-economic conditions to support the assessment of potential Project effects as part of Chance's Eagle Plains Project Proposal to YESAB.
